A rededication to the students, practitioners, and profession of midwifery; and to the women, mothers, babies, and families who receive health care from all those who study this book.

Helen Varney

For the mentors, midwives, and mothers who have shared with me their knowledge of midwifery and birth; and for David, my partner in everything I do.

Jan M. Kriebs

To Lisa L. Paine, CNM, DrPH, my midwifery mentor and friend, and to all those whose wisdom and vision inspires us to go further and to give more than we ever knew was possible to care for mothers and babies; and to Andy, my husband and soul mate, with whom so many dreams have come true.

Carolyn L. Gegor

Dedication to the Third Edition
In honor and memory of my beloved parents, Helene Hahn Varney and Theodore Roosevelt Varney.

Dedication to the Second Edition
In tribute to Therese Dondero and all other Certified Nurse-Midwives whose masterly contributions to our profession were tragically curtailed because of untimely death.

Dedication to the First Edition
For my students, peers, and colleagues; the profession of nurse-midwifery; and the women, mothers, babies, and families who receive health care from those who study this book.

Holy Births and Howling Babies

In my backyard there are nuns who live in a shaded brick building
next to the St. Stanislaus church and elementary school.
Together we rise before the sun is in the sky.
Behind the kitchen curtain, in the damp haze of morning,
I watch them walk in shades of blue robe.
They glide in white sneakers across the parking lot.
They are cool, calm, brisk.

Some day, I'll go see them
I'll ask for some lesson on prayer.
Because the thing is . . . I pray now.
Not *Dear God Almighty!*
Just slow, easy, quiet thoughts.

I pray when my patience is worn.
When my shoulders ache.
When my own voice becomes tiring to my ears.

I pray when my heart sits heavy with stories and faces of women.
A prayer for the 32 week babe.
A prayer for the lady with the skinny, squawking twins.
A prayer for the woman without a mother, or a lover, or a friend.
I pray when my cold hands run across a pregnant belly
and I feel a kick from the inside.

I pray for all my babies, *Be good to your mama.*
I pray for all my mothers, *Be strong, be good to this baby.*
I pray secretly and I pray slowly.

I pray for us, the midwives and almost-midwives.
I pray that we make the right decisions.
And I pray for those of us who make bad decisions.
Decisions we regret with outcomes we can't change.

I pray that we learn from our mistakes.
That with age comes wisdom.
I pray deeply and I pray completely.
For all of the hands and all of the bellies.
I pray for holy births and howling babies.

Preface to the Fourth Edition

This is a textbook written for all midwives. Midwives worldwide have a primary focus on pregnancy and birth in all types of settings. International concern for safe motherhood and the health and well-being of women builds on this core of midwifery. In the United States, the practice of midwifery encompasses the health care of women from puberty through senescence and from normal to high-risk, and the collaborative care of the medically or obstetrically complicated. To be with and provide care to women in all settings requires an extensive and in-depth knowledge base and skill competency. This book was written to provide both the student and the practitioner with the underlying theory, procedural know-how, and elaboration on the Hallmarks of Midwifery that enables the midwife to function with knowledge, safety, and caring in all settings. The book thus reflects a balance of art and science, a blend of spirituality and evidence-based care, and a commitment to being "with woman".

The book once again expanded with the fourth edition to provide more comprehensive coverage of the scope of practice of midwifery as the primary health care of women from puberty through senescence. Clinical content expansion is reflected in new chapters on Cultural Competence in Midwifery Practice, Primary Care and Midwifery, Nutrition in Women's Health, Common Diagnoses in Women's Gynecological Health, and Pharmacology and Midwifery. Other new chapters reflect increased comprehensiveness of material previously found in chapters such as Chronic Infectious Diseases, Complications of Gestational Age Assessment and the Postdate Pregnancy, Fetal Assessment in Labor, and Infant Feeding. A new chapter on International Midwifery and Safe Motherhood bespeaks acknowledgment of the role midwives have internationally in promoting and safeguarding the health and well-being of women. Two previous chapters were completely rewritten and retitled by new authors as Health Issues of Lesbian and Bisexual Women and Birth in the Home or Birth Center. Four new skills chapters were essential additions supplementing our clinical practice: Endometrial Biopsy, Sterile Water Papules, Hands and Knees Birth Position Hand Maneuvers, and Squatting or Supported Squat Birth Position Hand Maneuvers. Although Norplant has been removed from the market, the removal procedure was retained as there are still women who have the implants. All chapters, references, and bibliographies were meticulously scrutinized and comprehensively updated to reflect both expansion and evidence-based changes in our practice.

The book has more than doubled in size (a combination of page size and number of pages) since first published in 1980. The number of chapters has increased from 57 to 82. The preface and acknowledgments to each of the previous editions are included for historical purposes.

As with earlier editions, the comments and suggestions of readers are encouraged.

Finally, the fourth edition is the last edition of this book that I will author. The continuity and future of this book has been ensured by the two coauthors with whom I worked on this edition and who henceforth will be the authors of the book. They not only meet but exceed my requirements of having compatible clinical and educational philosophy with that upon which this book is structured, imposing expertise in clinical practice, exquisite writing and editorial talent, and absolute integrity in their work.

Helen Varney Burst
New Haven, Connecticut

Acknowledgments

The fourth edition has been a time of transition from a book with a single author to a book with three co-authors and preparing for two co-authors in the future. This enabled Helen Varney (HV) to take Jan Kriebs (JK) and Carolyn Gegor (CG) through the endless details and decisions of the entire process of book publishing from contract through writing, working with contributing authors, editing, copyediting, page proofs, front matter, permissions, art work, marketing, and relations with all the helpful people at Jones and Bartlett Publishers.

We want to thank all the contributing authors, some of whom comprehensively updated their chapters and others who authored new chapters which assured expansion of the book to cover all facets of the scope of our practice. All wrote magnificently and we are so proud and pleased to have them sharing their knowledge and expertise in this book that represents our profession. Five contributing authors responded with commitment and grace to personal requests for help in meeting formidable deadlines relatively late in the process and to them we are especially grateful: Mary Brucker, Karin Cadwell and Cindy Turner-Maffei, Bill McCool, and Carol Wood.

Each of us had the support of family, friends, and colleagues, without whom the book would never have been completed. HV expresses heartfelt gratitude to Margaret-Ann Corbett, CNM, MS, JD who has supported, encouraged, and enabled me to write the book through all four editions. In the end, it was Margaret-Ann who convinced me that I had to write the book one last time in order to facilitate an effective and fair transition. She then provided me with knowledgeable and wise counsel throughout, and the time, space, and sanity that I needed to do the work. Margaret-Ann's contributions to the book through the years defy an adequate thank you. I am also grateful to my brother and sister-in-law, T. William Varney, BS, CPA and Laura E. Varney, PhD for providing back-up dog walking and meals in Maine, and who gave of themselves and respected my need for time; to Catherine L. Gilliss, RN, DNSc, FAAN, Dean of the Yale University School of Nursing, for supportive understanding; and to my friends, family, and colleagues who sacrificed time together over and over again in order for me to work on the book.

JK expresses gratitude to my current and former partners at the University of Maryland: Carolyn L. Gegor, CNM, MS, FACNM, Mary E. Curran, CNM, MPH, Lisa McCullum, CNM, MSN, MPH, Jenifer Fahey, CNM, MSN, MPH, Rachel K. Payne, CNM, MS, IBCLC, Jennifer Kaye, CNM, MSN, and to Linda Sparks, our administrative secretary, all of whom made space in our practice for this book to grow. I am also grateful to Carol Snapp, CNM, MSN, who willingly reviewed and commented on material for me, and to Tekoa King, CNM, MPH and Lisa Summers, CNM, DrPH for their continual support this last year. Finally, I owe a great debt to my family: David, Rob, and Juniper, each of whom contributed time out of our lives so I could learn how to write a book, and then do it. Many thanks to each of these and all the other midwives and friends who believed I could do this.

Although my name (CG) appears as co-author, it is truly the work and love and support of so many people that has made this possible. I have to start with my husband, Andy, and daughters, Stacey and Brittany, whose love and support have sustained me and continue to make my life glow. I am grateful to my parents, Gordon and Sylvia Pearson who have always believed in me. The path that led me to this book began at Johns Hopkins under the mentoring of Lisa L. Paine, CNM, DrPH, FACNM and Timothy R. B. Johnson, MD who showed me the value of teaching, writing and mentoring as a means of improving the care for many women and babies, far beyond those I could actually care for myself. The midwives with whom I practiced: Lisa Summers, CNM, DrPH, Aileen MacLaren, CNM, DrPH, Jan Kriebs, CNM, MSN, FACNM, Emily DeFerrari, CNM, Mary Curran, CNM, MPH, Lisa McCullum, CNM, MSN, MPH, Jenifer Fahey, CNM, MSN, MPH and Rachel Payne, CNM, MS,

IBCLC have all taught me so much and were supportive of creating opportunities to care for women as well as to teach midwives, nurses, medical students, and residents the ways of midwifery. Linda Sparks has always provided invaluable administrative support. Thank you to each one.

We wish to express special thanks to the incredible team at Jones and Bartlett Publishers. First and foremost, we thank Penny Glynn, RN, ANP, PhD our editor who simultaneously cajoled and cared for us while unfailingly facilitating our efforts to get this book done; Karen Zuck, associate editor, who was always helpful but particularly invaluable with the permissions; Amy Rose, production editor, who was always open to author ideas and helpfully clear about what could and could not be done, Jenny McIsaac, production assistant, who carefully reviewed all the work and had endless essential questions and exhortations; Stephanie Magean, copyeditor, whose willingness to be simpatico with the author makes working with a copyeditor a pleasant experience; Joy Stark-Vancs, associate marketing manager, who sees involvement of authors as critical in the marketing process; and although not as directly involved in this edition, it was good to know that we had the continuing interest and support of Clayton Jones, CEO. Underlying their efforts is the philosophy of Jones and Bartlett to involve authors in all stages of production. This results in a real working relationship and partnership.

A number of people helped with specific aspects of the book. There were those who were helpful in offering suggestions, acting as a sounding board, and contributing information at just the right times: Mary Curran, CNM, MPH, Kathryn Kravetz, SNM, MSN, Lisa McCullum, CNM, MSN, MPH, Lisa Paine, CNM, DrPH, FACNM and Johanna K. Rizzardini, CNM, MSN. As with each edition of the book, Phyllis Long, CNM, MPH wrote helpfully, this time with commentary from students at the Institute of Midwifery, Women, and Health that raised our consciousness in the use of words. Proofreading was done by the co-authors and by Margaret-Ann Corbett, CNM, MS, JD, who did the majority of this work, Donna Diers, RN, PhD, FAAN, who saved the day at one critical point, Teresa Marsico, CNM, MEd, FACNM, and T. William Varney, BS, CPA. Grateful thanks to each. Margaret-Ann and Donna have the distinction of having done proofreading for all four editions of the book.

Carolyn Gegor and Jan Kriebs are indebted to Helen Varney Burst for giving us the honor, opportunity, and mentoring to participate in this book. Thank you for entrusting us with the profound responsibility to further the art and science of midwifery through this book.

Finally, we wish to thank all of the midwifery students with whom we have worked during our professional lives. It is from our students that we have learned, been stimulated, and renewed our commitment to midwifery and to the constant search for knowledge.

CG

Preface to the Third Edition

The third edition of this book marks a time of change and expansion in the profession. This change and expansion is reflected in the title and in the size of the book. The change in the title from *Nurse-Midwifery* to *Midwifery* reflects the recent actions of the American College of Nurse-Midwives and the ACNM Certification Council, which assumed responsibility for setting the standard for the practice of midwifery in the United States through the credentialing mechanisms of accreditation and national certification of both nurse-midwives and non-nurse-midwives.

The practice of midwifery in the United States has expanded and now entails the provision of primary care to women from puberty through senescence, including the maternity cycle and primary care of the well newborn. Thus, this edition of the book involved extensive rewriting, with significant changes in wording, the expansion of existing chapters, and the addition of several new chapters of content as well as the updating that largely comprises a revision. All chapters and bibliographies have been critically scrutinized and updated. Content has been expanded, added, or deleted as indicated.

What was Part IV on Management of the Interconceptional Period in the first and second editions has been renamed Health Care of Women and appears as Part II in the third edition. Many of the new chapters are in this section. This section also contains a chapter on primary care, which includes new and expanded material on the definition of primary health care of women; basic gynecologic care with an emphasis on the diagnosis and treatment of vaginitis/cervicitis and sexually transmitted diseases; pelvic inflammatory disease; Pap smears; diethylstilbestrol (DES) exposure; toxic shock syndrome; and premenstrual syndrome. The family planning methods in this section have been updated and expanded to include more natural methods of family planning, a chapter on long-term hormonal contraception, and information on emergency postcoital contraception.

The second edition added a chapter on out-of-hospital birth settings; the third edition takes the additional step of integrating all practice settings throughout the book. The second edition was in press just before the HIV/AIDS epidemic was generally recognized. The topics of HIV/AIDS and universal precautions are integrated throughout the third edition, in addition to being covered in depth in new chapters on the health care of women with HIV/AIDS and on universal precautions. Other new chapters address the full scope of practice of the midwife: preconception care, women and exercise, gynecologic and obstetric care of lesbian and bisexual women, substance abuse, midlife health, fetal assessment, Norplant insertion and removal, inserting an intrauterine pressure catheter, attaching a fetal scalp electrode, and circumcision. Kate McHugh has totally rewritten all the chapters in Part V on Newborn Care and added a new chapter on the primary care of the newborn in the first six weeks.

All told, the book has almost doubled in size (a combination of page size and number of pages) since the first edition was published 16 years ago. The preface and acknowledgments to the first and second editions are included in the third edition. I kept them in not only for historical purposes but also because in them I articulated why this book was originally written and the educational principles and beliefs on which this book is based. As always I welcome the comments of readers, including suggestions that will enable me to better meet the needs of our students, our colleagues, ourselves, and our profession in this book.

Acknowledgments

The third edition is the product of many helping hands. I am going to run the risk of naming them because I believe that contributions should be acknowledged publicly and because the third edition is truly the effort of a large number of people who believe in the book and its contribution to our profession. I hope not to offend anyone by unintended oversight. The contribution of each was invaluable.

The third edition would not have been written were it not for my friend Margaret-Ann Corbett, CNM, MS, JD. It was Margaret-Ann who saw me through the death of both of my parents, five major surgeries, and almost two years of daily occupa-

tional therapy for my right elbow and hand since the last edition of this book. Just as I began to feel my energy returning, Margaret-Ann spoke with me quite seriously about her concerns that the book was now out of date and what this could mean to the profession that I love so much. Throughout the subsequent year and a half it has taken to write the third edition, Margaret-Ann has provided continuous support, encouragement, wise counsel, and a sane balance in my life as well as help with obtaining permissions and proofreading. I am deeply grateful for all.

The Guardian Angels of *Varney's Midwifery, Third Edition* was what I named a group of Air Force nurse-midwives at Andrews Air Force Base. In addition to Captain Nancy Lachapelle, CNM, MS, the Squadron Leader of the Guardian Angels, the core group consisted of Lieutenant Colonel Debra Erickson-Owens, CNM, MS, Lieutenant Colonel Colleen Gutierrez, CNM, MS, Lieutenant Colonel Dorothea Morris, CNM, MS, and Major David Padd, CNM, MS. Major Marsha Atkins, CNM, ND was an early member of the group prior to being transferred to another Air Force base, and Major David Kutzler, CNM, MS joined the group in time for proofreading. Nancy wrote me a letter on behalf of the group, none of whom I knew, to volunteer their services in whatever way would be helpful to get out the third edition. The timing of her letter was shortly after Margaret-Ann's motivating talk, and after ascertaining the group's expectations and altruistic motivations, I took them up on their offer. The Guardian Angels, under Nancy's tutelage, divvied up and did the painstaking work of reading the entire second edition word for word and marking it for additions, deletions, changes, and updating. They then did the leg work of library research. With each chapter they sent copies of the latest articles and book references pertinent to the topics they believed needed to be changed, updated, or added. I wrote a large part of the third edition last summer in my home far down east on the coast of Maine a long way from any university libraries for health care professionals. The writing would not have been possible without the work of the Guardian Angels. Two of them, Nancy Lachapelle and Colleen Gutierrez, also drafted new chapters that I had requested and became coauthors on them with me. The Guardian Angels were unfailingly willing, cheerful, and on-time productive. All I had to do was ask and they would respond on a moment's notice to horrendous deadlines; the last time was for proofreading. How does one say thank you to guardian angels? But thank them I do, not only for the work they did for the book but for the fun I've had in getting to know them.

There are several authors to thank for new chapters in the third edition. In previous editions the only chapters totally written by someone other than me were the chapters on the newborn. If I thought something needed to be added to the book that I didn't know how to do, I learned it so I could write about it from experience, as I did with out-of-hospital birth, uterine exploration, and manual removal of the placenta for the second edition. This was not possible for the third edition. It was clear to me that I could not claim to be an expert in all the facets of nurse-midwifery practice that needed to be included in the third edition. I sought out the experts, and each responded with alacrity to my call for help without even asking about contracts or payment; their only interest was to contribute to the profession through writing for the third edition. I thank each of them—Sue Andrews, CNM, MAT, MSN; Ann Cowlin, MA, CSM; Vivian Lowenstein, CNM, CRNP, MSN; Nancy Jo Reedy, CNM, MPH; Mary Ellen Rousseau, CNM, MS; Carolyn Gegor, CNM, MS, RDMS, and Jan Kriebs, CNM, MSN; and Christina Krutsky, CNM, MSN, Jennifer Foster, CNM, MPH, Nina Kleinberg, CNM, MSN, Anne Morris, MD, and Kathleen Singleton, RN, MPH not only for their magnificent contributions but also for their support, unhesitating willingness, and the pleasure of working with them on their chapters.

A special thank you goes to Nancy Reedy, who came to Maine to coauthor Chapter 21 on antepartal complications with me. Nancy also wrote a new chapter on substance abuse, reviewed the old chapter on intrapartal complications to suggest revisions and put me in touch with Linda Bertucci, and through it all kept saying, "Helen, just tell me what you want me to do and I will do it for you." Working with Nancy was a happy time of reliving old memories, making new ones, being productive, and knowing that the new tables in Chapter 21 would be the type midwives would copy to put in their pocket clinical notebooks.

Linda Bertucci more than lived up to Nancy's recommendation and I am grateful for Linda's revision of the section in Chapter 25 on abnormal fetal heart rates and patterns. I am also grateful to Pat Paluzzi, CNM, MPH for sharing materials and for her help in integrating content on domestic violence.

My other visitor to Maine for the purpose of writing was Kate McHugh, CNM, MSN, author of all the chapters on the newborn. Kate told me that rewriting the neonatal chapters (in contrast to revising the previously written neonatal chapters for the

second edition) gave her the wonderful feeling of writing in her own voice. And a wonderful voice it is. Thank you, Kate, for elegant writing; shared purpose, values, and experiences; and friendship throughout.

In addition to my collection of books and the work of the Guardian Angels, two other people made my writing life in Maine possible without immediate access to a library. Thanks go to Mary Brucker, CNM, DNSc, who generously shared the results of her life-long habit of clipping and filing articles by sending me her most recent article files and the references for the educational modules in the Parkland School of Nurse-Midwifery. The other thank you goes to Mary Angelotti, MLS, MS, librarian in the Yale University School of Nursing Wiedenbach Reference Room, whose helpfulness was as close as my telephone and fax machine.

It was a special treat to work with an old friend separated by distance, Carmela Cavero, CNM, MS, FACNM, as coauthor of the chapter on natural methods of family planning. I had asked Carmela to review the old chapter and tell me honestly what she thought. She did and became coauthor of the chapter, for which I am grateful.

I am deeply grateful to Barbara Decker, CNM, EdD, FACNM, Director of the Yale University School of Nursing Nurse-Midwifery Program, for her caring, unfailing support, understanding, and positive reinforcement, and to Judy Krauss, RN, MSN, FAAN, Dean of the Yale University School of Nursing, for her continuing support, thoughtfulness, good humor, and generosity of time. Special thanks are due to Yale University School of Nursing faculty member Carrie Klima, CNM, MSN, who was the official photographer and spent hours taking and retaking pictures to satisfy not only her own but my and the production editor's demanding eyes. Yale University School of Nursing faculty Heather Reynolds, CNM, MSN, Mary Ellen Rousseau, CNM, MS, and Leslie Robinson, CNM, MSN and their patients posed for Carrie's camera lens, as did Yale University School of Nursing students Candice Becker, RN, SNM, MPH, Julianne Seymour, RN, BA, MSN, and Michelle Sullivan, RN, SNM, BSN. Thanks to all.

Several other CNMs also contributed to the effort to obtain pictures and figures in the book: Mary Bradish, CNM; Connie Breece, CNM, MSN; Mary Ellen Galante, CNM, MSN; Susan Thomforde, CNM, MSN; Susan Ulrich, CNM, DrPH; and Deanne Williams, CNM, MS. Henrietta Clews, CNM, MSN, Pat Cross, and Lucille Madri, AS, contributed in circumscribed but significant ways. Grateful thanks to each.

Toward the end, when every day meant a delay in when the book would be available, I traveled with page proofs to Palm Desert, Washington, D.C., and Maine seeking help from members of the ACNM Division of Accreditation Governing Board and Board of Review as well as from the Guardian Angels, Yale University School of Nursing faculty and students, family, and friends. Proofreading was done by Mary Brucker, CNM, DNSc; Nancy Clark, CNM, PhD; Margaret-Ann Corbett, CNM, MS, JD; Barbara Decker, CNM, EdD, FACNM; Jeanne F. DeJoseph, CNM, PhD, FAAN; Donna Diers, RN, MSN, FAAN; Theresa Gesse, CNM, PhD; Lieutenant Colonel Colleen Gutierrez, CNM, MS; Betty Hilliard, CNM, PhD, FAAN, FACNM; Carrie Klima, CNM, MSN; Major David Kutzler, CNM, MS; Captain Nancy Lachapelle, CNM, MS; Teresa Marsico, CNM, MEd, FACNM; Lieutenant Colonel Dorothea Morris, CNM, MS; Kristin Murray, RN, SNM, BA; Major David Padd, CNM, MS; Nancy Jo Reedy, CNM, MPH; Kelly Riordan, RN, SNM, BA; Betty Schlatter, CNM, PhD; Elizabeth S. Sharp, CNM, DrPH, FAAN, FACNM; Lara Slattery, BA; Gwen Spears, CNM, MSN, FACNM; and John Varney, BS, MBA. A heartfelt thank you to each.

One of the joys of the third edition has been my association with Jones and Bartlett Publishers, the new publishing company for the book. Their welcoming inclusion and philosophy of involvement of the author in all stages of production; eager willingness to listen and understand the complexities of our profession; and overall class act have been deeply appreciated. I thank all with whom I have been involved at Jones and Bartlett but wish especially to thank Clayton Jones, Mary Sanger, and Jan Wall. Jones and Bartlett's philosophy was shared by Lifland et al., Bookmakers, to whom Jones and Bartlett contracted the copyediting. Special thanks to Quica Ostrander who reversed my residual horror from the second edition with her very fine comprehensive copyediting and continuing communication throughout.

Finally, I thank all those who spoke to me with comments or suggestions to improve the book. Two wrote thoughtful and specifically detailed letters: thanks to Phyllis Long, CNM, MPH and to Paula Stephens-Bibeau and the 100th graduating class from the Frontier Nursing School of Midwifery.

Truly this has been a book from the profession to the profession.

Helen Varney Burst
New Haven, Connecticut

Preface to the Second Edition

The First Edition of this book reflected the basic practice of nurse-midwifery in the United States. The Second Edition addresses the full scope of nurse-midwifery practice in the United States, thereby adding the two ends of a continuum that extends from home birth to collaborative management of high-risk patients with physicians in tertiary medical centers.

The process of addressing the full scope of nurse-midwifery practice entailed a rethinking of the philosophy and definition of nurse-midwifery. A commonly held viewpoint is that nurse-midwifery is the management of the health care of *only* normal, or essentially normal, women. A review of our history is instructive because it is quickly obvious that nurse-midwifery was never limited to "normal" or "low-risk" childbearing women. The women in the remote areas of the Kentucky mountains in 1925, or in the Madera County, California project, or in Mississippi, or in the city hospitals of New York City, or any of the number of other underserved areas where nurse-midwives have reduced perinatal and infant mortality and prematurity rates and increased birth weights, were high-risk, or at-risk, and rarely low-risk. The education of nurse-midwives has always emphasized screening for the earliest possible signs and symptoms of an existing or developing complication. The profession has unshakably believed that nurse-midwives must work in a health care system that provides for physician consultation, collaboration, and referral. Such emphasis on screening and relationships with physicians clearly reflects concerns emanating from working with at-risk or high-risk populations from the beginning of our profession in the United States.

In the days when nurse-midwives worked only with underserved, and therefore at-risk or high-risk, populations, it was assumed that the nurse-midwife managed the care of the woman as long as she was essentially normal, consulted when there was any evidence of complications, and continued to care for the woman in a collaborative relationship with the physician. It was always entirely possible that if a woman remained essentially healthy that she would never see a physician. This did not deny, however, the role of the nurse-midwife in contributing to the collaborative management of at-risk or high-risk patients if they developed complications nor the focus of the nurse-midwife upon those aspects of childbearing which are normal in any woman, regardless of how complex her obstetric care becomes.

It was not until nurse-midwifery included the private patient sector in the early 1970s that nurse-midwives began taking care of women from an essentially healthy, largely normal or low-risk population. Many of these women were seeking health care that involved them and their families in knowledgeable participatory decision making and which supported natural, normal processes. They found this in the care given by nurse-midwives. Some of them were disenchanted with technology and displeased with routine hospital maternity care. Nurse-midwives responded by being advocates for the women (both normal and complicated) who remained within the hospital health care system and by providing care to carefully screened, normal childbearing women in out-of-hospital settings.

Being able to work with a variety of populations has meant that some nurse-midwives focus on one or another of these populations and thus apply the basic practice of nurse-midwifery to either end of the continuum. Those who work solely with a middle/upper class, educated, healthy population in an out-of-hospital setting have a different world view of the practice of nurse-midwifery than those nurse-midwives who work solely with a lower socioeconomic, complicated population in a tertiary medical center. This has led at times to a sense of dichotomy or of nurse-midwives on either end of the continuum being out of harmony with either accepted practice or with our basic definition. Not true. Our history encompasses the care of women in all settings. Our focus on normal does not define or limit our patient populations; it simply defines our area of expertise regardless of the population.

This edition of *Nurse-Midwifery* thus adds the two ends of the continuum. Chapter 20 is a new

chapter which focuses on out-of-hospital birth and the responsibilities of both the consumer and the nurse-midwife in that setting. At the other end of the continuum Chapters 9 and 14 on antepartal and intrapartal complications have been completely rewritten and expanded to reflect the contribution the nurse-midwife makes to the collaborative management of complicated patients. These two chapters also add topics not included in the First Edition such as size/dates discrepancy, small-for-dates, large-for-dates, postdates, oligohydramnios, preterm labor, etc. Chapters 57 and 58 on manual removal of the placenta and intrauterine exploration were added because of recognition that these are essential skills for a nurse-midwife to know in any setting in the event of an emergency. This led to changes in Chapters 17 and 19 on the management of third and fourth stage hemorrhage.

All chapters and bibliographies have been critically scrutinized, updated, and content expanded, added or deleted as indicated. I made a deliberate last-minute decision to retain the chapter on intrauterine contraceptive devices (Chapter 31) after they were removed from the market because (1) some women we care for still have them, (2) some Certified Nurse-Midwives practice in other countries where they are still available, and (3) I believe they someday once again will be available in the United States and we need to have that knowledge. The removal of Nisentil from the market did not happen until too late to make changes in Chapter 12. The dedication, preface, and acknowledgments to the First Edition were retained for historical purposes and because the purpose of this book and the educational principles used in its writing have not changed and are articulated in the preface to the First Edition.

Once again I welcome comments from readers including suggestions "which will enable me to ever better meet the needs of our students, our colleagues, and ourselves in this book."

Acknowledgments to the Second Edition

Writing a new edition is quite different from writing the original text. The original text was based on what I knew, had practiced and taught for a number of years. I wanted, however, in the Second Edition to include some aspects of practice with which I was not as well versed. Since I refuse to write what I do not know and have not done myself, writing the Second Edition required some preparation and expansion of my own scope of practice.

I owe a debt of gratitude to four very special CNM friends who generously gave of themselves and allowed me to practice with them in their settings. With three of them I had the greatest joy and fulfillment a teacher can have: that of working with former students who now were teaching me.

My odyssey for the Second Edition began with Judy Edwards, CNM, MS, with whom I began the transition away from 20 years experience in delivery rooms in tertiary medical centers. The patients in the obstetrical practice Judy is in deliver in a Level I New Hampshire community hospital which has a nursing staff supportive of all possible alternatives and delivery positions. Judy's experienced, laid-back and honest approach provided a safe setting for me to accept the welcome challenge of learning what for me were new methods of delivery.

My education in this vein culminated with Judy Kier, CNM, MSN in her combination birth center and home birth practice, Women's Health Care Associates in Houston, Texas. Under Judy's thoughtful, analytical, and articulate tutelage I expanded my mind in the realm of alternative modalities. I also learned the basics of out-of-hospital practice. This learning is reflected in Chapter 20. A special thank you goes to Cheryl, Tom, and Ashley Marie Linn who shared their life and home birth with me and to Susan Melnikow, CNM, who completely integrated me into the experience.

Susan Wente, CNM, MPH, Director of Midwifery at Baylor Medical College/Jefferson Davis Hospital in Houston, Texas, spent precious time with me as I learned the procedures of manual removal of the placenta and intrauterine exploration (Chapters 57 and 58). What Susan has accomplished in a health care and hospital system that has the largest number of deliveries in the country is a pre-eminent model which served to remind me of the immense impact public health oriented nurse-midwifery can have.

Therese Dondero, CNM, BSN, Director of Midwifery, North Central Bronx Hospital, New York, not only shared her unique setting with me but challenged me to remember my own early teachings and to rethink, again, the philosophy, definition, and scope of practice of nurse-midwifery. She entered this soul-searching thought process with me and then joined with me in the outcome of this process by coauthoring the total rewrite and expansion of Chapters 9 and 14. She also was influential in the review and discussion of parts of Chapters 3, 15, 17, 19, 20, 57, and 58. A year and a half of driving down and up the Merritt Parkway

to accomplish this not only reinforced my enjoyment of that drive but also built a fund of shared time and thoughts with Therese which I treasure.

Kate McHugh, CNM, MSN, accepted the job of reviewing, updating, and rewriting the section on the Neonate (Chapters 21, 22, and 23). Kate is a former neonatal intensive care nurse specialist and a former Yale nurse-midwifery faculty member who taught the Neonatal Module. It was good to once again work and enjoy lively and purposeful discussion with her.

I said in the preface to the first edition that I would welcome comments and suggestions. A few wrote thoughtful and specifically detailed letters: Doris Abbott, CNM, MPH, Patricia Deibel, CNM, BSN, Helen Gabel, CNM, MSN, Mary Alice Johnson, CNM, MSN, and Phyllis Long, CNM, MSN. Into this category must also go the helpful book review written by Mary Widhalm, CNM, MS. Many other CNMs wrote or spoke to me with useful tidbits which ranged from clinical observations to missing categories in the index. Elisabeth Genley, CNM, MSN felt so strongly about the deficits of the index while a student that she became the indexer for this edition. In addition, Rochelle Kanell, CNM, MS undertook the initial critical review of Section VI (Chapter 26, 27, 28, 29, 30, and 31) to identify content that needed to be updated and added.

Samuel G. Oberlander, MD, FACOG, Assistant Clinical Professor, Department of Obstetrics-Gynecology, Albert Einstein College of Medicine, Bronx, New York, graciously reviewed the new and updated material in Chapters 9, 14, 17, 19, 57, and 58 for obstetric theoretical accuracy. Ellen Harrison, MD, Associate Director of Medicine, Montefiore-North Central Bronx Hospital Affiliation and Assistant Clinical Professor, Department of Medicine, Albert Einstein College of Medicine, Bronx, New York was critically helpful in her review of the segments on hepatitis and tuberculosis. I retain, however, full responsibility for any inaccuracies and the determination of clinical judgment presented in this book.

Friends and family again played a critical role in the writing of the book. Margaret-Ann Corbett, CNM, JD, Anne Malley-Corrinet, CNM, MS, and Jerrilyn Meyer, CNM, MS took primary care of me as a person. My parents, Theodore R. and Helene Hahn Varney, sacrificed precious time for us to be together and were unfailingly interested and encouraging.

Finally, I wish to acknowledge the editorial help of Richard Zorab, Editor in Chief, and of Elizabeth McGuire, Production Manager, at Blackwell Scientific Publications; and of Patricia Sheehan. Richard was especially supportive and facilitative when contracted copyediting proved problematic and delayed the publication of this edition by several months.

A heartfelt thank you to all.

Preface to the First Edition

This book was written because it needed to be written. As a nurse-midwifery educator I quickly became aware of my students' frustration in trying to piece together what the practice of nurse-midwifery is from a conglomeration of American nursing and medical literature and English midwifery texts. The former was either too superficial or too much in depth with too little detail, while the latter were not always applicable to the practice of nurse-midwifery in the United States. This affected, in part, the content of this book. For example, the section on skills (Part VII) was written because the medical texts are woefully inadequate in explaining to non-physicians how to perform traditionally medical procedures. Consequently faculty in the different nurse-midwifery programs have written their own procedures or borrowed from other programs. Nurse-midwifery educators are characterized by their willingness to help each other and to share their materials with their peers. This has resulted in a sizable body of unpublished literature. What a student in any given program might actually get, however, varies considerably from program to program. The rest has been taught in the oral tradition from teacher to student, from demonstration to demonstration, from generation to generation. All have learned, and learned well, but at the price of frustration for the student and endless repetition for the teacher.

Several educational principles have guided the writing of this book. A primary one has been that learning takes place best when used. For this reason the anatomical, physiological, and psychological bases for what is being observed and the rationale for action are given together rather than in separate and discrete chapters. This has been reinforced by my belief that the nurse-midwifery management process is the core of any nurse-midwifery curriculum. I first articulated the rudiments of this process in Mississippi based in part on my observations and analyses of my own and others' thought processes when managing the care of patients. Others have since added their own interpretations. The one presented in this book is a composite drawn from many minds. Learning the nurse-midwifery management process is facilitated by basic educational principles of application and reinforcement. In turn, the design of the process is such as to foster the utilization of these basic educational principles in teaching.

This book has a definite hospital orientation, in part because this is what I know, and in part because this is where the basic education of students usually takes place. This orientation is not meant to imply any questioning of the value of out-of-hospital birth settings nor to reflect any personal reservations on my part in relation to them. Future editions of *Nurse-Midwifery* will include expanded coverage of nurse-midwifery practice in out-of-hospital birth settings, additional aspects of care during the interconceptional period, and comprehensive care of the pregnant adolescent as a specialty area.

Finally, I have designed this book so that it will be of value as a permanent reference not only to nurse-midwifery students but to all those who are involved in the care of women and of the childbearing family. I welcome comments from readers, including suggestions which will enable me to ever better meet the needs of our students, our colleagues, and ourselves in this book.

Acknowledgments to the First Edition

This book would not exist were it not for a number of helping and helpful people, some whose contributions have been highly visible and others who have been supportive in various indirect ways. There have been the many who posed for pictures, took pictures, sent pictures, sent professional literature and materials, typed, photocopied and, most of all, patiently waited. And there have been the many who have touched and shaped my life and beliefs in nurse-midwifery: from Ernestine Wiedenbach, CNM, MA, my teacher and mentor from the beginning; through nurse-midwifery faculty and staff in the institutions where I have studied; to the nurse-midwifery faculty, staff, and students at the University of Mississippi Medical Center (1969–1974); the faculty, staff, and students at the

Medical University of South Carolina (1974–1979); the faculty in the nurse-midwifery education programs I have served as a consultant; the Certified Nurse-Midwives who have shared so much with me during my terms of office as President of the American College of Nurse-Midwives; and now the faculty and students at Yale University.

There has been one person who has lived the book with me. To my friend, Margaret-Ann Corbett, CNM, MS, goes the most special acknowledgment and thank you for her never-failing encouragement, wise counsel, performance of innumerable detailed tasks, and provision of a sane counterbalance to the demands of the book.

A special acknowledgment and thank you also goes to Sally Ann Yeomans, CNM, MSN, who has given much personally and professionally out of her conviction that the book should be written. This included her assuming the Chairpersonship of the Division of Examiners of the American College of Nurse-Midwives which I held, so I would have the time to write.

A very special thank you must be said to Joy M. Brands, CNM, MPH, who rescued me and the book at one low point by volunteering to write the Neonatal section. She enlisted the aid of Mary J. Banigan, RN, PhD in that project and the results are Chapters 20, 21, and 22. They were assisted in their endeavors by Sally Ann Yeomans.

A number of professionals reviewed parts of the book. Foremost among these is Henry A. Thiede, MD, FACOG, Professor and Chairman, Department of Obstetrics-Gynecology, The University of Rochester School of Medicine and Dentistry and Strong Memorial Hospital. He reviewed the entire book for medical accuracy always with ready willingness and a prompt response. Alfred W. Brann, Jr., MD, FAAP and Linda Book, MD, FAAP, reviewed the section on the Management of the Newborn. Agnes Higgins, CM, BSc, PDT, FRSH, LLD, Executive Director of the Montreal Diet Dispensary, reviewed Chapter 8. Helen E. Browne, CNM, ScD (Hon.), CBE, Aileen Hogan, CNM, MA, Ruth Lubic, CNM, PhD, Agnes Reinders, CNM, MS in NEd., and Ernestine Wiedenbach, CNM, MA, reviewed parts of the first two chapters. Margaret-Ann Corbett, CNM, MS, and Linda Wheeler, CNM, EdD reviewed other chapters throughout the book. All reviewers undertook this work at my request as personal favors and I whole-heartedly thank them all, while assuming full responsibility for any inaccuracies which may exist.

I learned a great deal about the arts from Betty Goodwin, Chief, Section of Illustration and Design, Division of Audiovisual Production, Medical University of South Carolina, who drew the original illustrations in this book, and from John Watts Clark, ARPS, Supervisor of Photograph Department, Medical University of South Carolina, the photographer who took most of the original photographs in this book. Their helpfulness and pleasant ways made my learning what is entailed in their respective fields a most enjoyable experience.

I have known several editors throughout the process of writing this book. A special thank you goes to Christopher Campbell and Martha White Tenney of Blackwell Scientific Publications, Inc., and to Eleanor Mora. Without Chris and Marty urging and helping me through the last stages of production, the book would have stopped at the point of an edited manuscript. Special thanks must be given to Donna Diers, RN, MSN, FAAN, Dean and Professor of Yale University School of Nursing, for instigating and encouraging the contacts between Christopher Campbell and myself that led to the finalization and realization of the book.

In the end it was my local friends who enabled the book to be finished. The bulk of the six hundred pages of galleys was divided up and proofread by Joy Ruth Cohen, CNM, MSN, Margaret-Ann Corbett, CNM, MS, Anne Malley-Corrinet, CNM, MS, Donna Diers, RN, MSN, FAAN, Charlotte (Pixie) Elsberry, CNM, MSN, Elizabeth Grob, CNM, BSN, and Elizabeth Cole Rogers, CNM, MN.

Finally, not least but most, I acknowledge and thank my parents, Theodore R. and Helene Hahn Varney, who have provided both personal encouragement and financial support through the years it has taken to write this book, and in whose honor I have decided to publish this book under my maiden name.

CHAPTER

1

The Profession and History of Midwifery in the United States

> And it came to pass, when she was in hard labour, that the midwife said unto her, Fear not . . .
>
> *Genesis 35:17*

Midwifery is as old as the history of *Homo sapiens*. Midwives are referred to in the Book of Genesis; these Hebrew midwives are the first midwives found in literature. Fulfilling its meaning of "with woman," midwifery has survived through the centuries as birth, the renewal of life, continues through the ages.

Definitions and Practice

Midwifery is an internationally recognized profession with practitioners throughout the world. The following international definition of a midwife and her sphere of practice has been accepted by the International Confederation of Midwives, the International Federation of Gynaecology and Obstetrics, and the World Health Organization:

> A Midwife is a person who, having been regularly admitted to a midwifery educational programme, duly recognized in the country in which it is located, has successfully completed the prescribed course of studies in midwifery and has acquired the requisite qualifications to be registered and/or legally licensed to practise midwifery.
>
> She must be able to give the necessary supervision, care and advice to women during pregnancy, labour and the postpartum period, to conduct deliveries on her own responsibility and to care for the newborn and the infant. This care includes preventative measures, the detection of abnormal conditions in mother and child, the procurement of medical assistance and the execution of emergency measures in the absence of medical help. She has an important task in health counseling and education, not only for the women, but also within the family and the community. The work should involve antenatal education and preparation for parenthood and extends to certain areas of gynaecology, family planning and child care. She may practise in hospitals, clinics, health units, domiciliary conditions or in any other service. [1]

In the United States, midwifery education that meets the standards of the American College of Nurse-Midwives (ACNM) goes beyond the scope of practice considered midwifery in this international definition to include the primary health care of newborns and of women from puberty through senescence [2, 3]. The ACNM defines midwifery practice as conducted by Certified Nurse-Midwives and Certified Midwives as follows:

> The independent management of women's health care, focusing particularly on pregnancy, childbirth, the postpartum period, care of the newborn, and the family planning and gynecological needs of women. The Certified Nurse-Midwife and Certified Midwife practice within a health care system that provides for consultation, collaborative management or referral as indicated by the health

> status of the client. Certified Nurse-Midwives and Certified Midwives practice in accord with the *Standards for the Practice of Nurse-Midwifery*, as defined by the American College of Nurse-Midwives. [4]

The ACNM further states that "the education and preparation of CNMs/CMs described in the ACNM Core Competencies, qualify them to practice in a variety of settings including hospital, home and birth center" [5].

The ACNM defines a Certified Nurse-Midwife (CNM) as "an individual educated in the two disciplines of nursing and midwifery, who possesses evidence of certification according to the requirements of the American College of Nurse-Midwives" [6] and a Certified Midwife (CM) as "an individual educated in the discipline of midwifery, who possesses evidence of certification according to the requirements of the American College of Nurse-Midwives" [7].

Certification is conferred upon an individual who has met eligibility requirements for and successfully passed the national certification examination of the ACNM Certification Council, Inc. (ACC). Certification gives official recognition to an individual who has met professional standards for safe practice. This certification both protects the public and differentiates the well-educated, highly prepared ACC Certified Nurse-Midwives or ACC Certified Midwives, and their broad scope of practice, from other types of midwives.

Beliefs Characterizing Midwifery

A number of beliefs are central to midwifery practice and characterize the health care given by midwives. Collectively, these beliefs and their implementation comprise the midwifery model of care. These beliefs include facilitation of natural processes and nonintervention in these normal processes unless indicated; continuity of care; promotion and implementation of family-centered maternity care; advocacy for the woman and her rights and responsibilities; education of women for knowledgeable participation and decision making in their health care and for understanding their bodily processes; promotion of health care, disease prevention, and the reduction of maternal and infant mortality and morbidity; the role of the midwife within the community; and the contribution of the midwife within the health care system. These beliefs are further elaborated upon as Hallmarks of Midwifery in the ACNM *Core Competencies for Basic Midwifery Practice* [3].

The philosophy of the American College of Nurse-Midwives states beliefs that support and provide a base for the characteristics of health care given by nurse-midwives:

> Certified Nurse-Midwives believe that every individual has the right to safe, satisfying health care with respect for human dignity and cultural variations. We further support each person's right to self-determination, to complete information and to active participation in all aspects of care. We believe the normal processes of pregnancy and birth can be enhanced through education, health care and supportive intervention.
>
> Nurse-midwifery care is focused on the needs of the individual and family for physical care, emotional and social support and active involvement of significant others according to cultural values and personal preferences. The practice of nurse-midwifery encourages continuity of care; emphasizes safe, competent clinical management; advocates nonintervention in normal processes; and promotes health education for women throughout the childbearing cycle. This practice may extend to include gynecological care of well women throughout the life cycle. Such comprehensive health care is most effectively and efficiently provided by nurse-midwives in collaboration with other members of an interdependent health care team.
>
> The American College of Nurse-Midwives (ACNM) assumes a leadership role in the development and promotion of high quality health care for women and infants both nationally and internationally. The profession of nurse-midwifery is committed to ensuring certified nurse-midwives are provided with sound educational preparation, to expanding knowledge through research and to evaluating and revising care through quality assurance. The profession further ensures that its members adhere to the Standards of Practice for Nurse-Midwifery in accordance with the ACNM philosophy. [8]

Individual CNMs and CMs also articulate these beliefs when writing their practice or service philosophy or presenting to the public or teaching students. Nancy Fleming captured the spirit and substance of a discussion in 1993 by the ACNM Board of Directors of the elements that distinguish midwifery when she wrote *The Heart of Midwifery*:

> The heart of midwifery care for women and newborns lies more in the nature of that care than in its specific components. Midwifery practice has a firm foundation in the critical thought process and is focused on the prevention of disease and the promotion of health, taking the best from the disciplines of midwifery, nursing, public health, and medicine to provide safe, holistic care.
>
> Midwives are partners with women in the provision of health care, engaging in a dynamic reevaluation of each woman's unique health needs.
>
> Midwives would rather nurture a woman's progress with hands-on care than diagnose her problems from afar,
> . . . rather listen than lecture,
> . . . rather teach a health principle than treat an illness,
> . . . rather empower a woman to join in decision-making than decide for her,
> . . . rather urge her to speak for herself than to be her advocate,
> . . . rather instill a woman with trust in her body than demonstrate the midwife's technical proficiency
> **although midwives will do all these things when necessary.**
>
> Midwifery is a profession born of a woman's vision, nurtured in an understanding of women's developmental phases, and committed to assuring women in all populations that it is their birthright to be part of this unique care. [9]

These beliefs have had practical application throughout the history of nurse-midwifery in the United States. Through the Maternity Center Association in New York City, nurse-midwives were active in the 1930s in the provision of prenatal care and were in the forefront of the early movements in the 1940s related to family-centered maternity care, natural childbirth, preparation for childbirth and parenthood, inclusion of fathers or significant others in hospital labor and delivery rooms, and rooming-in.

Early History

The history of midwifery in the United States, for the purposes of this book, begins with the arrival of colonists in the New World. Midwives were among the first women to settle the colonies. Although surely there were midwives among the Native Americans, their history is as yet generally unknown and unresearched.

Midwives were considered vital to colonial community life and were treated with dignity. Special courtesies were extended to midwives, and arrangements were made to provide them with housing, land, food, and salary as payment for their services. This information is noted in town records and charters of the mid-seventeenth century. Midwifery was just one of many health care contributions colonial midwives made to the community. Often they also functioned as nurses who tended the sick and the dying and prepared the body after death, herbalists, and veterinarians.

During the nineteenth century, pioneer women crossed the plains in covered wagons, followed the Oregon and Sante Fe trails, settled the "Wild West," and bore children with the assistance of other women in the wagon trains, forts, or settlements who functioned as midwives in the situation [10]. Mormon history documents the honorable role and heroic functioning of midwives during their trek from Illinois to Utah in 1846 and 1847.

Despite the initial honor accorded midwives in the colonies and their importance to other segments of the population through the years, a series of factors reduced midwifery from a respected profession to one in disrepute by the early twentieth century. These factors included religious attitudes, economic demands, replacement by physicians, inadequate education, a lack of organization, an influx of immigrants, and the low status of women.

Factors Leading to Disrepute

Religious factors plagued midwives from the beginning. Most of the early midwives came from England, where in the seventeenth century the licensing of midwives took place under the auspices of the Church of England. Criteria were moralistically judgmental; they emphasized good character and granted the ability to denounce sins and to baptize. The midwives' oath included a vow to pressure the mother into naming the true father. The results of such actions were not always appreciated. On the other hand, in the Puritan communities midwives were often suspected of witchcraft, especially if a malformed baby was born.

By the early eighteenth century, compensation was not always adequate for the midwife; practic-

ing midwifery was no longer economically feasible. This was especially true in the rapidly growing towns and cities. There was no organization or authority to establish guidelines for fees.

In European society in the late eighteenth century, it was fashionable to have male midwives (physicians) for lying-in. This trend soon crossed the ocean, where physicians capitalized on it. Fox offers this analysis of the historical roots of antipathy toward the midwife:

> As the practice of medicine became highly competitive, physicians and medical students were advised that their presence at a delivery would insure the entire family as grateful patients thereafter. For example, the outspoken and highly influential Dr. Walter Channing, of Harvard, objected strongly to the practice of midwifery by women in his "Remarks on the Employment of Females as Practitioners in Midwifery," (1820) and pointed out that "Women seldom forget a practitioner who has conducted them tenderly and safely through parturition—they feel a familiarity with him, a confidence and reliance upon him which is of the most essential mutual advantage.... It is principally on this account that the practice of midwifery becomes desirable to physicians. It is this which ensures to them the permanency and security of all their other business." [11]

Male physicians thus replaced female midwives.

The eighteenth and nineteenth centuries mark a time of rapid development in medical and nursing science and of discoveries and teaching pertinent to obstetric practice. These developments included the end of the Chamberlen family secret of forceps and the refinement of these instruments, technical advances that decreased the risks involved in cesarean section, pioneering efforts in obstetric anesthesia, conquest of puerperal fever, emergence of modern nursing in the 1860s, and inclusion of obstetrics in medical practice. Physician promises of relief from pain during childbirth, the use of chloroform by Queen Victoria during childbirth in 1850, the corresponding evolution of understanding the nervous system with the development of spinal methods of analgesia and anesthesia [12], the need for women receiving obstetric analgesia and anesthesia to be in the hospital, and the lack of access to hospitals by midwives all contributed to the decreased use of midwives.

The observations and teachings of William Smellie (1697–1763), who developed teaching manikins and kept meticulous records of his patients, identified the mechanisms of labor and refuted any number of myths and misconceptions. The anatomical studies of William Hunter (1718–1783) included discoveries pertaining to the lymphatic system, placental circulation, and pregnant uterus. William Shippen, Jr. (1736–1808), the first lecturer on obstetrics, and Samuel Bard (1742–1821), author of the first American textbook on obstetrics, are credited with promoting obstetrical teaching in the United States. All made measurable contributions to the science and art of obstetrics.

These developments, new knowledge, and teachings were not accessible to the midwife because of the relative isolation of midwives from one another and the lack of schools, national organizations, journals, legal recognition, or other means of communication among midwives. Any one of these structures would have provided a channel for learning. Without them, the knowledge and practice of the midwife became sadly out-of-date while medicine advanced and modern nursing began.

The Industrial Revolution at the end of the nineteenth century brought an influx of immigrants from a number of European countries who formed pockets of cultural communities within cities. Each such community had its own midwives who came from the "old country." The vast majority were well-prepared midwives in their own country [13] but had the combined problems of not speaking English and not having access to the existing health care system. Their African-American counterparts in the rural South also could not gain access to the health care system and were poorly educated because of racism. These "granny" midwives frequently passed the practice of midwifery from mother to daughter, learned through experience, and relied heavily on patience, home remedies, and prayer, as these were the only resources available to them and the women they served. Lack of licensure, organization, and formal education programs also contributed to preventing both the urban immigrant midwives and the black rural South midwives from being a part of the official health care system.

The low status of women in general at the beginning of the twentieth century affected the work of midwives. Norma Swenson, in her analysis of social factors affecting the history of midwifery in the United States, makes the following comments:

> But the final and I think more significant point was that the status of women at the turn of the century was at a particularly low ebb. At that point in time women were regarded as economically exploitable but at the same time socially and politically incompetent, in the sense that they were perceived as being unfit to exercise good judgment concerning their own affairs or the affairs of others, and in fact were legally prevented from doing so. Paternal domination of home and society was at an all-time high.
>
> It was then in this kind of atmosphere that midwives were outlawed and women were, therefore, in effect blamed for the appalling conditions under which mothers and babies died at that time, when in fact women were powerless to control social conditions, and coped as midwives as well as they could with circumstances which were largely the product of a man-made industrial and social revolution. [14]

These events and social factors combined by the end of the nineteenth century to create a system of health care education and service to which the descendants of the midwives in the colonies, the urban ethnic immigrant midwives, the African American rural midwives in the South, and the Native American midwives could not have access.

The Early Twentieth Century

The first two decades of the twentieth century are notable for the recognition of woefully inadequate maternity care and subsequent actions taken to improve this care and for the establishment of two organizations: the Children's Bureau in Washington, D.C. and the Maternity Center Association in New York City. Both of these agencies have had an immense influence on the development of maternal-infant health care and of nurse-midwifery.

In 1906, a study was made of maternal and infant mortality in New York City. The study, attributed to the New York City Health Department, stated that more than 40 percent of deliveries were attended by approximately 3000 "incompetent and ignorant" midwives. Although the midwives were no more responsible than the physicians for the high maternal and infant mortality rates at that time, they bore the brunt of the blame. In reality, other factors of obstetrical care contributed to maternal and infant mortality at that time:

1. The hospital was not viewed as a setting for obstetrical care, so few hospital resources were available for treatment of emergencies or complications arising during childbirth in the home (where the vast majority of deliveries took place).
2. The study of obstetrics was not an identified essential component of medical education, except in isolated teaching institutions.
3. The practice of obstetrics was virtually limited to the intrapartal and postpartal periods.
4. Few state laws applied to the licensure and regulation of midwives.
5. No organized system of education for midwives existed.

Progress in improving care was slow. In 1915, the registration of births was a requirement in only ten states. It was not until 1935 that the registration of births became mandatory in every state.

The Children's Bureau

In 1903, Lillian Wald, a nurse and founder of Henry Street Settlement and Visiting Nurse Association in New York City, suggested the formation of a federal children's bureau. President Theodore Roosevelt recommended a bill to establish such a bureau in 1909, but it was 1912 before the U.S. Congress passed a bill, which President Taft signed, establishing the Children's Bureau.

The first act of the Children's Bureau was to conduct a study of infant deaths, which, according to available statistics, produced an infant mortality rate of approximately 124 per 1000 live births. It is to the Children's Bureau's credit that in analyzing the data from its first study, the organization identified the inescapable link between infant health and maternal health during the maternity cycle. The Children's Bureau then conducted studies of maternal mortality and conclusively established the importance of early and continuous prenatal care in reducing both maternal and infant mortality. Thanks to this information, the idea of prenatal care gained respectability and the concept of health care throughout the intraconceptional period began to grow.

The Maternity Center Association

In 1915, the New York City health commissioner made another study of maternal and infant mortality. The findings of this study, which again demon-

strated the connection between mortality and lack of prenatal care, led to the formation of a plan whereby the city was zoned and a maternity center was established in each zone. The first such maternity center opened in 1917. The need for central organization quickly became evident, and the Maternity Center Association (MCA) was established in 1918. By 1920, MCA had 30 maternity centers in New York City. From this network grew MCA's first endeavors in developing teaching materials and educational exhibits for use by individuals and agencies. In 1921, the association decided to concentrate its efforts on a demonstration of providing complete maternity care in one district and to cease the scattered efforts being carried out in its many centers, although some of the other clinics were still maintained for a while longer. This decision was based on the belief that most nursing agencies and hospitals caring for families were now giving sufficient emphasis to prenatal care in their health care services.

In the meantime, MCA and the Henry Street Visiting Nurse Association collaborated on a study that illustrated the value of specialized maternity care within a generalized public health nursing program. Subsequently, MCA embarked on an intensive educational program in maternity care for the public and for professional health personnel, especially physicians and public health nurses.

MCA eventually expanded its efforts beyond New York City; it endeavored to supply information about the need for maternity care to expectant parents throughout the United States. Mother's Day was dedicated to this endeavor for several years, with an emphasis on saving mothers' lives. The mayors of cities made Mother's Day proclamations regarding saving mothers' lives, and ministers preached their Mother's Day sermons on the subject, using packets of educational materials sent by MCA.

On the basis of their demonstration of providing complete maternity care, their collaboration with the Henry Street Visiting Nurse Association, and a study of maternity care in other countries, MCA concluded that there was a need to prepare nurses to do normal obstetrics and discussed opening a school of nurse-midwifery. This idea was temporarily thwarted in the early 1920s by bitter opposition from both medicine and nursing and by a lack of cooperation from city officials.

The "Midwife Problem"

In the early twentieth century, there was a debate over what was known as the "midwife problem." The factors mentioned earlier as contributing to the disrepute of midwifery converged between 1912 and 1914 to turn the licensing and practice of midwives into a heated issue. During this time, medical schools began to include obstetrics in their curricula, and obstetrics became an established medical specialty by 1930. Obstetric care began to move out of the home into the hospital, and laws were passed to regulate the practice of the indigenous midwives. A heated debate ensued.

On one side of the debate were a majority who believed that all midwifery should be abolished; on the other side were those who believed midwives could perform a valuable function. The former feared the status midwives would gain if they achieved legal recognition and promoted the idea that improving the practice of midwives was an impossible task. Those in favor felt midwifery was practical given proper training, licensing, and supervision.

Two significant events took place while the debate raged. The first event grew out of reality. Some states had already passed laws granting legal recognition to midwives and including requirements and specifications aimed at control of their practice. These laws were passed in an effort to reduce high mortality rates, as it was evident that the medical profession could not assume the entire task of obstetric care. In the South, licensure, education, and supervision of African American midwives was facilitated by the Sheppard-Towner Act from 1921 to 1929 [15]. This legislation assigned money, administered through the Children's Bureau, for providing better maternal-infant care. Included in the Act was the specification that public health nurses should be employed for the instruction of untrained midwives.

As a result of these laws to regulate midwifery practice, several midwifery schools were established. The best known of these schools were the Bellevue School of Midwifery in New York City and the Preston Retreat Hospital in Philadelphia. The Bellevue School of Midwifery, designed to instruct indigenous midwives in meeting requirements for practice, operated from 1911 until 1935, when it was closed by order of the New York City commissioner of hospitals, a physician. In his opinion, changing social and medical standards rendered the school superfluous and an unnecessary expense to the city. To support his action, he cited a decrease in the number of midwives as deliveries in hospitals had increased to 81 percent of all births in New York City [16]. The Preston Retreat was a mater-

nity hospital founded in 1836. In 1916, a practical nurse education program was started, and in 1923 a course in midwifery was started that eventually had both practical nurses and Registered Nurses for students. Enrollment dwindled but the midwifery course continued until 1960. It is not known when RNs were first admitted to the course [17].

The second significant event was the introduction of nurse-midwives from Europe. Nurse-midwives had proved their effectiveness in European countries, where they were an established part of the health care system.

The Frontier Nursing Service

The first nurse-midwives to practice in the United States were British-trained nurse-midwives brought to this country in 1925 by Mary Breckinridge as part of her plan to provide health care for people in the remote rural areas of the Kentucky mountains. This endeavor was organized as the Kentucky Committee for Mothers and Babies in May 1925; through a change in its articles of incorporation, it became the Frontier Nursing Service (FNS) in 1928. Thus, FNS traces its history back to, and dates itself from, 1925.

Breckinridge was admirably suited for the task she undertook. Her qualifications included a family background and upbringing that gave her a wealth of influential contacts, professional preparation as a Registered Nurse in the United States and as a State-Certified Midwife in England, personal and professional life experiences, and a carefully self-designed program of observation and study of the Highlands and Islands Medical and Nursing Service in Scotland, concentrating on the Outer Hebrides with further study in England. From this background she crystallized a plan involving outpost nursing centers staffed by nurse-midwives and backed by a medical director located at a small, local, rural hospital. Breckinridge's program was to be administered by a director, overseen by an executive committee and board of trustees, and supported by local committees throughout the United States. Before the work began, a survey of births and deaths in the region where the nurse-midwives planned to work was conducted to provide baseline data for subsequent statistics and research. In her book *Wide Neighborhoods* [18], Breckinridge writes in fascinating detail of the myriad activities, people, concerns, and problems involved in bringing her plan to fruition.

The work and record of the Frontier Nursing Service (Figure 1-1) are legendary. The records kept during the earlier years were in accord with a statistical system set up by the Carnegie Corporation and tabulated by statisticians from the Metropolitan Life Insurance Company. In 1951, the FNS statistics showed that 8596 registered nurse-midwifery patients had been delivered since 1925, 6533 of whom were delivered in mostly primitive homes, with a

FIGURE 1-1 A nurse-midwife of the Frontier Nursing Service in a home in Kentucky, circa 1950. (Reproduced by permission from Frontier Nursing Service, Hyden, Kentucky.)

gross maternal death rate of 1.2 per 1000 for the 25 years studied. This rate was in contrast to national maternal mortality rates of 6.73 per 1000 in 1931, 3.76 per 1000 in 1940, and 0.83 per 1000 in 1950, or an average of 3.4 per 1000 for the same overall period of time. In addition, a comprehensive scope of health care services had been brought to the people, including general dental, pediatric, medical, and surgical services; general eye, tonsil, and worm treatment services; special tuberculosis and trachoma services; and social services supported by Alpha Omicron Pi, the national sorority of social workers, as its national philanthropic project.

World War II had a great effect on the Frontier Nursing Service, both in staffing levels and in the direction the war mandated for nurse-midwifery education at FNS. Great Britain had been both the source of British nurse-midwives working in the Frontier Nursing Service and the provider of midwifery education for U.S. Registered Nurses, who were sent to Great Britain for their education and returned to work at FNS. With the advent of war, the British nurse-midwives wanted to return to their homeland to be of service to their country. It became evident that a long-deferred plan for an educational program in nurse-midwifery had to be instituted immediately. The Frontier Graduate School of Midwifery started with a class of two students in November 1939. By the summer of 1976, 460 nurse-midwives had graduated from the school. In 1970, the school changed its name to the Frontier School of Midwifery and Family Nursing when a Family Nurse Program was begun. This program closed in 1991 and then was resurrected in 1999 as the Community-Based Family Nursing Education Program (CFNP). In the meantime, midwifery education at FNS continued without pause, and in 1989 became the Community-Based Nurse-Midwifery Education Program (CNEP).

The Frontier Nursing Service did not have, however, the first nurse-midwifery education program in the United States.

The First Nurse-Midwifery Education Programs

The Manhattan Midwifery School [19]

The first school established specifically to educate graduate nurses to be midwives was the Manhattan Midwifery School, which opened in New York City in 1925. Although the Preston Retreat course in midwifery started in 1923, it is not known when it first admitted graduate nurses in addition to practical nurses, though it is thought to have occurred some time later.

The Manhattan Midwifery School was affiliated with the Manhattan Maternity and Dispensary, a hospital specializing in maternity care. The midwifery course was initiated by Emily A. Porter, an R.N. and Superintendent of the Hospital, and placed under the jurisdiction of the hospital's School of Nursing. Plans were formulated during 1924, and there were three graduates from the four-month course in 1925. The 1927 *Annual Report of the Manhattan Maternity and Dispensary* states that "this is the only school in the country offering such a course at present." Mary M. Richardson, R.N., B.S., a public health nurse who was a graduate of St. Luke's Hospital in New York City and of Columbia University Teachers' College, studied midwifery at the Hospital for Mothers and Babies in London and became the Directress of the School of Nursing, including the course in midwifery, in 1928. Two of the 1928 graduates went to work with the Frontier Nursing Service. By 1929, the course was six months in length. The 1931 *Annual Report* noted that Mary Richardson had left as Directress of Nursing to return to public health work and that the course had ended:

> The Midwifery Course for graduate nurses started in 1925 has been discontinued during the last year as it was becoming more and more difficult to get enough District cases to take care of the needs of Medical Students.... It was the first and only Midwifery School for graduate nurses in the country. We are glad to hear that a similar one has recently been opened in New York City—The Lobenstine Midwifery Clinic to which we may refer our many applicants.

There were at least 18 graduates of the Manhattan Midwifery School [19].

The Lobenstine Midwifery School

The School of the Association for the Promotion and Standardization of Midwifery was more commonly known as the Lobenstine Midwifery School, named for one of the charter members, Dr. Ralph Waldo Lobenstine. The Association for the Promotion and Standardization of Midwifery was the creation of the Maternity Center Association in New York City. MCA was convinced of the need for nurse-midwives whose preparation would com-

bine U.S. education in obstetric nursing with the education received by the professional European midwife. Much had happened to create a more favorable atmosphere since the abortive attempt by MCA in the early 1920s to establish a nurse-midwifery education program. There was growing recognition of how obstetric conditions in the United States compared poorly with those in other countries, which had much lower mortality rates and well-organized systems of educated and supervised midwives. Publicity spread about the conclusive proof gathered by the Frontier Nursing Service of the value of a system utilizing nurse-midwives, the work of Maternity Center Association in parent education, and its demonstration with the Henry Street Visiting Nurse Association of the value of specialized maternity nursing care.

The Association for the Promotion and Standardization of Midwifery was incorporated in early 1931 by three members of the medical board of the Maternity Center Association and its general director, Hazel Corbin, R.N. Ralph Waldo Lobenstine, M.D., chairman of the medical board of MCA since 1918, was one of the charter members, as was Mary Breckinridge, director of the Frontier Nursing Service. Lobenstine worked tirelessly until his death in 1931 to bring about the establishment of nurse-midwifery services and education. The determination of the members of the Association for the Promotion and Standardization of Midwifery and the financial support of a group of 60 former patients and friends of Lobenstine led to the establishment of the Lobenstine Midwifery Clinic, Inc., in November 1931.

Organizational and administrative details of the clinic were worked out, and a curriculum was designed for the school, the latter guided by British curricula but modified to meet the needs, cultural patterns, and health care systems in the United States. Hattie Hemschemeyer, a public health nurse educator, was named director of the Lobenstine Midwifery Clinic and School. Rose McNaught, a public health nurse who had obtained her midwifery preparation in London and then returned to work at the Frontier Nursing Service, was loaned out by FNS to help develop the program and joined the Lobenstine staff as a clinician and faculty member. The school opened in September 1932 and had six graduates in 1933, including Hattie Hemschemeyer. The memorial funds that had been pledged to establish and maintain the school and clinic for three years were exhausted in 1934. Therefore, in 1934, Maternity Center Association and the Lobenstine Midwifery Clinic consolidated under the name and auspices of Maternity Center Association, which also assumed administrative and financial responsibility for the School of the Association for the Promotion and Standardization of Midwifery. Thus MCA traces the history of its school of nurse-midwifery back to 1932.

The nurse-midwifery services provided through the clinic consisted of antepartal care and patient education at the clinic, intrapartal and postpartal care in the patient's home except when hospitalization was required for medical reasons, and postpartum checkups at 14 days and 6 weeks in the clinic. Four attending obstetricians provided their services at medical clinics and round-the-clock consultation and, if necessary, were present in the patient's home for delivery. During the 26 years the Lobenstine Clinic provided clinical services (1932–1958), a total of 7099 deliveries were attended, of which 6116 took place in patients' homes. The maternal mortality rate of the clinic was 0.9 per 1000 live births, as contrasted to a maternal death rate of 10.4 per 1000 live births for the same geographic district as a whole and 1.2 per 1000 live births for a leading hospital in New York City.

The Maternity Center Association School of Nurse-Midwifery (Figure 1-2) graduated 320 students between 1933 and 1959, utilizing the services

FIGURE 1-2 A new nurse-midwifery student (Margaret Thomas) in the 1930s being greeted by faculty member Rose McNaught at the Maternity Center Association Lobenstine Clinic and School. (Reproduced by permission from Maternity Center Association, New York, New York.)

provided by the Lobenstine Clinic for educational purposes. In 1958, it moved inside a major medical and educational institution, and was established in the Downstate Medical Center, State University of New York in Brooklyn, New York; students used Kings County Hospital for clinical experience. This move was facilitated by Hazel Corbin, R.N., executive director of MCA, Marion Strachan, C.N.M., director of the nurse-midwifery program, and Louis Hellman, M.D., chairman and professor of obstetrics and gynecology at Downstate Medical Center and Kings County Hospital.

Subsequent Programs of Education

Almost all of the nurse-midwifery and midwifery education programs today that are accredited by the Division of Accreditation of the American College of Nurse-Midwives can trace their beginnings to the Maternity Center Association's School of Nurse-Midwifery because they were started by either graduates or students of graduates of the MCA program. The exceptions are the Frontier School of Midwifery and a handful of programs started by Frontier Nursing Service graduates.

There were seven nurse-midwifery education programs nationwide by the end of the 1950s. They are listed here with their starting dates, names, and locations as of 1960:

1932 School of the Association for the Promotion and Standardization of Midwifery (became the Maternity Center Association School of Nurse-Midwifery in 1934; affiliated with Downstate Medical Center, State University of New York and Kings County Hospital, Brooklyn, New York, in 1958; also includes an early affiliation of MCA and Kings County Hospital with Johns Hopkins University during 1958–1960)

1939 Frontier Graduate School of Midwifery of the Frontier Nursing Service, Hyden, Kentucky

1945 Catholic Maternity Institute School of Nurse-Midwifery, Santa Fe, New Mexico

1947 Catholic University of America, Washington, D.C. (affiliated with Catholic Maternity Institute)

1955 Columbia University Graduate Program in Maternity Nursing, New York City, New York

1956 The Johns Hopkins University Nurse-Midwifery Program, Baltimore, Maryland

1956 Yale University Graduate Maternal and Newborn Health Nursing Program, New Haven, Connecticut

Three of these programs subsequently closed: Catholic Maternity Institute (1968); Catholic University of America (1968), which had the distinction of being the first nurse-midwifery education program to be part of a master's degree program; and the Johns Hopkins University Nurse-Midwifery Program (1981). In addition to the closure of the Manhattan Midwifery School in 1931 and the Preston Retreat School of Midwifery in 1960, two other schools opened and closed during the 1940s:

1941–1946 The Tuskegee School of Nurse-Midwifery in Tuskegee, Alabama; a joint project of the Macon County Health Department, the Children's Bureau, the Julius Rosenwald Fund, Tuskegee University, and the Alabama State Department of Health. Graduated 31 students [20].

1942–1943 The Flint-Goodridge School of Nurse-Midwifery in New Orleans, Louisiana; in connection with Flint-Goodridge Hospital and Dillard University. Graduated two students [21].

The 1940s and 1950s

The early graduates from MCA went into a variety of positions, the only common denominator being their goal of improving maternity care. The majority of graduates either practiced or taught clinical nurse-midwifery in MCA or FNS programs or became involved with various aspects of public health. A number of nurse-midwives in public health went to work in state health departments in positions designed for the supervision and teaching of indigenous midwives. These positions were in keeping with an original purpose of the Sheppard-Towner Act—that public health nurses be employed for the instruction of untrained midwives. As many of the early MCA graduates were also public health nurses, they were ideally prepared for working in rural maternity care, where the majority of indigenous midwives practiced.

Other graduates held positions as maternal-child health consultants for state boards of health or within the federal bureaucracy. Still other graduates became involved in the nurse-midwifery education programs at Tuskegee Institute in Alabama and Flint Goodridge in Louisiana.

In 1944, members of the Medical Mission Sisters, a Roman Catholic order, who were graduates of the MCA program started the Catholic Maternity Institute (CMI) in Santa Fe, New Mexico. CMI long stood as an outstanding example of what could be accomplished through intera-

gency cooperation and commitment to patient care. Births took place in the home or in La Casita, the first nurse-midwifery birth center.

In the middle and late 1940s, graduates of MCA at Yale University were central in developing the concept and practice of rooming-in and in studying the effects of natural (prepared) childbirth and family-centered supportive care on a woman's antepartal, intrapartal, and postpartal experience.

The 1950s saw the development of three more educational programs by MCA graduates at Columbia University, Johns Hopkins University, and Yale University. Maternity Center Association was directly involved in initiating two of these programs (Columbia and Johns Hopkins) by sending nurse-midwives to start them. The 1950s also saw the founding of the American College of Nurse-Midwifery. The history of this professional organization is detailed later in this chapter.

In the 1940s and 1950s, there was considerable demand for nurse-midwives to serve as nursing educators in maternity nursing; to fill nursing service staff, supervisory, and consultant positions in hospital obstetrics departments; and to act as consultants in federal and international health organizations. These employment possibilities, combined with a lack of opportunities for clinical nurse-midwifery practice, created the situation in which a large percentage of the early graduate nurse-midwives did not actually practice clinical nurse-midwifery. In a 1954 survey, 147 nurse-midwives identified 426 job positions they had held since graduation. Of these 426 job positions, 27 percent had been as a staff nurse-midwife [22].

The 1960s

Opportunities to practice clinical nurse-midwifery were severely limited for a nurse-midwife graduating in the early 1960s. Only two states and one city legally recognized the practice of nurse-midwifery at that time: New Mexico, Kentucky, and New York City. Another state, Maryland, had nurse-midwives practicing under an old granny midwife law.

In brief, a graduate could join the faculty of one of the existing nurse-midwifery education programs; practice at Catholic Maternity Institute in Santa Fe, Frontier Nursing Service in Kentucky, Baltimore City Hospital and Johns Hopkins University in Baltimore, or Kings County Hospital or Cumberland Hospital in New York City; or go to an overseas mission field. A few other isolated service positions or projects existed but generally were not known or, as in the case of the Madera County project in California, offered only short-term employment by virtue of being demonstration projects. Therefore, the majority of graduates of that era went into teaching, supervisory, administrative, or consultative positions in related fields. This situation led to the need for refresher programs for nurse-midwives wanting to return to the practice of clinical nurse-midwifery when, less than a decade later, service sites in which to practice expanded rapidly.

In the late 1950s and the 1960s, nurse-midwives made a deliberate and concerted effort to get into hospitals, as that was where the majority of births (approximately 70 percent at that time) now took place. The movement of nurse-midwives into hospitals brought concepts of family-centered maternity care and a consumer advocate to childbearing women who delivered in hospitals. Nurse-midwives were now working in both in-hospital and out-of-hospital settings.

By 1967, approximately 23 percent of 468 employed nurse-midwives responding to a questionnaire [23] were actually practicing clinical nurse-midwifery. This number represented a substantial increase from the 11 percent practicing in 1963. Of the 468 employed nurse-midwives who responded to the 1967 survey, 103 (22 percent) worked in foreign countries, mostly through church missions or international health organizations. Fifty-six percent of the employed nurse-midwives were in service areas related to nurse-midwifery but were not actually practicing nurse-midwifery (working in obstetrics, pediatrics, maternal-child health programs, and public health departments as supervisors, administrators, staff nurses, head nurses, consultants, educators, and researchers); 75 percent held positions above the staff level. Of the 23 percent practicing nurse-midwifery, 35 percent were also on faculties of schools of nurse-midwifery; 53 percent gave nurse-midwifery services throughout the maternity cycle; and the remaining 12 percent functioned as nurse-midwives in one or more, but not all, of the phases of the maternity cycle.

Development of opportunities to practice clinical nurse-midwifery remained slow into the late 1960s, with a few isolated areas utilizing practicing nurse-midwives and the remaining nurse-midwives contributing to maternal-infant health care in related fields. It was not until 1968, when nurse-mid-

wives were employed in the Maternal-Infant Care (MIC) nurse-midwifery program in New York City to practice in community clinics linked with hospitals, that previously unheard-of employment opportunities for nurse-midwives to practice midwifery began to be available [24]. The first nurse-midwife to practice within the Indian Health Service was in 1969 [25].

Five nurse-midwifery education programs opened in the 1960s, four of which subsequently closed (the second date is the closing date):

1960–1981 University of Puerto Rico/Caparra Heights District Hospital
1963–1972 New York Medical College Graduate School of Nursing Nurse-Midwifery Program, New York City
1965 University of Utah Graduate Maternal-Infant Nursing Program
1966–1975 Ponce District Hospital, Ponce, Puerto Rico
1969–1985 University of Mississippi Medical Center Nurse-Midwifery Program

A number of obstacles contributed to this slow development in practice and education. Paramount among these were misconceptions and stereotypes regarding nurse-midwives. These mistaken ideas led to outright hostility by some professionals. At the same time, other professionals came to believe in and support the development of nurse-midwifery. Hostility and support have emanated from both professional groups of colleagues with whom nurse-midwives work: physicians and nurses.

Following are some of the misconceptions and stereotypes often heard during that period of time that hindered the development of nurse-midwifery in the 1960s, as well as the factual rebuttals given at that time:

- *Stereotype:* Midwives are all alike. Frequently, when only the midwife part of nurse-midwife is used or heard, the word conjures up a negative image. This image is of the good-hearted, loving, but untrained midwife either of past history or in rural areas of the South today or functioning as a birth attendant for those disenchanted with the present health care system. It leads to the irrational conclusion that nurse-midwives are an uneducated menace representing a backward step into illiteracy in the provision of maternal-infant health care.
- *Fact:* The name *nurse-midwife* actually specifies exactly who and what a nurse-midwife is. Either part of the name alone does not fully describe the unique profession of the nurse-midwife in the United States. The *nurse* part recognizes the prerequisite education in nursing, differentiates the nurse-midwife from the historical or contemporary lay midwife, and assures a continuing emphasis on patient education, support, and counseling. All Certified Nurse-Midwives are Registered Nurses. Two-thirds of the nurse-midwifery education programs are offered in schools granting a master's degree. The *midwife* part of the name recognizes the additional specialized preparation and functioning of the nurse-midwife, tempers the medical focus in normal obstetrics, and identifies the nurse-midwife with professional midwife counterparts the world over.
- *Misconception:* Nurse-midwives are trying to be "little doctors." In general, physicians think that nurse-midwives don't know "their place," while nurses think that nurse-midwives have "sold out" to the physicians and are, therefore, traitors to nursing.
- *Fact:* Nurse-midwifery is a clearly defined profession. Nurse-midwives believe fervently in who they are, what they have to offer, and what they can do. In fact, lack of acceptance for years by both medicine and nursing meant that the profession of nurse-midwifery attracted only those individuals who were highly dedicated and committed to contributing to the improvement and provision of maternal-infant health care in this capacity.

Nurse-midwives are experts in the normal childbearing cycle. They wish to be precisely who they are and to do precisely what they do—encourage and facilitate natural, normal childbearing processes with a minimum of interference; educate, support, and instigate personal and family growth; foster self-confidence and independence; dispel fear; and provide a calm atmosphere of acceptance and caring.

Nurse-midwives are neither sell-outs nor traitors to either nursing or medicine. Instead, they realistically recognize the need for having the support of both the nursing and the medical professions in order for real growth in nurse-midwifery to take place. For the benefit of mothers and babies, nurse-midwives continue to seek accord with both.

The 1970s

In the late 1960s and early 1970s, everything changed. Suddenly nurse-midwifery was not only acceptable but inundated with requests for practitioners and berated for the lack of nurse-midwives

to meet the demand. The late 1960s and early 1970s were a time of rapid development in nurse-midwifery, with widespread proliferation of nurse-midwifery services and educational programs that continued through the decade.

By the end of the 1970s, nurse-midwifery education had proliferated to a total of 22 basic educational programs, thereby doubling in 10 years the number of programs developed during the preceding 37 years. Fifteen new programs opened during this period of time, of which six subsequently closed (the second date is the closing date):

1972 University of Illinois at Chicago Nurse-Midwifery Program
1971–1975 Loma Linda University Nurse-Midwifery Program, California
1973 University of Minnesota Nurse-Midwifery Program
1973 Medical University of South Carolina Nurse-Midwifery Program
1973 Georgetown University Nurse-Midwifery Program, Washington, D.C.
1973–1984 St. Louis University Graduate Program in Nurse-Midwifery, Missouri
1973–1985 Meharry Medical College Nurse-Midwifery Program, Nashville, Tennessee
1973–1998 University of Kentucky Nurse-Midwifery Program
1975 University of Medicine and Dentistry of New Jersey Nurse-Midwifery Program
1975 University of California, San Diego Nurse-Midwifery Program
1974–1997 U.S. Air Force Nurse-Midwifery Program, Andrews Air Force Base, Maryland
1976 Emory University Nurse-Midwifery Program, Atlanta, Georgia
1977–1985 University of Arizona Nurse-Midwifery Program
1978 University of Miami Nurse-Midwifery Program, Florida
1978 San Francisco General Hospital/University of California San Francisco Interdepartmental Nurse-Midwifery Education Program

The proliferation of educational programs overextended the existing resources for clinical experience for students. A workshop of nurse-midwifery education and service directors focusing on their interdependence was held in 1973. The group divided into task forces to make recommendations for solutions to the serious lack of clinical experience available to students. These recommendations were forwarded from the workshop to the ACNM Board of Directors [26]. Nurse-midwives cooperated with one another in the provision of clinical facilities and clinical faculty for educational purposes. This effort has meant sacrifice on the part of many for the preservation of the profession; the joy and motivation of the practicing nurse-midwife comes from providing services directly to women, their babies, and their families.

A number of factors contributed to this unprecedented growth in nurse-midwifery education and practice sites:

1. Official recognition by organized obstetrics. A joint statement in 1971 by the American College of Obstetricians and Gynecologists, the Nurses Association of the American College of Obstetricians and Gynecologists, and the American College of Nurse-Midwives recognized and supported the development and utilization of nurse-midwives [27].
2. Increased visibility and involvement of the women's movement and feminism, which increased feelings of self-worth and self-confidence in all women. These attributes led to a natural alliance between women who wanted to participate in and be responsible for their childbearing experience and nurse-midwives, who facilitate the natural and normal processes, provide family-centered care, and promote parental self-determination.
3. Recognition by the consumer. An increasing number of articles about the "new midwife" were published in major magazines such as *Redbook*, *Newsweek*, *Life*, and *McCall's*, in Sunday newsmagazines, and in newspapers such as the *New York Times* and the *Wall Street Journal*. Greater consumer awareness and the satisfaction of those experiencing nurse-midwifery care and writing about it led to consumer demand for nurse-midwifery services.
4. Use of nurse-midwives in federally funded projects such as Maternal-Infant Care (MIC), Family Planning monies (314E), Agency for International Development (AID), and demonstration projects geared toward improving maternal-infant health care and providing family planning services. Through these projects, more professionals became familiar with nurse-midwifery. This familiarity dispelled misconceptions, and many physicians and nurses subsequently became ardent supporters of nurse-midwifery.
5. The children of the post–World War II baby boom were having babies during the mid-1960s and 1970s. This population peak meant that there was not, and would not be, a sufficient

supply of obstetricians to care for all of the childbearing women in the country. This shortage of obstetricians, combined with the small number of general practitioners doing obstetrics, highlighted the lack of human resources during this period of time. This shortage led to scrutiny of how best to use the optimal capabilities of each health care worker and promoted commitment to the obstetric team concept, which included utilization of the nurse-midwife.

6. Demonstration of the efficacy of the obstetric team concept. The effectiveness of nurse-midwives had been statistically proved repeatedly since the first studies at the Frontier Nursing Service [28], in the Madera County Demonstration Program in California in the 1960s [29], in every service where nurse-midwives had worked, and in the team concept, which decreased by half the infant mortality in Holmes County, Mississippi, in the early 1970s [30].
7. The involvement of nurse-midwives in interconceptional health care (i.e., family planning, human sexuality, and gynecological screening) and in neonatal care including promotion of parenting. This involvement fully rounded out nurse-midwifery management throughout the childbearing cycle, thereby providing continuity of care to the developing family.

The credentialing mechanisms of individual national certification as a Certified Nurse-Midwife and the accreditation of nurse-midwifery education programs were well established by the early 1970s. A decade later, both ACNM credentialing mechanisms were recognized by umbrella organizations with that purpose: certification was recognized by the National Commission of Health Certifying Agencies, and accreditation of basic nurse-midwifery education programs was recognized by the U.S. Department of Education.

The first private practice with nurse-midwives began in the early 1970s [31]. With the consumer "discovery" of the nurse-midwife came a burgeoning of private practice nurse-midwives, and another inhibiting misconception was laid to rest:

- *Misconception:* Nurse-midwifery is second-class care for second-class citizens. It follows that nurse-midwives can be utilized only for care of the indigent and will never be accepted by middle- and upper-class patients.
- *Fact:* By the mid-1970s, nurse-midwives were in practice with physicians all over the country, taking care of middle- and upper-class patients. According to a 1976–1977 survey by the American College of Nurse-Midwives [32], approximately 26 percent of all nurse-midwives practicing nurse-midwifery worked in some form of private practice arrangement. Nurse-midwives are well accepted by these women, who often prefer to be seen in the office and to be delivered by the nurse-midwife as long as their condition does not require the physician member of the team. This preference is largely a result of the time the nurse-midwife spends explaining and teaching during the office visits, the commitment of the nurse-midwife to the woman throughout labor, and the practical application of the beliefs of the nurse-midwife in promoting a family-centered, normal childbearing experience. This preference places the obstetrician in the difficult position of feeling displaced at the same time that the obstetrician is initially introducing the nurse-midwife into his or her private practice and is creating the environment in which women will come to accept the nurse-midwife by virtue of the care the nurse-midwife gives them. Mutual professional understanding and patience are required in order for the woman to obtain the maximum benefit and advantages of the physician/nurse-midwife team approach.

The misconception arose from the fact that nurse-midwifery practice for years took place mainly in large medical centers and city hospitals serving the medically indigent or in remote rural areas with few physicians. This initial concentration of nurse-midwives in settings serving women from lower socioeconomic groups occurred because the nurse-midwife's professional services were welcomed first in areas where help was most desperately needed.

During the 1970s, nurse-midwifery had become not only acceptable but also desirable and demanded. After years of struggling for existence, nurse-midwives now faced the problem of a severe shortage of supply to meet the demand. The first edition of this book (1980) discussed the conflicting pressure on nurse-midwives in the 1970s:

> On the one hand is the need for providing quantity services sufficient to warrant the expense of utilizing nurse-midwives by the established health care system and the need for nurse-midwives to be able to function within this system to benefit mothers and babies either desiring or needing care in the system. On the other hand, there is a small but growing number of consumers who are dissatisfied with the health care provided by the system, who desire care outside of the system, and who look to nurse-midwives for support and services. Lack of

> response with childbirth alternatives (e.g., hospital birthing rooms, childbirth centers, or carefully selected home births) further disenchants the consumer with professional health care and fosters the development of often untrained lay midwives or birth attendants, and a do-it-yourself movement. Affecting this conflict is the issue of nurse-midwives being able to collect third party payment for services. The resolution of this conflict has far-reaching implications and ramifications and constitutes the challenge nurse-midwifery has had in the latter half of the 1970s. [33]

Lay midwifery developed in the 1970s in response to the disenchanted childbirth consumers who wanted to give birth to their babies outside of the hospital. The term *lay midwifery* in the 1970s and 1980s referred to all non–nurse-midwives, whose preparation in midwifery was highly variable. Today the term refers to noncredentialed midwives. Some lay midwives prefer to call themselves traditional, community, empirical, or independent midwives. Sometimes the term *direct entry* is misused to mean lay or noncredentialed apprenticeship-prepared midwives. The term *direct-entry midwives* originated many years ago in England, where non-nurses completed a formal educational program leading to the same credentialed and regulated professional midwifery as nurse-midwives. Lay midwifery struggled with its early identity, as lay midwives disagreed sharply among themselves regarding the desirability of formal education, standards, credentialing, and regulation.

A number of groups and organizations supportive of lay midwifery and home birth sprang up during the 1970s: NAPSAC (National Association of Parents and Professionals for Safe Alternatives in Childbirth), HOME (Home Oriented Maternity Experience), ACHI (Association of Childbirth at Home International), and NMA (National Midwives Association). Existing organizations such as ICEA (International Childbirth Education Association) and La Leche League added their support. The first national meeting of lay midwives took place in 1977 in El Paso.

The 1980s

By the 1980s, nurse-midwives were practicing in the full range of possible arenas—from clinics and federally funded programs to HMOs and hospitals, from being employed by physicians to employing the physicians—and providing a full range of services, from in-hospital delivery services to out-of-hospital delivery services or a mix of both. By this time nurse-midwives were perceived to be competitors for the obstetric health care dollar. Supportive physicians continued to enable nurse-midwifery practice to exist by providing necessary physician consultation, collaboration, and referral systems; opposing physicians tried to restrict the growth of nurse-midwifery through state legislative battles over statutory recognition of nurse-midwives, mandated third-party reimbursement, and prescriptive authority; denial of hospital practice privileges; and pressure on supportive physicians vis-à-vis their malpractice insurance. The entire situation was exacerbated by the fact that there was an overabundance of physicians, which would continue for the foreseeable future. In the view of many physicians, nurse-midwives were no longer needed.

An investigative congressional hearing into the problems faced by nurse-midwives was held in 1980, and the Federal Trade Commission became actively concerned with possible and real restraint-of-trade issues. At the same time health care costs had become unacceptably high and some services run by nurse-midwives were demonstrating that they were cost-effective.

A survey of nurse-midwives in 1971 showed that 37 percent of the respondents were in the direct practice of nurse-midwifery, compared with 23 percent in 1967 and 18 percent of those nurse-midwives practicing in the United States in 1963. By 1976–1977, 51 percent of 1218 respondents living in the United States and replying to a questionnaire [32] were actually practicing nurse-midwifery. Within the 15 years from 1963 to 1978, active nurse-midwifery services increased from six services in three states and New York City to multiple services in 35 states, with more in planning stages. By 1982, 67 percent of 1584 survey participants living in the United States stated they were practicing nurse-midwifery [34]. In 1984, nurse-midwives were practicing in all 50 states; by 1988, nearly 80 percent of the respondents to an ACNM survey were in nurse-midwifery practice and education [35]. The legal practice of nurse-midwifery had spread from three states and New York City in 1963 with its legal status in the other states largely unknown, to a very clear legal status in all 50 states and four jurisdictions (District of Columbia, Guam, Puerto Rico, and the Virgin Islands) as a result of extensive and intensive work by the legislation

committee of the American College of Nurse-Midwives.

From practicing almost exclusively in large medical centers, city hospitals, and remote rural areas in the early 1960s, nurse-midwives had moved into every possible type of setting by the late 1970s and early 1980s. Because continuity of care is an essential component of nurse-midwifery care, a nurse-midwife may work in more than one practice setting.

The late 1970s and early 1980s also saw the rapid development of out-of-hospital childbirth centers, with Maternity Center Association spearheading this movement. Chapter 35 details the history of out-of-hospital childbirth centers.

Lay midwives organized themselves in 1982 with the creation of the Midwives Alliance of North America (MANA) to include midwives in Canada and Mexico as well as the United States. Membership is diverse; it includes anyone who chooses to call herself or, rarely, himself a midwife and reflects a complete range of educational preparation and experience. MANA established an Interim Registry Board (IRB) in 1986 to create an examination and maintain a registry of midwives who passed the examination. The examination was first administered in 1991, and the IRB subsequently separated from MANA and incorporated as the North American Registry of Midwives (NARM). In 1991, the National Coalition of Midwifery Educators, an organization separate from MANA and the MANA Education Committee, formed the Midwifery Education and Accreditation Council (MEAC).

The 1990s and Early 2000s

The early 1990s witnessed another growth spurt in nurse-midwifery education programs, in part as a result of states' recognizing the quality and cost-effectiveness of nurse-midwifery care and funding programs within their states. The ACNM set the goal of having 10,000 Certified Nurse-Midwives by 2001. In 1995, slightly more than 5000 had been certified. With the increased number of new programs, the growing number of students in existing programs, and the advent of community-based long-distance learning, the trajectory to the goal was on target. In mid-2001, the total number of persons ever certified was 9327, including 28 Certified Midwives.

During the 1980s and 1990s, the number of programs again doubled, so that by the end of the century 45 accredited basic nurse-midwifery education programs existed, one of which was also an accredited basic midwifery education program. A listing of all the current education programs accredited by the ACNM Division of Accreditation can be obtained from the ACNM Web site [36]. Seven of the 38 programs that opened during these two decades subsequently closed:

1982–1987 Stanford University Midwifery Education Program, Stanford, California

1981–1988 Rush University Nurse-Midwifery Program, Chicago, Illinois

1982–1999 University of California, San Francisco/University of California, San Diego, Intercampus Nurse-Midwifery Program

1986–1998 Education Program Associates Midwifery Education Program, San Jose, California

1991–1996 University of Alabama Nurse-Midwifery Program

1993–2001 University of Rochester Nurse-Midwifery Program, New York

1995–2002 University of Missouri Nurse-Midwifery Program

The health care system started to move in the direction of managed care in the early 1990s. Nurse-midwives once again found themselves struggling to be recognized and "at the table" both nationally and locally for far-reaching decisions affecting the health care system and nurse-midwifery practice. Practical preparation for establishing nurse-midwifery practices and services increasingly focused on business aspects of a practice, including marketing, budgets, financial concerns and policy issues, methods of determining productivity, billing and coding, and effective business practices. The Nurse-Midwifery Service Directors Network wrote *An Administrative Manual for Nurse-Midwifery Services*. In addition to its long existing *Guidelines for Establishing a Nurse-Midwifery Practice*, the ACNM put together a marketing packet for CNMs and handbooks on managed care and managed care contracting. In 1996, the Midwifery Business Institute was started by nurse-midwives at the University of Michigan School of Nursing and the University of Michigan Health System; both institutions co-sponsor this annual conference.

The ACNM Division of Accreditation (DOA) was first recognized by the U.S. Department of

Education (USDOE) as a national accrediting body in 1982. Recognition has been renewed as proscribed by the USDOE ever since. In 1989, the ACNM Board of Directors (BOD) stated that "The ACNM will actively explore, through the DOA, the testing of non-nurse professional midwifery educational routes." In 1990, the DOA determined that in order to address the charge from the BOD, it was necessary to first identify those nurse competencies that were assumed to be brought by a Registered Nurse to a nurse-midwifery education program. The DOA completed this task in 1994. These competencies were combined with specified prerequisite courses into an ACNM DOA document entitled *Skills, Knowledge, Competencies, and Health Sciences Prerequisite to Midwifery Practice* [37].

In 1994, the ACNM, in response to requests from state regulatory agencies, took the leadership role in setting the standards for the credentialing of non-nurse midwives. The immediate impetus for this effort was the growing use of licensed health care professionals, most often physician assistants, to practice midwifery without educational preparation or credentialing for this role. Using, at a minimum, the same criteria as for nurse-midwifery education programs, the ACNM DOA developed criteria for basic midwifery education programs for non-nurse midwives, and the ACNM Certification Council committed itself to the testing and certification of graduates from ACNM DOA-accredited midwifery programs who would receive the credential of Certified Midwife (CM) [37]. These direct-entry midwives meet the same end point academic and clinical objectives as Nurse Midwives: providing primary care to women from puberty through senescence with an emphasis on the maternity cycle and practice in all settings (hospital, birth center, and home).

The first educational program for non-nurse midwives preaccredited by the ACNM DOA was established in 1996. The first graduates from this program were in 1997, and in 1999 the program was fully accredited. Two other direct-entry midwifery programs have since been preaccredited by the ACNM DOA. In May 2001, the U.S. Department of Education renewed its recognition of the ACNM DOA for preaccreditation and accreditation of nurse-midwifery education programs and recognized the expansion of the scope of its activities to include preaccreditation and accreditation of direct-entry midwifery education for the non-nurse.

In the meantime, the Midwifery Education and Accreditation Council (MEAC), which had evolved from the lay midwifery movement in the 1970s and 1980s, organized and defined itself in terms of accrediting education of non-nurse direct-entry midwives in the maternity cycle and out-of-hospital—especially home birth—practice only. MEAC applied for and received recognition from the U.S. Department of Education as an accrediting body in January 2001. MEAC-accredited programs prepare graduates for the examination of the North American Registry of Midwives (NARM) and recognition as a Certified Professional Midwife (CPM). In 2001, the National Association of Certified Professional Midwives was formed with the purpose of establishing a professional organization and setting national practice standards for CPMs.

Credentialed midwifery at the beginning of the millennium now encompassed both nurses and two types of direct-entry non-nurses leading to certified midwives (CNM, CM, CPM) with different educational processes and two very different scopes of practice but well defined and distinguishable from the noncredentialed lay midwife.

The American College of Nurse-Midwives

The American College of Nurse-Midwives (ACNM) is the national professional organization for Certified Nurse-Midwives and Certified Midwives. Its mission is to promote the health and well-being of women and infants within their families and communities through the development and support of the profession of midwifery as practiced by CNMs and CMs [38]. Incorporated in 1955, the ACNM was founded as the outgrowth of a series of circumstances that rendered its creation necessary.

Early efforts to organize met with difficulties. An organizational meeting in 1940, chaired by Hattie Hemschemeyer, resulted in the formation of the National Association of Certified Nurse-Midwives (NACNM). Bylaws were written but the organization never evolved beyond this point. A 1944 meeting of nurse-midwives, again called by Hattie Hemschemeyer to discuss formation of a national organization, led the group to reject the option of establishing a new organization as financially and time/effort-prohibitive. The group also rejected the option of working to make the FNS-related American Association of Nurse-Midwives (AANM) become the national organization they envisioned because the AANM "did not

admit colored nurse-midwives." Instead, the group accepted an offer from the integrated National Organization of Public Health Nurses (NOPHN) to establish a section for nurse-midwives [39].

As a section of the NOPHN, nurse-midwives could define themselves, share information and knowledge, and start the process of setting educational and practice standards for the profession. In 1949, the nurse-midwifery section published the first national descriptive data gathered about nurse-midwives [40]. The NOPHN was dissolved in 1952 following a general reorganization of the national nursing organizations. While the NOPHN was absorbed into the American Nurses Association (ANA) and the National League for Nursing (NLN), these organizations did not make any provision for a recognizable entity of nurse-midwives. Instead, the nurse-midwives were assigned to the ANA's Maternal and Child Health Council and the NLN's Interdivisional Council, which encompassed the areas of obstetrics, pediatrics, orthopedics, crippled children, and school nursing. The membership and concerns of the NLN council were simply too broad to serve as a forum or voice for nurse-midwifery. Being part of the ANA's Council would have meant that nurses who were not midwives would be making decisions about nurse-midwifery practice and education. Ironically, even though nurse-midwives were in positions of leadership in maternal-child nursing in educational, professional, and federal organizations pertaining to health care, they were usually not thought of as being nurse-midwives.

The Committee on Organization

As the identity of nurse-midwives could not be maintained in the existing situation, the nurse-midwives present at an ANA convention in the spring of 1954 agreed to establish The Committee on Organization. Sister M. Theophane Shoemaker, the director of the Catholic Maternity Center in Santa Fe, New Mexico, was chair of the committee.

The Committee on Organization, though claiming its progress was slow and tedious, had within two months identified reasons for organizing; discussed ways in which organization could be accomplished; written a definition of a nurse-midwife; identified the functions of a new organization if one was to be established; set educational standards for nurse-midwifery schools, including a statement of purpose and basic admission requirements; designed and mailed a questionnaire to locate nurse-midwives and ascertain their desire to organize; written and mailed two of the eventual six *Organization Bulletins of The Committee on Organization*; and organized a meeting of nurse-midwives for December 1954.

Forty-six nurse-midwives attended that meeting, during which they reviewed the work done to that point and the results of the questionnaire (to which 147 nurse-midwives had replied), and approved the definition of a nurse-midwife and a statement of purposes of a nurse-midwifery organization. The major issue, however, was how organization could be accomplished. Four possible options had been identified:

1. Organization within the American Nurses' Association (ANA) as a conference group
2. Organization within the National League for Nursing (NLN) as a council
3. Reorganization of the American Association of Nurse-Midwives (AANM) into a national organization
4. Formation of an entirely new organization of nurse-midwives to be known as the American College of Nurse-Midwifery

The American Association of Nurse-Midwives had been started in 1929 as the Kentucky State Association of Midwives, incorporated by nurse-midwives working with the Frontier Nursing Service. Mary Breckinridge, then director of the Frontier Nursing Service, was the continuing president of AANM during her lifetime. Its function was akin to that of an alumnae association, although membership was not limited to alumnae. Efforts to reach out to the AANM to persuade its members to reorganize were made by Sr. Theophane Shoemaker and Hattie Hemschemeyer. Mary Breckinridge, however, stood firm in her belief that nurse-midwives should be part of the nursing organizations and that the structure of the AANM would not change [39]. AANM, therefore, was eliminated as a possible option based on its members' analysis and statement of preference not to be considered.

The remaining options were either to organize within one of the national nursing organizations or to create a new organization. The decision was deferred until letters requesting a conference group and a council, respectively, were submitted to, and replies were received from, ANA and NLN. The letters were approved during the meeting.

The NLN expressed interest and concern but pointed out that its bylaws for organization of a council would not meet the needs of the nurse-midwives. The reply from the ANA was not encouraging. The ANA was interested in a plan to establish

an interdisciplinary committee of the ANA and the NLN, with additional representatives from the public, to study the improvement of the care of mothers and children. The nurse-midwives could be a part of this committee.

This information was published in the fourth *Organization Bulletin*, along with the plans for the next meeting of The Committee on Organization and a request for comments regarding what was emerging as the obvious direction for organization. At its meeting in May 1955, The Committee on Organization voted unanimously to proceed with the formation of the American College of Nurse-Midwifery. Those present based their action on the facts that all the other options had essentially been ruled out, that 133 of the 147 nurse-midwives answering the questionnaire had responded positively to the idea of belonging to a new organization of nurse-midwives, that formation of a separate organization obviously seemed to be the only way that nurse-midwives could work together and accomplish the goals that had been delineated in the statement of purposes, and that only one response had been received to the request for comments regarding this direction. The Committee on Organization had done such a splendid job of keeping all the nurse-midwives informed and involved that there was nothing further to be said.

The Committee on Organization then began working to incorporate and establish the new organization. The incorporation of the American College of Nurse-Midwifery took place on November 7, 1955, in the state of New Mexico. New Mexico was chosen because it was one of the few states in which nurse-midwives were practicing and incorporation there involved the least amount of red tape, time, and expense.

The ACNM as an Organization

The first annual meeting of the American College of Nurse-Midwifery was held November 12 and 13, 1955, in Kansas City, Missouri. Hattie Hemschemeyer, director of the Maternity Center Association School of Nurse-Midwifery, was elected the first president of the ACNM. In her first message to members in the *Bulletin of the American College of Nurse-Midwifery*, she wrote about the driving force and movement of nurse-midwifery in terms that remain equally valid today:

> The College must select carefully the work it undertakes and then do well the work it has undertaken. We need to work with dedication and conviction. We are beginning at a time when education has concentrated too heavily on techniques and too little on the human factors involved. It is essential that education relate in a responsible and practical way with the problems and moral issues of our times.
>
> We nurse-midwives are a specialized group and our education, experience, and service have led us to the considered conclusion that in our present society it is neither desirable nor necessary to eliminate specialization. We believe that creative imagination, plus the ability to utilize ideas, is one of the most powerful influences in the world today. . . .
>
> The nurse-midwives have not substituted rationalization nor routines for reason; they have not been helpless when it comes to effecting mass movements for the care of human beings where helplessness, faith in reason, responsibility, and the dignity of the individual were concerned. They know the difference between supplying verbal allegiance and action. . . .
>
> We have a pioneer job to do, and if we work as well and as constructively in a group as we have in the past as individuals, we can help to improve professional competence, provide better service and educational programs, and make fuller use of resources. The future looks bright. [41]

On the ACNM's tenth anniversary, Hemschemeyer stated, "Our identity as a College gives us fundamental rights and grave responsibilities" [42].

In 1956, both the American College of Nurse-Midwifery and the American Association of Nurse-Midwives were accepted into the International Confederation of Midwives (ICM) upon the recommendation of England and Scotland and the unanimous vote of the executive council of the ICM. In 1969, the American Association of Nurse-Midwives (AANM) merged with the American College of Nurse-Midwifery (ACNM) to form the American College of Nurse-Midwives (ACNM). In October 1972, the American College of Nurse-Midwives hosted the triennial congress of the ICM in Washington, D.C., when Lucille Woodville, then nursing consultant to the Bureau of Indian Health Affairs and past president of the ACNM (1969–1971), was president of the ICM (1969–1972).

The objectives of the American College of Nurse-Midwives, first expressed in the Articles of Incorporation in 1955, as amended through May 2000, reflect both nurse-midwifery's concern for quality health care for women and infants and the

assumption of the "grave responsibilities" alluded to by Hattie Hemschemeyer:

That the objectives of said corporation shall be

1. To study, develop and evaluate standards for midwifery care of women and infants as provided by Certified Nurse-Midwives (CNMs) and Certified Midwives (CMs);
2. To study, develop and evaluate standards for nurse-midwifery and midwifery education;
3. To support and assist in the development of nurse-midwifery and midwifery services/practices;
4. To evaluate and accredit nurse-midwifery and midwifery educational programs;
5. To determine the eligibility of individuals to practice as Certified Nurse-Midwives and as Certified Midwives;
6. To facilitate and coordinate the efforts of Certified Nurse-Midwives and Certified Midwives who in the public interest provide quality services to individuals and childbearing families;
7. To establish channels for communication and cooperation with other professional and non-professional groups who in the public interest share the objectives of ensuring sufficient quality services to individuals and childbearing families;
8. To establish channels for interpretation of midwifery as practiced by CNMs and CMs to allied professional and non-professional groups on a regional, national and international basis;
9. To promote research and the development of literature in the field of midwifery as practiced by CNMs and CMs;
10. To speak for all members of the College in relation to issues affecting the professional affairs of Certified Nurse-Midwives and Certified Midwives;
11. To provide professional services to members of the College;
12. To promote the College as a leader and major resource in the development and promotion of high quality care for women and infants, nationally and internationally. [43]

The seal of the ACNM (Figure 1-3) reflects basic philosophical beliefs of nurse-midwifery. Rita Kroska, who designed the seal in 1955, interprets its symbols as follows:

> The large shield is comprised of four symbols: a small shield of stars and stripes exemplify the United States of America; three intertwined circles exemplify the family with the lower circle containing crosshatching to illustrate the crib containing the child; a tripod with flames rising exemplifies continuance and warmth in dedication to the American family; and, lastly, the large shield contains an undulating band above the tripod but beneath the smaller shield and circles. The undulation portrays movement, persistence, steadiness, and steadfastness to the word written within. That word is *VIVANT*, an expletive in French which means *Let Them Live!* It is there to fill out the sentence of the symbols, to give emphasis short of exclamatory oath, that of unremitting dedication to safeguarding and promoting the health and wellbeing of family life, particularly the mother and infant.
>
> The large shield is encircled by a ribboned band containing the inscription, "AMERICAN COLLEGE OF NURSE-MIDWIVES, NEW MEXICO, Nov. 7, 1955." Originally, between 1955 and 1969, the word "nurse-midwives" was "nurse-midwifery," and without the year 1929 included within the inscription. The two changes took place in 1969 when the American Association of Nurse-Midwives with headquarters at the Frontier Nursing Service in Wendover, Kentucky, and the American College of Nurse-Midwifery joined and became the American College of Nurse-Midwives. The year 1929 was the founding of the American Association of Nurse-Midwives. [44]

Activities of the ACNM

The membership of the American College of Nurse-Midwives has been characterized from the beginning by its dedication, commitment, hard work, articulateness, personal sacrifice, vision, and pioneering spirit. The annals of the ACNM's brief history are peopled with creative giants who were also willing to do the necessary detail work while dipping into their own pocketbooks to finance it. Starting with a charter membership of 124, the

ACNM had grown to a membership of 860 by its twentieth anniversary in 1975. By 1980 the membership, now including students, had increased to more than 1500, by 1984 to 2534, and by 1995 to more than 5000. This figure reflects the fact that approximately 85 percent of the total number of Certified Nurse-Midwives belong to the ACNM. Seventeen nurse-midwives attended the first annual meeting in Kansas City in 1955; 291 members attended the twentieth annual meeting in Jackson, Mississippi, in 1975. Convention attendance first passed the 1000 mark with 863 members and 138 guests at the 1984 Philadelphia meeting, and more than 2000 attended the Washington, D.C., meeting in 2000.

The rapid expansion of nurse-midwifery and proliferation of nurse-midwives placed stress on the professional organization. The total number of nurse-midwives tripled in less than ten years (1975–1984). The organization faced having to change from a small, intimate group of hard-working, dedicated nurse-midwives with a relatively simple organizational structure to a large group with an organizational structure and management style that could cope with a rapid increase in membership without losing its dedication and ideals. This goal was met. The productivity of the American College of Nurse-Midwives since its founding in 1955 is inspirational and shows what a small group can do.

The ACNM has undergirded every aspect of nurse-midwifery: education, practice, recognition, legislation, credentialing, insurance, communication, research, and interprofessional and interorganizational relationships. The founding of the ACNM was described as follows: "To support individual efforts the nurse-midwives have banded together.... This provides them with an official mouthpiece for education, a base for common planning and discussion" [45]. Almost a century ago the lack of any national organizations, journals, system of education, legal recognition, or access to the health care system led to the "midwife problem and debate." Today the ACNM provides or works for all of these mechanisms of survival and speaks for the profession of nurse-midwifery and midwifery as practiced by CNMs and CMs.

CHAPTER

2

Basics of Management of Care

Primary Care and Scope of Practice

In 1992, the American College of Nurse-Midwives formally acknowledged the historical and ongoing link between nurse-midwifery and public health and issued a statement entitled *Certified Nurse-Midwives as Primary Care Providers*. This statement was revised in 1997 to include Certified Midwives and to add the term *Case Managers* in the title [1]. The statement is as follows:

> It is the position of the American College of Nurse-Midwives that Certified Nurse-Midwives (CNMs) and Certified Midwives (CMs) are providers of primary health care for women and newborns.
>
> Care by CNMs and CMs incorporates all of the essential factors of primary care that include evaluation, assessment, treatment and referral as required. The model of health care practiced by CNMs and CMs is focused on ambulatory care of women and newborns and emphasizes health promotion, education and disease prevention and sees the woman as central to the process of providing such care.
>
> Care by CNMs and CMs includes preconception counseling, care during pregnancy and childbirth, normal gynecological services, contraceptive care and care of the peri- and post-menopausal woman. With health education as a major focus, the goals are to prevent problems and to assist women in developing and maintaining healthy habits.
>
> CNMs and CMs are often the initial contact for providing health care to women, and they provide such care on a continuous and comprehensive basis by establishing a plan of management with the woman for her ongoing health care. Such care by the CNM and CM is inclusive and integrated with the woman's cultural, socioeconomic and psychological factors that may impinge on her health status.

This statement and the ACNM definition of midwifery practice (see Chapter 1) essentially define the scope of practice of midwifery as the primary health care of newborns and of women from puberty through senescence. Primary health care by midwives emphasizes disease prevention and health promotion. Inherent in the approach of the midwife is patient education and inclusion of the woman in participatory decision making about her own health care.

The Committee on Primary Care of the Institute of Medicine (IOM) defined primary care in 1978 as having five attributes: (1) accessible, (2) comprehensive, (3) coordinated, (4) continuous, and (5) accountable. In 1990 the Health Resources and Services Administration of the U.S. Public Health Service characterized primary care as community-based, family-centered, culturally sensitive, coordinated, comprehensive, continuous, and physically, temporally, and financially accessible. In 1996, the IOM Committee on the Future of Primary Care recommended adoption of a new definition, based on the 1978 definition but expanded to emphasize a multidimensional integrated health care delivery system. The 1996 IOM definition of primary care "is the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the con-

text of family and community" [2]. All of the words in these definitions describe the practice and beliefs of nurse-midwives.

In addition, the midwife specifically focuses on adolescents initiating pelvic health care and undergoing their first pelvic examination, female psychological growth and development throughout the lifespan, substance-abusing women, premenstrual syndrome, lesbian health care, female occupational health hazards and care, homeless women, gynecologic and psychologic trauma related to rape and battering, infertility concerns, physical changes and care of postmenopausal women, women (including pregnant women) with HIV/AIDS, women in prison, female sex workers, and the grief process. This is not an exhaustive listing. Midwifery has always been associated with pregnancy, childbirth, the postpartum period, and care of the newborn, but it also has a particular focus on family planning and gynecologic health care and screening. Gynecologic health care encompasses pelvic health care and management of infections and sexually transmitted diseases, menstrual concerns ranging from the normal physiologic processes involved in menarche and menopause through premenstrual syndrome to amenorrhea or dysfunctional uterine bleeding, differential diagnosis of lower abdominal and pelvic pain, and screening for breast and pelvic malignancies and disease.

As the health care provider whom women often see first for their gynecologic or childbearing health care, the midwife becomes the primary care provider in screening the total woman for normality and health in all her body systems, managing the care of women with routine personal health care needs and minor conditions or diseases, and referring women to medical specialists as needed. Midwives conduct a woman's annual physical examination with appropriate initial or interval history, laboratory testing, and adjunctive studies. The requisite screening assessment (history, physical and pelvic examination, laboratory tests, and adjunctive studies) is outlined later in this chapter.

Independent and Collaborative Management of Care

"Nurse-midwifery practice is the independent management of women's health care . . . within a health care system that provides for consultation, collaborative management or referral as indicated by the health status of the client . . . " [3]. In addition to including the concepts of both independent management and collaborative management within the definition of nurse-midwifery practice, the American College of Nurse-Midwives has issued separate statements specifically addressing each of these concepts [4,5]. These documents acknowledge that midwifery care is primarily intended for healthy women but state that CNMs and CMs can continue to be instrumental in the care of women who develop medical, gynecological, or obstetrical complications. Working with these women may involve the midwife in one of three processes:

1. *Consultation*. The advice or opinion of a physician or another member of the health care team is sought while the midwife retains primary responsibility of the woman's care.
2. *Collaboration*. The midwife and physician jointly manage the care of a woman or newborn who has become medically, gynecologically, or obstetrically complicated. The goal of collaboration is to share authority while providing quality care within each individual's scope of practice. The ability to share responsibility, mutual respect, trust, and effective communication between the midwife and physician is essential for successful collaborative management of quality care.
3. *Referral*. The midwife directs the client to a physician or another health care professional for management of a particular problem or aspect of the client's care.

"Independence and collaboration are not mutually exclusive" [6], but instead work together in an approach that benefits the woman and her baby. Midwives are experts on normality; when providing health care to the normal woman, the midwife practices independently. However, normality does not define or limit the patient populations of a midwife [7]. Nurse-midwifery's long history of service to underserved and vulnerable populations has demonstrated repeatedly the reduction of infant mortality and morbidity in these at-risk and high-risk complicated and complex populations [8]. No matter how much at risk or how complicated her pregnancy or gynecological status, certain components of any woman's condition and situation are normal and need attention. The contribution of a midwife in collaborative management of care includes protection and facilitation of whatever processes are normal, provision of information on safe options, inclusion of the woman in decision

making, inclusion of the woman's family, advocacy, teaching and counseling, and provision of continuity of care [7]. In many situations, collaborative management by the midwife and the physician is not only desirable, but also the most appropriate and safest approach to providing a woman with the best possible care [9].

The ACNM definition of referral implies a continuing relationship with the woman and is in keeping with the midwifery philosophy of continuity of care. Sometimes referral takes the form of outright transfer of the woman to a physician specialist. It has always been the function of a nurse-midwife to screen women for the earliest signs and symptoms of medical conditions or pregnancy complications in order to refer women who need the special skills of an obstetrician/gynecologist, geneticist, cardiologist, urologist, surgeon, gastroenterologist, or other practitioner. According to Clark-Coller, the litmus test for transfer is "whether, if transferred, the woman would gain anything specific that would benefit her care." She further clarifies that transfer should not be based on risk status but instead should take place "when there is demonstrated pathology that is outside the scope of our practice" [10]. At other times referral takes the form of obtaining medical management of a specific complicating disease when the woman is pregnant (e.g., hepatitis; see Chapter 8). In this situation, the midwife continues to manage the care of the pregnancy or enters into collaborative management of the woman's care. This continuity is in keeping with the meaning of the word midwife, "with woman," regardless of her risk status and locale [7]. The midwife does not "dump" or "punt" a pregnant woman through referral if medical or obstetrical complications arise. Rather, the midwife seeks the best balance of medicine and midwifery for the individual—hence the discussion of collaborative management. Shah identifies the hallmark of competent primary care as "knowing when to treat, when not to treat, when to just closely monitor, and when to refer the patient for consultation and/or medical intervention" [11].

The Management Process

The management process is a clinical problem-solving, decision-making, care-giving process that originated in nurse-midwifery in the early 1970s [12,13]. It provides a method of organizing thoughts and actions in a logical sequence for the benefit of both the patient and the health care provider. This process is described in terms of expected behaviors of the clinician, which clearly state the thought process and action involved. The descriptors elucidate the behavioral level at which each step is to be achieved so as to provide safe, comprehensive patient care. Because the management process follows a logical sequence, it is also useful to students in learning the management of care of patients because it provides a means of pulling together isolated fragments of knowledge, findings, skills, and judgments into a meaningful whole and focuses on the transition into the role of patient management.

The management process consists of seven sequential steps, which are periodically refined. It starts with the collection of a database and ends with evaluation. The seven steps constitute an overall framework that is applicable in all situations. Each step then may be broken down into finite tasks that vary in accord with the condition of the woman or newborn. It should be recognized that these steps are taken in collaboration with the woman and whomever she wishes to involve, or in collaboration with the parent(s) of the newborn. The seven steps follow:

1. Investigate by obtaining all necessary data for complete evaluation of the woman or newborn.
2. Make an accurate identification of problems or diagnoses and health care needs based on correct interpretation of the data.
3. Anticipate other potential problems or diagnoses that might be expected because of the identified problems or diagnoses.
4. Evaluate the need for immediate midwife or physician intervention and/or for consultation or collaborative management with other health care team members, as dictated by the condition of the woman or newborn.
5. Develop a comprehensive plan of care that is supported by explanations of valid rationale underlying the decisions made and is based on the preceding steps.
6. Assume responsibility for the efficient and safe implementation of the plan of care.
7. Evaluate the effectiveness of the care given, recycling appropriately through the management process for any aspect of care that has been ineffective.

The steps of the management process are essentially self-explanatory. However, a brief discussion

and examples of tasks that may be included in each of these steps may clarify the thinking involved in this action-oriented clinical process.

The first step is the gathering of a complete database for evaluation of the woman or newborn. This database includes a history, physical and pelvic examination as indicated, review of the current chart or old hospital records, and review of laboratory data and reports of adjunctive studies—in short, all pertinent information from all sources that has a bearing on the condition of the woman or newborn. The midwife gathers a complete initial database even if the woman or newborn has a complication that will be presented to the consulting physician for collaborative management. At times step 1 may overlap with steps 5 and 6 (or be part of a continuing sequence) as obtaining additional necessary data from laboratory tests or other diagnostic studies may be part of the plan. Sometimes the midwife will need to begin with step 4.

The second step evolves from the database: the interpretation of the data into specifically identified problems or diagnoses and health care needs. The words problems and diagnoses are both used, as some problems cannot be defined as diagnoses but do need to be considered in developing a comprehensive plan of care. Problems are frequently related to how the woman is experiencing the fact of her diagnosis and are often identified by the midwife's focus on the experiencing individual person. For example, the diagnosis might be that the woman is pregnant, and a related problem might be that the woman does not want the pregnancy. Another example is a woman in her third trimester who is frightened by her impending labor and delivery. Being frightened does not fit any category of standard diagnostic nomenclature but certainly creates a problem that needs to be explored, and a plan needs to be developed for reducing this fear. Health care needs may be identified from the problems and diagnoses or may be separate. For example, a health care need of a woman may be for an annual gynecologic examination. Problems or diagnoses may or may not be identified from these findings.

The third step—identifying other potential problems or diagnoses based on the current set of problems and diagnoses—is a matter of anticipation, prevention when possible, watchful waiting, and preparation for any eventuality. This step is vital to safe care. Take, for example, a woman with an overdistended uterus. The midwife should consider the possible reasons for the overdistention (e.g., polyhydramnios, large-for-dates baby, gestational diabetic mother, or multiple gestation) and then anticipate, take precautionary measures, and be prepared for the possibility of an immediate postpartum hemorrhage as a result of uterine atony from the overdistention. In the event of a single large baby, the midwife should also anticipate and be prepared for the possibility of shoulder dystocia and the need for infant resuscitation. Another example is the woman with sickle-cell trait. The midwife should be alert to the possibility of this woman developing a urinary tract infection, which in turn increases the possibility of either premature labor or a small-for-dates baby. Simple preventive measures, pertinent history taking at each prenatal visit, laboratory tests for asymptomatic bacteriuria, and immediate therapeutic treatment if a urinary tract infection does develop are indicated for a woman with sickle-cell trait.

The fourth step reflects the ongoing nature of the management process not only during periodic primary care or prenatal visits, but also while the midwife is continuously with the woman, such as when she is in labor. New data are constantly obtained and evaluated. Some data indicate emergency situations in which the midwife must act immediately in the interest of the life of the mother or baby (e.g., third stage or immediate postpartal hemorrhage, shoulder dystocia, or a low Apgar score). Some data indicate a situation requiring immediate action while awaiting the intervention of the physician, such as a prolapsed cord. Other situations are not emergencies but may require physician consultation or collaborative management. Early signs of preeclampsia require physician consultation. On the other hand, an initial history, physical, and pelvic examination that yield the findings of heart disease, diabetes, or any other major medical problem require collaboration with a physician for management of the pregnant woman with these complications. The condition or situation of a woman or newborn may require consultation or collaborative management with other health care team members such as a social worker, a nutritionist, or a neonatal clinical nurse specialist. The midwife evaluates each clinical situation to determine the most appropriate health care team member for management of the care of the woman or newborn.

The fifth step—developing a comprehensive plan of care—is determined by the preceding steps, is an outgrowth of the identified current and anticipated problems or diagnoses and health care needs, and also involves obtaining any missing or neces-

sary additional pieces of information for the database. A comprehensive plan of care not only includes what is indicated by the condition of the woman or newborn and any related problems, but also outlines anticipatory guidance for the woman or parent as to what to expect next, teaching and counseling, and any necessary referrals for social, economic, religious, family, cultural, or psychological problems. In other words, anything that pertains to any aspect of health care is included in the plan. A plan of care must be mutually agreed upon by the midwife and the woman or parent in order to be effective, because it is the woman or parent who ultimately will or will not implement the plan. Therefore, tasks carried out in this step include formulation and discussion of the plan with the woman or parent as well as confirmation of agreement.

All decisions made in developing a comprehensive plan of care must reflect a valid rationale based on pertinent, appropriate, and up-to-date theoretical knowledge and validated assumptions about what the woman or parent will or will not do. Rationale based on unvalidated assumptions of a person's behavior, erroneous or deficient theoretical knowledge, or an incomplete database is not valid and yields care that is incomplete and may be unsafe.

The sixth step is implementation of the comprehensive plan of care. This step may be done wholly by the midwife or in part by the woman or parent, the midwife, or other health team members. If the midwife is not doing it herself, she assumes responsibility for assuring that it is indeed done. In settings where the midwife collaborates with a physician and contributes to the management of care of women with complications, the midwife may assume responsibility for the implementation of the collaborative comprehensive plan of care. Efficient implementation minimizes time and costs and enhances the quality of care. A critical component of implementation is documentation that is timely, accurate, and thorough.

The final step—evaluation—is really one of checking whether the plan of care actually met the needs-for-help identified in step 2 as problems, diagnoses, or health care needs. The plan is deemed effective if it did and ineffective if it did not. It is possible for parts of the plan to have been effective while other parts were ineffective. Perceiving the management process as a continuum, it is necessary to recycle any ineffective care back through the management process to identify why it was ineffective and to adjust the plan of care accordingly. The management process as a fluid continuum also enables the clinician to readily respond to any actual or potential change in the condition or situation of a woman or newborn.

Because this book is clinically oriented, a modified version of the first five steps of this management process is used in presenting the content in the management sections. The steps are modified for the purpose of adding relevant theoretical knowledge necessary as background information for clinical management of the woman or newborn. Because the management process takes place in the clinical setting and because the last two steps depend on the clinical condition and situation of the woman or newborn, it is not possible to include them in this textbook.

Screening for Abnormality and Differential Diagnosis

Screening for abnormality and making differential diagnoses are vital, but unfortunately sometimes misunderstood, functions of the midwife. It is important to be clear about what these two functions involve.

The primary diagnosis made by the midwife is one of normality, and the role of the midwife includes continual screening of the woman or newborn for deviation from normal. The midwife must be astutely alert to what is abnormal and to complications that may develop, both generally in different patient populations and in relation to a specific patient situation. The midwife must differentiate between normal minor discomforts and medical conditions or diseases or, in pregnancy, complications of pregnancy. For example, the pregnancy discomfort of nausea and vomiting of the first trimester is not the same as hyperemesis gravidarum, nor is it a sign of hydatidiform mole. Likewise, rightsided round ligament pain must be differentiated from appendicitis, false labor differentiated from true labor or a urinary tract infection, bloody show differentiated from frank bleeding, and so forth.

To make differential diagnoses the midwife must know, in depth and in detail, normal obstetrics, gynecology, and newborn care; primary care aspects of women's health; and normal findings of the history, physical assessment, and pelvic examination in order to detect when a deviation from

normal exists in a woman or newborn. A thorough knowledge of the signs and symptoms of pregnancy complications is invaluable in the recognition of deviations from normal. Recognition of the signs and symptoms of medical conditions and diseases and an understanding of how pregnancy affects preexisting medical conditions and diseases is also required. The purpose of being knowledgeable in all these areas is to be able to screen the patient (woman or newborn) for abnormality and to differentiate normal from abnormal.

Differential diagnosis by a midwife does not mean pretending to be an expert diagnostician of medical conditions and diseases and pregnancy complications. If the midwife finds a medical abnormality, discussion with the consulting physician is in order for further evaluation and management of the complication. When caring for women, the midwife then enters into a relationship with the consulting physician for the collaborative management of the care of the woman, a relationship that benefits from each professional's expertise: the physician for management of the medical, obstetrical, or gynecological complication and the midwife for management of those aspects of the woman that continue to be normal. In those situations in which referral or transfer is indicated, the midwife involves the woman in the planning and arrangements so she does not feel abandoned in fact or in perception. At no time does the midwife abandon the woman. Appropriate transfer of care, when properly done, is not abandonment. On the other hand, care of babies by the midwife generally does not extend beyond the neonatal period. The midwife counsels the mother regarding a pediatric care provider for the baby during the pregnancy. In the event of a neonatal abnormality or complication, the baby usually is transferred to the care of the pediatric care provider of the mother's choice, who will collaborate with a neonatologist if indicated.

The midwife begins the process of differential diagnosis. It is not enough, for example, for a midwife to consult with a physician about a woman whose labor is failing to progress normally. The midwife needs to provide the physician with a report that includes specific data indicating differentiation between hypertonic and hypotonic uterine dysfunction and, further, differentiation as to possible causes, such as cephalopelvic disproportion (the report should detail the midwife's clinical evaluation of the pelvis, station, asynclitism, and estimated fetal weight); poorly timed administration of analgesia; psychological or environmental interference; or malposition or malpresentation of the fetus.

For other complications, the midwife goes beyond the initial signs and symptoms indicating a medical condition or pregnancy complication and orders laboratory or other adjunctive tests for confirmation or further evaluation of the diagnosis before discussing a plan of management with the consulting physician. Complications in this category may include suspected diabetes, unresponsive anemia, small-for-dates and large-for-dates fetuses, multiple pregnancy, endometritis, and postdates.

Finally, there are a number of medical conditions or pregnancy complications that a midwife both diagnoses and treats as a primary care provider. These commonly include such conditions as sinusitis, upper respiratory infections, urinary tract infections, vaginitis/cervicitis, uncomplicated sexually transmitted diseases, breakthrough bleeding with oral contraceptives, need for RhoGAM, need for rubella vaccine, need for hormone replacement therapy, and so forth.

Limits of practice are established by a state's legal definition of practice; by ACNM's definition and statements on practice; by the ACNM *Standards for the Practice of Midwifery*; by local and institutional standards of practice, policies, clinical practice guidelines, and delineated practice privileges; and by a midwife's own limitations of knowledge and capabilities. Thus there are four types of limits—legal, professional, local, and personal [14]—and they have certain elastic qualities.

There is a precise thought process involved in making differential diagnoses. This process must be followed in sequence to ensure that a diagnosis is not missed. The thought process starts with the recognition of a sign or symptom either indicative of abnormality or needing further evaluation. The next step is to list all the possible conditions, diseases, or complications of which the sign or symptom could be indicative. The third step is to go through the list methodically, obtaining additional pertinent data (from history, physical, pelvic, laboratory, or other adjunctive studies) that will either confirm or rule out each condition, disease, or complication on the list. All findings are documented, and unless the condition, disease, or complication can be independently managed by the midwife, the midwife discusses the situation with the consulting physician for further evaluation and collaborative management of care. The consultation with the physician and resulting plan of care are also documented on the patient's chart.

Physical Assessment for a Database

The following presentation on history, physical and pelvic examination, laboratory tests, and adjunctive studies is not meant to be a definitive work on the subject of physical assessment. Several excellent textbooks detailing the content of and procedures and skills used in physical diagnosis are listed in the bibliography. What is presented here, rather, is an outline of what is included in a history, physical and pelvic examination, laboratory tests, and adjunctive studies that will initially screen a woman for abnormality and determine normalcy. Assessment of the neonate is discussed in Chapters 37, 39, and 80.

Before 1970, routine physical assessment by nurse-midwives consisted primarily of thorough examination of the breasts and the pelvis; limited examination of the mouth, throat, thyroid gland, abdomen, and extremities; and hemoglobin, hematocrit, urinalysis, and Pap smear. In the early 1970s, however, nurse-midwives added interconceptional care to their services by virtue of their involvement in family planning and in accord with their philosophy of providing continuity of care. It became clear from nurse-midwives' work in family planning that the only physical examination many women received from year to year was the one the nurse-midwives were doing when the woman returned for her annual or semiannual family planning visit. Obviously, the physical examination being done was inadequate for purposes of detecting medical problems not related to contraceptive methods. The solution was for nurse-midwives to learn the content, procedures, and skills of a total history and physical examination. Physical assessment was added to the curriculum in nurse-midwifery education programs, and in-service education was held for staff nurse-midwives. By 1974, physical assessment was an accepted part of nurse-midwifery practice. The comprehensiveness of this examination has increased through the years, in keeping with the expansion of nurse-midwifery practice into gynecology and the primary care of women from puberty through senescence.

A screening examination is aimed at detecting relatively gross evidence of abnormalities and disease. Any such findings start the process of formulating a differential diagnosis for discussion with the consulting physician or referral to a medical specialist. The midwife has the responsibility of obtaining a relevant history in relation to any abnormality detected. This history becomes part of the midwife's report to the consulting physician or specialist and addresses the following questions:

Is the woman aware of the abnormality?

What brought the abnormality to her attention (e.g., she has pain; she was told during a previous physical)?

Are any related symptoms present?

How long has the abnormality been present, and what has been its course since discovery?

Has the woman ever been seen and treated for the abnormality?

By whom?

When?

What was the diagnosis as the woman understands it?

What was the treatment?

How effective was the treatment?

Is she continuing to receive care for this abnormality?

In taking a history and doing a physical and pelvic examination, midwives go into greater detail in those areas germane to childbearing, pregnancy, gynecology, and family planning than is usual for a woman admitted to a medical unit for a diagnostic workup. This is not surprising, because most often a woman sees a midwife for preventive health care or conditions related to the reproductive tract. For this reason the following outline of a history, physical and pelvic examination, and laboratory tests lacks detail for some body systems but offers considerable detail for aspects specifically related to women's health care. It includes concerns about domestic violence, occupational hazards, sexually transmitted diseases, HIV/AIDS, and substance abuse. It also includes skills, detailed in Part 8, that are not strictly related to the reproductive system but are frequently used. Examples include checking for costovertebral angle (CVA) tenderness, because urinary tract infections are a common complaint of women, and checking deep tendon reflexes, essential in evaluating the possible severity of preeclampsia.

History

Principles of History Taking (Figure 2-1):

1. Introduce yourself and state what you are going to do and your purpose for doing it.
2. Observe all rules of interviewing:
   a. Use open-ended, not closed-ended, questions.
   b. Ask only one question at a time.
   c. Avoid leading questions or questions that "put answers in the woman's mouth."

FIGURE 2-1 A midwife taking a woman's history.

   d. Clarify what the woman's behavior means to her.
   e. Use a level of terminology the woman will understand.
3. Be tactful and respectful of the woman's right to privacy about her person and personal life at all times.
4. Listen to the woman with interest and concern, and be responsive to what she is saying. For example, if she is talking about a past difficult time in her life, a response denoting sympathetic understanding is appropriate.
5. Be responsive to requests for clarification or information.
6. Be precise, thorough, and accurate in obtaining all essential information.
7. Keep the history taking focused without wasting time on a wandering line of questioning.
8. Screen out and do not record any irrelevant material.
9. Allow the woman time to answer. Don't interrupt unless she starts to ramble or you need clarification.
10. Listen to the woman carefully. She may in one answer give an answer to a later question as well. If so, don't repeat the later question. Also, don't make her repeat what she just said because you weren't paying attention.
11. Follow up on unclear responses, pertinent information, or pertinent information not directly related to the current question.
12. Be sure you understand what the woman is saying. Accents and expressions vary from one part of the country to the next. Don't hesitate to ask the woman to spell or explain words she is using.
13. Do not express negative judgments through facial expression, body language, or tonal inflection.
14. Provide as much privacy from being overheard as possible.
15. Speak in well-modulated, soothing, calming tones.
16. Maintain eye contact—don't always be reading from the history form, writing responses, and charting.
17. Don't ask a question unless you can explain to the woman your reason for asking it. A woman may consider social, sexual, economic, educational, occupational, and housing information extremely personal. Not all of the information that can be obtained in these areas is necessary information. You should obtain such information only with a purpose, because otherwise the woman may interpret your questioning as prying into her personal life and react accordingly. For example:
   a. Housing is important to ascertain. Some women are homeless, and life in shelters limits their ability to maintain personal hygiene and exposes them to a higher incidence of certain diseases, such as tuberculosis. Other women may be in group homes for drug rehabilitation, mental retardation, protection from domestic violence, etc.
   b. Sexual and substance use histories have become imperative as part of screening for sexually transmitted diseases and for HIV/AIDS.
   c. Before talking about diet and meal preparation with a woman, you should know if she does the grocery shopping and meal preparation. When possible, include the person who does these chores in your discussion if it is not the woman herself.
   d. Before talking about taking showers or soaking in a tub of warm or hot water, you should know what bathing facilities a woman has, if any.
   e. Knowing a woman's occupation and household responsibilities is important in identifying risks for such job-related injuries as carpal tunnel syndrome and environmental hazards, and, if pregnant, in ascertaining appropriate job restrictions and planning rest periods with her feet elevated.

Identifying Information

1. Name
2. Age
3. Race/ethnicity
4. Gravida and para
5. Address/telephone
6. Religion

7. Marital status
8. Occupation
9. Date of interview

Chief Complaint (CC)

The reason the woman is seeing you in the clinic, office, emergency room, birth center, hospital, or her home, as stated in her own words (may relate to any body system).

History of Present Illness (HPI) (relates to the chief complaint or problem)

1. Date and time of onset
2. Mode of onset
3. Precipitating or predisposing factors related to onset
4. Course since onset, including duration and recurrence
5. Specific location
6. Type of pain or discomfort and severity or intensity
7. Other associated symptoms
8. Relationship to bodily functions and activities
9. Description of quality (color, consistency) and quantity (amount, volume, or number), if applicable (e.g., rash, discharge, bleeding)
10. Factors influencing the problem, either aggravating or relieving
11. Previous medical help (and from whom) for this problem; diagnosis and treatment
12. Effectiveness of any treatments or medications used (self- or medically initiated)

Past Medical and Primary Care History (includes social history)

1. Childhood diseases/immunizations, such as measles (type), mumps, or chickenpox
2. Recent laboratory screening tests for infectious diseases (e.g., hepatitis, measles, tuberculosis, HIV); date, result
3. Major illnesses (e.g., pneumonia, hepatitis, rheumatic fever, diphtheria, polio)
4. Hospitalizations; date, reason
5. Surgery; date, reason
6. Accidents; fractures, injuries, unconsciousness
7. Blood transfusions; date, reason, reaction
8. Allergies (e.g., food, hay fever, environmental, dust, animals; asthma)
9. Drug allergies
10. Alcohol abuse/alcoholism; treatment
11. Drug abuse/addiction; substance(s), treatment
12. Habits
    a. smoking (amount; duration)
    b. alcohol (amount; duration)
    c. caffeine (coffee, tea, sodas, chocolate)
    d. "recreational" drugs (substance, amount; duration)
    e. safety (seat belts, helmets)
13. Sleep patterns
14. Diet/malnutrition
15. Exercise/leisure activity
16. Occupational hazards: position (standing, sitting), strain (eye, muscle), ventilation, exposure to toxic chemicals
17. Environmental hazards: air, water, sewage, lack of window screens, open fireplace, lead paint
18. Childhood physical/sexual abuse
19. Domestic violence/battering/rape/isolation: historical, current; safety
20. Genetic screening tests, when applicable (e.g., sickle cell, Tay-Sachs, G6PD, fragile X, cystic fibrosis); results
21. Specific diseases
    a. diabetes
    b. heart disease (diagnosis, e.g., mitral valve prolapse), including rheumatic fever
    c. tuberculosis
    d. asthma
    e. liver/hepatitis
    f. kidney/urinary tract infections (UTI)
    g. varicosities/thrombophlebitis
    h. glandular/endocrine (diagnosis, e.g., hypo/hyperthyroidism)
    i. gastrointestinal (diagnosis e.g., gastric ulcer)
    j. cancer
    k. hypertension
    l. HIV/AIDS
    m. mental illness (diagnosis: e.g., depression, bipolar)
    n. epilepsy
    o. blood dyscrasias, such as anemia (type)
    p. eating disorders (diagnosis, e.g., bulimia, anorexia)
22. Medications
    a. prescription
    b. nonprescription

Family History (pertains to mother, father, siblings, grandparents, aunts, and uncles)

1. Mother, father, siblings
    a. age
    b. status, i.e., living and well? If deceased, what was the cause of death?

2. Mental retardation
3. Cancer
4. Heart disease
5. Hypertension
6. Diabetes
7. Kidney disease
8. Mental illness
9. Congenital anomalies
10. Multiple pregnancies
11. Tuberculosis
12. Epilepsy
13. Blood dyscrasias, such as anemia (type)
14. Allergies
15. Genetic disorders
16. Autoimmune disorder (e.g., lupus)

Menstrual History

1. Age at menarche
2. Frequency; range if irregular
3. Duration
4. Amount of flow
5. Characteristics of flow (e.g., clots)
6. Last menstrual period (LMP); duration and amount normal?
7. Dysmenorrhea
8. Dysfunctional uterine bleeding, i.e., intermenstrual spotting or bleeding, menorrhagia, metrorrhagia
9. Sanitary product use (tampons, pads)
10. Toxic shock syndrome
11. Premenstrual symptoms/premenstrual syndrome (PMS)
12. Perimenopausal symptoms

Sexual History

1. Type of sexual relationship (heterosexual, homosexual, bisexual)
2. Monogamous relationship or number of partners
3. Partner monogamous or number and type of partners
4. Sexual frequency, satisfaction
5. Satisfaction with sexual relationship
6. Problems
   a. insufficient foreplay
   b. insufficient lubrication
   c. lack of personal consideration
   d. pain, vaginismus
   e. fear of becoming pregnant
   f. fear of hurting fetus, if pregnant
   g. problems of partner (e.g., impotence, premature ejaculation)
   h. postcoital bleeding
   i. sexual violence

Obstetric History

1. Gravida/para (four- or five-digit system)
2. Rh and ABO blood type
3. Each pregnancy
   a. date of termination
   b. weeks gestation
   c. where delivered, i.e., hospital (name), childbirth center (name), home
   d. length of labor
   e. type of delivery (spontaneous, C-section, forceps, vacuum extraction)
   f. RhoGAM received
   g. any obstetric, medical, or social problems
      (1) during pregnancy (e.g., preeclampsia, UTI, domestic violence)
      (2) during labor and delivery (e.g., malpresentation, malposition, preeclampsia, eclampsia, pitocin induction, pitocin stimulation, major perineal laceration, cervical laceration)
      (3) during postpartum period (e.g., UTI, hemorrhage, uterine infection, depression, domestic violence)
   h. weight of baby at birth
   i. sex of baby
   j. any congenital anomalies or neonatal complications (e.g., jaundice, respiratory problems)
   k. status of infant at birth (alive or dead)
   l. present status of infant (e.g., living and well, problems, cause of death)

Gynecological History

1. Infertility
2. Diethylstilbestrol (DES) exposure
3. Vaginal infections (i.e., monilia, bacterial vaginosis)
4. Sexually transmitted diseases (STD) (i.e., chlamydia, syphilis, gonorrhea, herpes, trichomonas, condylomata acuminata)
5. Chronic cervicitis
6. Endometritis
7. Pelvic inflammatory disease (PID)
8. Cysts (Bartholin's, ovarian)
9. Endometriosis
10. Myomas
11. Pelvic relaxations (cystocele, rectocele)
12. Polyps
13. Breast masses

14. Abnormal Pap smears
15. Biopsies (cervical, endometrial, breast)
16. Gynecological cancer
17. Gynecological surgery
18. Rape

Contraceptive History

1. Whether contraception is wanted
2. Knowledge of contraceptive options
3. Present contraceptive method
   a. type
   b. satisfaction
   c. side effects
   d. consistency of use
   e. length of time using this method
4. Previous contraceptive methods
   a. types
   b. duration of use for each
   c. side effects of each
   d. reasons for discontinuing each

Hormone History

1. Reason for use of contraceptive hormones (e.g., to regulate menses)
2. Hormone replacement therapy
   a. present, past, how long used
   b. type
   c. side effects

Douching History

1. Frequency
2. Method
3. Solutions used
4. Reasons for douching
5. Length of time woman has been douching
6. Last time douched

Review of Systems

The review of systems (ROS) is a structured inquiry about past or current symptoms or complaints related to each body system. Because some examiners prefer to do the review of systems during the physical examination, usually in the interest of saving time, and because it makes sense to ask questions about specific systems, organs, or body parts while they are being examined, the ROS is included in the following outline of the physical examination and designated as such. Combining the ROS with the examination has caused information about some systems (the lymphatic and hematopoietic systems, the central nervous system, and the endocrine system) to be split up so as to tie them to specific body structures. The advantage of proceeding this way is that it eliminates repetition.

Physical Examination

Principles of Doing a Physical Examination (Figure 2-2):

1. Wash your hands immediately before doing the examination.
2. Be sure that your fingernails are clean and cut to a length that will not hurt the woman.
3. Warm your hands prior to touching the woman by washing them in warm water, rubbing them together, or holding them under a lamp.
4. Tell the woman what you will be doing in general. During the examination itself, tell the woman more specifically what you will be doing just before doing it—that is, let her know where you will be touching her, what you want her to do, and whether this portion of the examination will be uncomfortable.
5. Use a touch that is gentle yet firm enough not to tickle the woman and as firm as needed to elicit accurate information.
6. Let your approach and touch bespeak respect for her body as well as respect for her right to modesty and privacy.

FIGURE 2-2 A midwife doing a physical examination of a woman.

7. Drape the woman in such a way that only the area being examined at that particular point during the exmaination is exposed.
8. Organize your examination as follows:
   a. Progress from head to toe.
   b. Minimize movement of the woman; e.g., while having her sit up so you can inspect her breasts, also listen to her lungs from the back, observe and palpate for spinal deformities, and check for CVA tenderness rather than having her return to a sitting position several times during the examination.
   c. Wait until the end of the examination to touch parts of the body that will require you to rewash your hands (e.g., the bottom of her feet).
   d. Make sure the examination progresses in the same way for every woman; this will help you to remember everything.
9. Be alert for any inconsistency between the woman's history and your physical findings.
10. Share your findings with the woman. If she is anxious about something that you find to be normal, immediately tell her your findings. If you find something that concerns you because it may be a possible deviation from normal, tell her that you are not sure of what you have found and want a physician to check it. Remember, it is the woman's body and she has a right to know everything about it. Be honest and truthful with her.

Physical Measurements

1. Temperature
2. Pulse
3. Respirations
4. Blood pressure
5. Height
6. Weight

General

ROS:

1. Woman's evaluation of own health status
2. Woman's evaluation of own dietary patterns
3. Unusual weight changes
4. Weakness
5. Fatigue
6. Malaise
7. Fever, chills, sweating
8. Woman's evaluation of own emotional status
9. Ability to carry out activities of daily living

Observations:

1. Appropriateness of appearance for age
2. General nutritional status
3. Apparent state of health
4. General personal appearance
5. General mental and emotional state: speech; appropriateness of mood or affect; general mood (e.g., anxiety, depression); orientation to time, place, person; memory; logic and coherence of thought processes; general behavior (e.g., hostile, friendly, cooperative, confused)
6. Striking or obvious findings (e.g., pallor, cyanosis, respiratory distress, persistent cough, voice or speech abnormality, facial asymmetry, orthopedic abnormalities)
7. General posture, gait, body movements

Skin and Hair

ROS:

1. Skin
   a. pruritus
   b. rashes
   c. moles: any change noted
   d. lesions
   e. tendency to bruise
   f. general character (i.e., dry, oily)
   g. hirsutism
2. Hair and scalp
   a. general character (i.e., dry, oily)
   b. loss of hair
   c. wearing wig or not; if so, why
   d. scalp infections, dandruff, lice

Observations and examination:

1. Skin
   a. temperature
   b. color: pigmentation, pallor, cyanosis, jaundice
   c. moisture
   d. turgor
   e. moles
   f. scars
   g. rashes, lesions, bruises
   h. patterns of injury, showing repetition of injury: fresh or in various stages of healing (e.g., cigarette burns)
   i. tumors
2. Hair and scalp
   a. hair pattern
   b. scalp infections, dandruff, lice, lesions
   c. bald spots (alopecia)
   d. general character (i.e., dry, oily)
   e. lumps

Head

ROS:

1. Headaches: location, duration, time of day when they occur, frequency, type of pain, severity, relief measures and their effectiveness, any known causative factors, associated symptoms (e.g., nausea and vomiting, dizziness)
2. Dizziness
3. Syncope (fainting)
4. Sinusitis

Observations and examination:

1. Size, shape, contour, symmetry
2. Facial symmetry
3. Location of facial structures
4. Involuntary movements
5. Tenderness over frontal and maxillary sinuses

Eyes

ROS:

1. Blurring of vision
2. Scotomata (blind spots in vision)
3. Diplopia (double vision)
4. Spots before eyes
5. Flashing lights
6. Pressure or pain symptoms
7. Photophobia (sensitivity to light)
8. Lacrimation (excessive tearing)
9. Discharge, redness, burning
10. Woman's evaluation of her own visual acuity and any recent changes
11. Glasses or contact lenses: for what, last time eyes examined, last time prescription changed
12. Injuries
13. Diseases or conditions

Observations and examination:

1. Eyelids: closure, edema, signs of infection, blinking, squinting, masses, lesions, ptosis (drooping eyelid)
2. Eyelashes: matting from discharge, absence
3. Lacrimal ducts: signs of infection, tenderness
4. Involuntary eye movements
5. Color of lower conjunctival sac
6. Color of sclera
7. Abrasions or opacities of lens and cornea
8. Strabismus (cross-eyes)
9. Size, shape, and equality of pupils
10. Parallel movement of eyes and gross visual fields
11. Pupillary reaction to light and accommodation
12. Protrusion of eyeball and intraocular pressure as determined by finger tension
13. Ophthalmoscopic examination
    a. presence of red reflex
    b. color and outline of optic disc
    c. color, size, and shape of retinal vessels
    d. hemorrhagic areas
    e. color and shape of macula and fovea
    f. papilledema

Ears

ROS:

1. Woman's evaluation of her own hearing acuity and any recent changes
2. Earaches
3. Discharge
4. Tinnitus (ringing in the ears)
5. Vertigo (lack of balance)
6. Infections, injuries
7. Pain

Observations and examination:

1. Enlargement or tenderness of mastoid
2. General hearing acuity
3. Placement of ears on head
4. Shape, growths, lesions, and discharge noted in auricles and outlets of external ear canal
5. Color, obstruction, lesions, edema, discharge, foreign objects in external auditory canal
6. Otoscopic examination of tympanic membrane
    a. color
    b. bulging or retraction
    c. bony landmarks
    d. cone of light: presence or absence
    e. scars, perforations

Nose

ROS:

1. Nasal obstruction (difficulty with nasal breathing)
2. Epistaxis (nosebleeds)
3. Discharge: nasal and postnasal
4. Woman's evaluation of her own sense of smell
5. Injuries
6. Frequency of colds

Observations and examination:

1. Flaring of nares
2. Deformity or septal deviation
3. Symmetry, size, placement, including symmetry of nasolabial fold
4. Patency of nostrils
5. Perforation of nasal septum
6. Nasal speculum examination

a. size, signs of infection, edema of turbinates
b. polyps, growths, obstructions
c. ulcerations, lesions, bleeding points
d. discharge
e. color of mucosa

Mouth and Throat

ROS:

1. Toothaches
2. Bleeding, lesions, pain, or edema of gums
3. Extractions and dentures
4. Any difficulty with chewing or swallowing
5. Pain, lesions, bleeding, or edema of lips
6. Pain, lesions, tumors, or bleeding of mouth
7. Pain, lesions, color, texture, tumors, bleeding, edema of tongue
8. Frequency of sore throats
9. Number of cigarettes per day
10. Surgery (e.g., tonsillectomy)
11. Woman's evaluation of own sense of taste
12. Hoarseness or voice change
13. Any difficulty with talking or speech
14. Dental care

Observations and examination:

1. Odor of breath
2. Lips: symmetry, color, lesions, edema, tumors, fissures
3. Mouth and mucosa: lesions, tumors, plaques, intactness of palate, color, vascular spots
4. Teeth: state of repair, missing teeth, caries
5. Gums: bleeding, lesions, edema, tumors, color, retractions, pus/exudate
6. Tongue: symmetry, position, texture, color, lesions, tumors, moistness, coating, mobility, deviation
7. Uvula: deviation, size, enlargement
8. Oropharynx: signs of infection in posterior pharynx, tonsillar fossae, and tonsillar pillars; inflammation, edema, bleeding, exudate, pus patches, color, lesions, tumors, size, symmetry, and enlargment of tonsils

Neck

ROS:

1. Pain or stiffness
2. Limitation of motion
3. Node enlargement or tenderness
4. Thyroid enlargement; history of goiter
5. Injuries, deformities
6. Thyroid (endocrine system)
   a. sensitivity to environmental temperature and weather changes
   b. amount of sweating (excessive?)
   c. changes in scalp and hair, breasts, skin, genitalia, neck, secondary sex characteristics
   d. changes in emotional lability
   e. changes in heart rate, tremors, nervousness
   f. change in body weight in relationship to appetite
   g. change in energy levels and activity pattern
   h. results of previous BMR (basal metabolism rate) and thyroid function tests
   i. known history of thyroid disease and medications

Observations and examination:

1. Enlargement or tenderness of the salivary, submaxillary, anterior, posterior, and deep cervical, preauricular and postauricular, and supraclavicular lymph nodes and glands; size, shape, consistency, and mobility of any palpable nodes and glands
2. Carotid pulse
3. Abnormal pulsations
4. Vein distention
5. Range of motion
6. Enlargement or tumor of parotid gland
7. Enlargement, tumor, symmetry, size, shape, tenderness, or nodules of thyroid gland
8. Symmetry and deviation (position) of trachea

Cardiorespiratory System

ROS:

1. Dyspnea (shortness of breath)
2. Orthopnea
3. Tachypnea
4. Wheezing
5. Cough
6. Pleurisy
7. Sputum production: color, consistency, amount
8. Hemoptysis
9. Chest pain
10. Stridor ("crowing" inspiratory sounds)
11. History of bronchitis, pneumonia, asthma
12. Any contact with tuberculosis
13. Date of last chest x-ray film and result
14. Night sweats
15. Palpitations
16. Cyanosis
17. Dependent edema
18. Any known abnormalities of heart rate or rhythm
19. History of rheumatic heart disease, anemia, hypertension, coronary artery disease

Observations and examination:

1. Chest and lungs
   a. configuration, deformities, symmetry, shape, masses, lesions, scars of chest structure and walls
   b. intercostal and/or subclavicular retractions or bulging
   c. equilateral respiratory excursion and symmetry with respiratory movement
   d. rate, depth, rhythm, and type (chest, abdominal) of respirations
   e. tactile fremitus
   f. auscultation of lungs
      (1) normal breath sounds
      (2) rales
      (3) rhonchi
      (4) wheezes
      (5) friction rub
      (6) adventitious sound
2. Heart
   a. size
   b. location of point of maximum impulse (PMI)
   c. palpable thrills, rubs, impulses, shocks
   d. observable bulgings, heavings, pulsations
   e. auscultation of heart
      (1) rate, rhythm, and quality of heart sounds at the four valvular areas
      (2) extra sounds, murmurs, splitting, rubs, thrills

Breasts

ROS (see Chapter 52 for a more complete history related to the breasts):

1. Pain
2. Nipple discharge
3. Lumps, biopsies
4. Whether woman does breast self-examination

Observations and examination:

See Chapter 52 for observations, examination, and significance of findings.

Abdomen (Gastrointestinal System)

ROS:

1. Appetite, anorexia (lack of appetite)
2. Nausea or vomiting
3. Heartburn
4. Eructation (belching)
5. Hematemesis
6. Pain
7. Flatulence
8. Color of stools
9. Character of stools (soft, diarrhea, constipation)
10. Any recent change in bowel habits or stools
11. Jaundice
12. Rectal itching, pain, bleeding, hemorrhoids, sphincter control
13. Known history of gallbladder disease, liver disease (hepatitis), appendicitis, colitis, ulcers, pancreatitis, parasites, hernia
14. Food allergies and idiosyncracies
15. Any gastrointestinal x-ray examinations; date and results
16. Use of cathartics, laxatives, antacids, and antiemetics
17. Pancreas (endocrine system)
    a. polyuria, polydipsia, polyphagia in relation to food ingestion
    b. hypoglycemia symptoms (weakness, nervousness, sweating, tachycardia, hunger) in relation to food ingestion
    c. known history of diabetes

Observations and examination (Figure 2-3):

1. Symmetry, shape, contour, scars, distention, striae, lesions, pigmentation, bruises, abnormal pulsations

FIGURE 2-3 A midwife palpating a woman's abdomen.

2. Masses, tenderness, organomegaly, rigidity, guarding, distention, peristaltic activity
3. Femoral pulses
4. Umbilical, inguinal, or femoral hernias
5. Diastasis recti
6. Enlargment or tenderness of inguinal lymph nodes
7. Rectal examination, done at the time of the pelvic examination. See Chapter 56 for observations, examination, and significance of findings.

Genitourinary System

ROS:

1. Urinary
   a. frequency
   b. urgency
   c. dysuria
   d. hematuria
   e. nocturia
   f. suprapubic, flank, or low back pain
   g. polyuria or oliguria
   h. pyuria (pus in urine)
   i. incontinence
   j. known history of urinary tract infections or kidney stones
2. Adrenal (endocrine system)
   a. changes in melanin pigmentation of skin
   b. weakness
   c. symptoms suggesting hypoglycemia
   d. postural hypotension
3. Genitals
   a. lesions
   b. signs of trauma
   c. discharge: character, color, odor, pruritis
   d. sexually transmitted diseases*
   e. douching history*
   f. menstrual history*
   g. sexual history*
   h. obstetrical history*
   i. family planning history*
   j. date and results of last Pap smear
4. Endocrine system
   a. hirsutism
   b. known history of gonadal insufficiency; hormone therapy

Observations and examination:

1. Urinary: CVA tenderness (see Chapter 54 for methodology and significance of findings)
2. Genitals: See Chapter 56 for observations, examination, and significance of findings.

Muscular-Skeletal-Vascular Systems

ROS:

1. Joint pain, stiffness, swelling, redness, heat
2. Muscle weakness, cramps, pain, twitching, tremors, paralysis, paresthesia, atrophy
3. Skeletal pain, injuries, deformities (e.g., scoliosis, lordosis, kyphosis)
4. Limitation of motion in back or range of motion of the extremities
5. Edema of extremities
6. Varicose veins, intermittent claudication (leg or calf muscle pain when walking or exercising), leg heat or tenderness
7. Known history of arthritis, gout, muscular dystrophy, thrombophlebitis, bursitis, osteomyelitis, fractures, disk disease, sciatica

Observations and examination:

1. Curvature and mobility of the spine
2. Spinal column vertebral tenderness
3. Radial and pedal pulses
4. Skeletal deformities
5. Range of motion of extremities
6. Edema: finger, fascia, ankle (pedal), pretibial
7. Varicosities; calf heat and/or tenderness
8. Heat, swelling, or redness of joints
9. Homan's sign
10. Length, size, edema, lesions, redness, skin temperature, tenderness or pain, muscle atrophy, contractures, color, scars, or involuntary movements of the extremities
11. Deep tendon reflexes**
12. Clonus**
13. Clubbing, cyanosis, or other abnormality of nails
14. Needle marks or tracks
15. Tremors of fingers

Review of Other Systems

Central Nervous System

1. General
   a. syncope, loss of consciousness, convulsions, vertigo

* Do not repeat if this information was already obtained as special sections of the history or under the past medical history.

** See Chapter 55 for observations, examination, and significance of findings.

   b. known history of meningitis, encephalitis, stroke
2. Mental status
   a. speech disorders, memory disorders
   b. emotional status, nervousness, mood; orientation to time, place, and person
   c. change in sleep pattern, insomnia, activity pattern
   d. history of "nervous breakdown," depression
3. Motor
   a. clumsiness of movement (ataxia), weakness (paresis), paralysis
   b. tremor or muscle twitching
4. Sensory
   a. radicular or neuralgic pain (head, neck, trunk, extremities)
   b. paresthesia (burning or crawling skin sensation)
   c. hypoesthesia (decrease in tactile sensation)
   d. anesthesia (loss of sensation)
   e. hyperesthesia (excessive sensitivity of skin or special senses)

Lymphatic and Hematopoietic Systems

1. Lymphatic: lymph node swelling
2. Hematopoietic
   a. unusual or excessive bruising or bleeding; bleeding tendencies of skin or mucous membranes
   b. known history of anemia and treatment, blood transfusion and reaction, blood dyscrasias, exposure to radiation or toxic agents

Laboratory Tests and Adjunctive Studies

Laboratory tests and adjunctive studies are an essential component of physical assessment. Which tests and studies are performed as part of a routine screening vary based on the age of the woman, her risk status (e.g., if she has been exposed to sexually transmitted diseases or tuberculosis), and whether she is pregnant. At a minimum, for all ages and regardless of status with respect to pregnancy, an assessment should be made of the need to screen for vaginal infections or sexually transmitted diseases and the following lab tests and adjunctive studies done:

1. Hemoglobin/hematocrit
2. Total cholesterol
3. Urinalysis
4. Pap smear

Additional tests for the pregnant woman are covered in Chapter 22 on antepartal examinations.

Older women should also receive the following tests and adjunctive studies:

1. Occult blood
2. Mammography
3. Triglycerides and lipid profile in addition to plasma cholesterol
4. Thyroid studies
5. Proctosigmoidoscopy (every 3–5 years)

As laboratory values vary somewhat from one laboratory to another, each laboratory publishes the range of normal values for each test done in that laboratory. It is essential that you review a given laboratory's range of normal for a test. If the woman is pregnant, you should then adjust interpretation of the test results for known normal physiologic changes occurring during pregnancy in order to determine whether the laboratory report indicates a normal physiologic state or suggests a deviation from normal that requires further evaluation.

CHAPTER

3

Cultural Competence in Midwifery Practice

JO-ANNA L. RORIE, CNM, MSN, FACNM

The United States is an abundantly pluralistic society, as evidenced by the dramatic demographic changes revealed in the data collected for the 1990 Census. In contrast to the European roots that predominated among earlier immigrants, 25 percent of today's population traces its roots to Africa, Asia, or the Pacific Islands, or to Latino and Arab countries [1, 2]. One aim of midwifery care is to provide culturally competent care to all women across the life span. Culturally competent practice is particularly important for midwives in a country as diverse as the United States. To provide such care, midwives must understand the importance of each woman's cultural frame of reference. Midwives serve a rich and varied tapestry of women from a multitude of populations. The data from the 1991 study entitled "Nurse-Midwifery Care to Vulnerable Populations in the United States" is a visit and practice analysis of 5.4 million annual patient visits conducted by CNMs [6]. According to this study, 71 percent of these visits were made to women and infants from vulnerable populations; 42 percent were to women of a race or ethnicity other than European American (including 19.4 percent Black, 15.8 percent Latino, 2.6 percent Native American, and 3.3 percent Asian) [7]. The majority of those visits was for maternity care and included client education and counseling, two core components of midwifery care. On average, midwives spend 22 minutes with women during an established visit [4, 5]. According to the 1998 *Nurse-Midwifery Practice Survey*, CNMs described the population they served as nonwhite, immigrant, and uninsured [3].

Because health care is a cultural construct—emerging from beliefs about the characteristics of disease and the impact on the human body—cultural issues are primary in the provision of health services treatment and preventive intervention [8]. Midwives must thus be prepared to deliver care in a culturally competent manner and to ensure that our own lack of knowledge about others does not impair the delivery of such care. Cultural competence is a set of behaviors, attitudes, and policies that enable a system, agency, or individual to function effectively with culturally diverse clients and communities. Competence also implies skills that help to translate beliefs and orientation into action and behavior within the context of daily interaction with women and their families. Cultural competence refers to a health care provider's ability to honor and respect those beliefs, interpersonal styles, attitudes, and behaviors of clients as well as the multicultural staff who are providing services. These values must be incorporated at all levels—from policy and administration to clinical practice [9, 10].

Cultural competence is also a process in which the nurse-midwife gets in touch with his/her own culture and its influence on clinical practice. This is the first step in cross-cultural effectiveness. Culture implies an integrated pattern of human behavior that includes the thoughts, communications, actions, customs, beliefs, values, and institutions of racial, religious, socioeconomic, educational, occupational, or geographic groups. Culture defines all aspects of health care—how health care information is received and perceived, what is considered to

be a health problem, how symptoms are expressed, who and where treatment should be provided, and what type of treatment is acceptable and affordable [1, 8, 11]. To begin to understand the concept of culture and the plethora of world views that each person brings to a situation, it is important to keep the following three points in mind:

1. Culture is not static; it is dynamic and ever changing; the cultural practices that individuals remember and practice from their country or place of origin are often different from the practices that are occurring in that same place today.
2. Culture, language, ethnicity, and race are not the only determinants of a person's values, beliefs, and behaviors. Occupation, socioeconomic status, cultural upbringing, and educational level have an influence on how individuals define and view themselves.
3. In describing any culture or cultural practice, within-group differences are as great as across-group differences. In other words, no culture and no ethnic, linguistic, or racial group is monolithic. There are wide variations in attitudes, beliefs, and behaviors. To assume that people who share a common culture and language are alike is to make a dangerous mistake [11].

The Demographic Shift

The United States has become a global village. There have been major population changes as a result of immigration patterns and significant increases among racially, culturally, ethnically, and linguistically diverse populations already residing in the United States. The 1990 Census data revealed that the number of persons who spoke a language other than English at home rose by 43 percent to 28.3 million. Of these, nearly 45 percent indicated that they had trouble speaking English. The results of a 2000 survey conducted by the Census Bureau reveal that one in every ten persons in the United States is foreign born. Currently, the U.S. foreign-born population comprises the largest segment of any time in the past 50 years—a trend that is expected to continue. To further illustrate the need for culturally competent health care interventions, the Children's Defense Fund predicts that before 2010 there will be 9.5 million children of other races and 6.2 milllion fewer white, non-Latino children in the United States. By the middle of the twenty-first century, the average U.S. resident will trace his or her roots to Africa, Asia, the Pacific Islands, Latino, and Arab countries [1, 12].

Nowhere are the divisions of race, ethnicity, and culture more sharply drawn than in the area of health care. "The Institute of Medicine (IOM) defines disparities in health care as racial or ethnic differences in the quality of healthcare that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention." [8] Disparities in the incidence of illness and death among women of color persist. In recognition of these disparities the federal government has targeted several areas of health status, including infant mortality and committed resources [12]. Nationally, health care organizations are struggling with the challenges and opportunities of responding effectively to the needs of individuals and families from racially, ethnically, culturally, and linguistically diverse groups. The incorporation of culturally competent strategies within primary health care systems remains a great challenge for many communities. The *National Standards for Culturally and Linguistically Appropriate Services in Health Care* issued by the U.S. Department of Health and Human Services (HHS) reports that there currently is no agreement across health professional specialties on what specifically constitutes individual cultural competence or how it is best measured [8]. However, numerous reasons justify the need for cultural competence in the health care system at the patient-provider level. According to the Pew Health Professions Commission recommendations issued in 1998, the development of cultural competence is a priority [2, 12]. This is important for midwives who provide services in a variety of women's health care settings throughout the United States. Midwives may provide care for a childbearing woman from Africa who has been ritually circumcised, an Arabic Muslim woman who can only be examined by a female provider, or a Hispanic woman newly arrived from Central America who does not speak English.

According to the 2000 Census, there are 281.4 million persons living in the United States, of whom 143 million are female. Of this number, 27 million females are members of racial and ethnic minority groups [13]. Because of economic, social, and cultural barriers, these women are in poor health, have fewer health services, and bear the burden of poor health outcomes. Women of color in the United States encompass four major groups (which are listed in descending order of the size of the populations): (1) African American, (2) Hispanic, (3) Asian American/Pacific Islanders, and (4) American

Indian/Alaska native. The majority all-White population is referred to as Caucasian. Slightly more than 100 million or 71.6 percent of American females are Caucasian not of Hispanic origin [8, 9, 10].

Women of Color Population Overview

When discussing racial and ethnic terms, the language is often confusing. The Office of Management and Budget (OMB), an agency that defines racial groups, issued new standards in 1997 for collecting and presenting data on race and ethnicity. These standards recognized two categories of ethnicity (Hispanic or Latino) and five categories of race: (1) Asian, (2) American Indian or Alaska Native, (3) Native Hawaiian or Other Pacific Islander, (4) Black or African American, and (5) White. These categories are neither anthropologically nor scientifically based. In addition, the 2000 Census allowed respondents to self-identify and mark or select one or more races. The Office of Minority Health (OMH) within the Department of Health and Human Resources classifies minorities into the following main groups: (1) African American/Black, (2) Hispanic/Latina, (3) Asian American, Native Hawaiian, and Other Pacific Islanders, and (4) American Indian/Alaska Native. The term "of color" describes racial, ethnic, and national groups [15, 16, 17, 18, 19].

African-American/Black Women

According to the OMH, the term "African American or Black" refers to people having origins in any of the Black race groups in Africa. It is estimated that 10 million Africans were transported as slaves from the coast of West Africa to this country as part of the greatest migration in American history. They came from several African tribes including Ibo, Ashantis, Fanti, Mandingo, and Senegalese. The first landing took place in 1619, 244 years before the signing of the Emancipation Proclamation [20]. The 2000 Census included people who reported themselves to be Black, African American, or Negro or wrote in entries such as Nigerian, Jamaican, or African American. Of the 281.4 million people in the United States in 2000, 12.9 percent (36.4 million) reported themselves to be African American or Black. Non-Hispanic Black women outnumbered non-Hispanic Black males by nearly 1.9 million. In 1999, 17.5 million, or 12.5 percent of all females living in the United States were African American, not of Hispanic origin, 54 percent of all African Americans lived in the southern United States [11].

African-American women are more likely to die from breast cancer than are women from any other ethnic group, although the incidence rate of newly diagnosed cases is about 13 percent lower for them than for White women. The five-year survival rate for African-American women who are diagnosed with breast cancer is 71 percent compared with 86 percent for White women. Heart disease is the leading cause of death among African-American women and they have the highest death rate from stroke of all women (see Table 3-1). When compared with mothers of non-Hispanic white infants, mothers of African-American infants are 145 percent more likely to experience an infant death. Between 1996 and 1998, the difference in this rate between Blacks and Whites increased from 2.0 to 3.1. Among African-American women, the low birth weight rate remains twice that of White women. Recent data indicate that even among highly educated upper-income African-American women disparate rates of adverse outcomes persist [11, 16, 21, 22, 23].

Hispanic/Latina Women

In 2002, 12.5 percent of the U.S. population was Hispanic. The term "Hispanic" is an ethnic identity used by the federal government to classify those who

TABLE 3-1 Leading Causes of Mortality Among Women in the United States, by Race and Ethnicity

White	African American	Hispanic/Latina	Asian American	American Indian/ Alaska Native
Heart disease	Heart disease	Heart disease	Malignant neoplasms	Heart disease
Malignant neoplasms	Malignant neoplasms	Malignant neoplasms	Heart disease	Malignant neoplasms
CVD (including stroke)	CVD (including stroke)	CVD (including stroke)	CVD (including stroke)	Unintentional injuries
Chronic obstructive pulmonary diseases	Diabetes mellitus	Diabetes mellitus	Unintentional injuries	Diabetes mellitus

Source: Cross et al. *Towards a Culturally Competent System of Care*. Washington: CASSP Technical Assistance Center, 1989.

identify ties to Spain as part of their heritage. Most Hispanics in the United States trace their origin to Mexico, Puerto Rico, Cuba, Central America, or South America. The majority are Roman Catholic. The earliest forebears of this group were Spanish colonists from Mexico who came in the late 1500s to live in what is now the southwestern United States. Today, 43 percent of Hispanics live in the western United States. In 1999, Hispanic females of any race numbered 15.7 million, comprising slightly more than 11 percent of the U.S. female population. Many Hispanic women are recent immigrants. The leading causes of death among Hispanic/Latina women are the same as for African-American women [20, 24, 25, 26] (see Table 3-1).

Asian American and Pacific Islander Women

Asian American/Pacific Islander (AAPI) is a category that refers to people having origins in any of the original people of the Far East, Southeast Asia, Cambodia, China, India, Japan, Philippines, Hawaii or other Pacific Islands, and Thailand. In the 2000 Census 11.9 million Americans, 4.2 percent report themselves as Asian, with Chinese being the largest Asian group; 5.4 million are female. Nearly 75 percent of this population group are foreign born, including an increasing number of immigrants and refugees from Southeast Asia. Asian Americans and Pacific Islanders speak more than 100 different dialects. Nearly 66 percent speak an Asian or Pacific Islander language at home. Approximately 35 percent are linguistically isolated, living in households where no one aged 14 or older speaks English "very well." The 5.4 million females in this population group who are not of Hispanic origin comprised 3.8 percent of all U.S. females in 1999.

The four leading causes of death for AAPI women are all cancers combined, heart disease, stroke, and unintentional injuries (see Table 3-1). Due to a lack of data, relatively little is known about the health status of AAPI women. According to Surveillance, Epidemiology, and End Results (SEER) data, the highest age-adjusted incidence rate of cervical cancer occurs among Vietnamese women. A major barrier to care for AAPI women is the lack of linguistically and culturally appropriate services. Women of color for whom English is not the primary language often experience difficulties obtaining even the most basic health promotion and disease prevention information [14, 27, 28].

American Indian/Alaska Native Women

According to the Office of Minority Health, American Indian/Alaska Native is a category that refers to persons having origins in any of the original peoples of North and South America, including Central America. They are members of more than 500 federally recognized tribes as well as many recognized or unrecognized tribal organizations. The largest tribal groups are Navajo, Sioux, Blackfeet, Cherokee, Latin American Indian, Choctaw, Chippewa, Iroquois, and Pueblo. The largest Alaska Native tribe is Eskimo. Of the 281.4 million people in the United States in 2000, 4.1 million (1.5 percent) reported themselves to be American Indian or Alaska Native. Slightly more than 1 million females, or 0.7 percent of all U.S. females, belonged to this population group in 1999. Forty-three percent of all American Indians live in the western United States. The states with the largest American Indian population are California, Oklahoma, and Arizona.

The four leading causes of death among American Indian/Alaska Native women are heart disease, all cancers combined, unintentional injuries, and diabetes (see Table 3-1). Infants born to American Indian/Alaska Native women accounted for a disproportionate number of Fetal Alcohol Syndrome (FAS) deaths. Native American women consider alcohol abuse to be the primary health issue affecting their families, and alcohol and its multigenerational effects are thought be at the root of many of the health-related problems they experience. The death rates associated with alcoholism are much higher than they are among women of all other races. American Indian/Alaska Native women who abuse alcohol and drugs rarely receive treatment; instead they are often sent to jail where they lose their parental rights [14, 29, 30].

Cultural groups often forgotten by our health care system are women prisoners and homeless women. In 1998, 84,000 women were incarcerated, 22 percent of all arrestees. Approximately 67,000 of these women were mothers of children under 18 years of age, and 26 percent of all incarcerated females were women of color. Eighteen percent of all drug arrests involved women of childbearing ages; half of all incarcerated women were serving sentences for drug related crimes (32, 33].

Culturally Competent Care

The diversity among women of color accounts for a wide variance in health status, health behaviors, and health care needs. As primary care providers, midwives must ensure that women from vulnerable populations have access to a culturally responsive

health care system. Cultural competence requires commitment to an ongoing process [2].

The "cultural competence continuum" can help midwives meet the health care needs of a culturally diverse population. The "cultural competence continuum" (Figure 3-1) describes six distinct levels of competence, ranging from destructiveness to proficiency. Originally developed by Terry Cross et al. to describe six stages of competence at the organizational level [31], it has since been adapted for use at the individual level. It is especially helpful in the identification of cultural deficits and the targeting of areas in need of development and improvement. The cultural competence continuum also provides a framework for the recognition of practitioner and service intervention biases [2, 31].

The characteristics of the cultural competence continuum can be summarized as follows [31]:

1. *Destructiveness:* The attitudes, policies, and practices that are exhibited can be destructive to a culture. At the individual level, people in this phase believe that everyone should be more like the "mainstream."
2. *Incapacity:* A biased, authoritarian system lacks the capacity to facilitate growth in culturally diverse groups. Individuals at this level lack cultural awareness skills and believe that the dominant group is racially superior.
3. *Blindness:* A "we're all human" approach is used, wherein culture, ethnicity, and race make no difference in how services are provided.
4. *Precompetence:* Also known as "cultural sensitivity," wherein there is a desire and attempt made to deliver services in a manner respectful of cultural diversity. In general, there is awareness about the set of norms, values, and beliefs associated with a particular group, and how these affect group interactions and experiences.
5. *Competence:* There is an acceptance of, and respect for, cultural norms, patterns, beliefs, and differences. Individuals accept the influence of their own culture in relation to other cultures and are willing to examine components of cross-cultural interactions.
6. *Proficiency:* These individuals move beyond accepting, appreciating, and accommodating cultural differences to developing skills to interact in culturally diverse settings. There is a motivation toward developing culturally therapeutic approaches, and hiring staff who are specialists in cultural competence.

Application of the Cultural Competence Continuum

The following scenarios illustrate three phases along the cultural competence continuum.

Scenario 1

Background Information Tran is a 21-year-old Vietnamese woman Gravida 1, Para 0 who registered for prenatal care at 16 weeks gestation. Since she arrived from Vietnam nine months ago, Tran has been living with her aunt, who has accompanied her to the clinic. The FOB is a 25-year-old Vietnamese man, currently unemployed. He has lived in the United States for three years with his aunt and uncle. Both he and Tran speak no English.

Tran was raised in a small village in the mountains of Vietnam where her mother sent her at the age of three because she could not afford to take care of her. When her mother died, Tran was brought to the United States by her aunt, the owner of a small jewelry store. The aunt does not intend to accompany Tran on all of her visits. Displeased about this pregnancy, she has told Tran that she and her boyfriend will have to find a place to live when the baby is born. Tran has little formal education and can read only at a fourth grade level. Social service has tried on numerous occasions to encourage Tran to take the English as a Second Language classes at the local church. Tran attended one class and refuses to return; the reason is unknown.

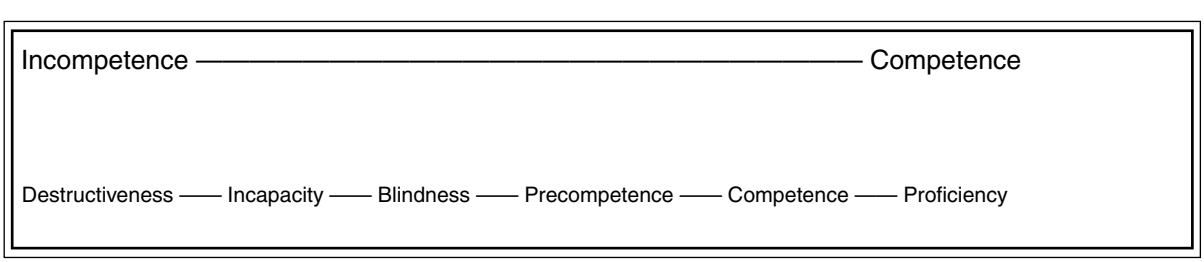

FIGURE 3-1 Cultural competence continuum. *Source:* Cross et al. [31].

Tran has been labeled a poor historian by the OB staff at the health center. Tran has come to the clinic with facial and upper body bruises, and the midwife suspects that she is being battered. The midwifery service has two Vietnamese outreach workers in the clinical setting. One of the outreach workers, Lan, plans to accompany Tran for labor support. Lan has asked Tran about the bruises. She denies being beaten, and claims she obtained the bruises by falling and bumping into things.

The hospital where Tran is going to deliver has no Vietnamese staff employed in any capacity. The night that Tran goes into labor the outreach worker has a personal family crisis and is unable to provide any support. Tran's aunt is away on business. The FOB accompanies Tran to labor and delivery, but he leaves and goes to the waiting room, where he remains. He does not see Tran again until she is being sent to the postpartum floor.

Tran has a spontaneous birth of a baby girl. Lan comes to the hospital the next day to help Tran with newborn care and to prepare for going home. The social service staff at the hospital are suspicious of Lan and do not believe she is translating their concerns regarding Tran's possible history of battering. Communication shuts down between Tran and the hospital staff. Tran is discharged home from the hospital on the second postpartum day.

Analysis This case study suggests a very typical precompetence. The health center has responded to the community needs by hiring two Vietnamese outreach workers. The hospital, an extension of Tran's health care system, is not responsive to this population's need. The next step on the continuum would be for the hospital administration to provide translation coverage and to meet with the health center administration to implement hospital and community-based strategies to assist women from other cultures who they know will be receiving care at the hospital. According to the Culturally and Linguistically Appropriate Services recommendations, health care organizations receiving federal funding must offer and provide interpreter service at no cost to patients with limited English proficiency [8].

Scenario 2

Background Information Marie is a 26-year-old CNM who is a recent graduate of her nurse-midwifery program. She is working at an urban health center in Boston doing full-scope midwifery in fulfillment of her National Health Service Corps obligation. Of Irish and Italian decent, Marie was raised in a military family. Her family of origin has settled in Illinois. She plans to return to Illinois to marry and join a physician/CNM practice when her obligation is completed in two years.

Gwendolyn is a 25-year-old African-American woman with five previous births who presented late for prenatal care. All of Gwendolyn's children have been in state custody. The first four are in the temporary custody of her mother, and she has custody of her two-year-old daughter. Now living in a shelter, Gwendolyn is waiting for her Section 8 (affordable housing) designation. She has a past history of depression treated with Prozac and individual counseling. She stopped taking the Prozac when she found out she was pregnant and decided not to return for counseling. Gwendolyn has been in drug treatment on seven separate occasions in five different programs. Drug free for 10 months, her urine toxicology was negative x1.

Gwendolyn has 4 siblings that she is not willing to talk about. It has been two years since she has spoken to her mother, who refuses to allow her any access to her children. Gwendolyn dropped out of school in the seventh grade. When she comes to the clinic, she is demanding and argumentative with the clinic staff. She rarely keeps appointments, as public transportation to the clinic is difficult. The shelter where she stays is a 35-minute drive. She comes to the clinic when she can get a ride. The FOB is the same for all of her children. The relationship is abusive; the FOB is currently in prison serving a two-year sentence for battering her. She has been evicted from two apartment buildings because of persistent fights between her and the FOB.

Gwendolyn's second prenatal care visit with Marie does not go well. Marie is frustrated with Gwendolyn because she arrives at the clinic unannounced, having missed her last two appointments. Gwendolyn's weight is 340 pounds, her blood pressure is 120/68, and her urine 2+ glucose, neg. protein. Marie tells Gwendolyn she will have to wait because there are two patients before her. Gwendolyn agrees and goes to the cafeteria to get something to eat. When she and Marie meet for the visit, she has a list of physical complaints she wants to discuss.

Gwendolyn's goals for the visits are to speak to the outreach worker regarding housing and to obtain an ultrasound for sex determination because she would like to start collecting clothes for her baby. Marie wants to get a one-hour glucose test, and urine for toxicology as she thinks Gwendolyn has relapsed.

Gwendolyn refuses to give a urine sample and accuses Marie of looking for an excuse to take her

baby away. Marie refuses to discuss another ultrasound and tells Gwendolyn that she "might as well write her a check for $500 now because an ultrasound for sex determination is a waste of the taxpayers' money." She also tells Gwendolyn that she will not be seen at the clinic unannounced again without an appointment. Gwendolyn leaves and goes to the clinic director's office and files a complaint of discrimination.

Marie tells the clinic director that she regrets the encounter and that she resents the charge of discrimination, as it would not matter to her what color Gwendolyn was. She says that she regards Gwendolyn as noncompliant and a drain on the clinical resources. The clinic director tells Marie that other staff members have heard her describe Gwendolyn using terms like "train wreck" and "walking wounded." Marie's response is that Gwendolyn has no business bringing another child into the world. Marie isolates herself and does not speak to any of the staff for the rest of the day. Gwendolyn transfers her care to another service.

Analysis This scenario is complex in nature, illustrating several overlapping issues. There is cultural blindness on the part of both the provider and the client. Marie believes that she treats all clients the same, regardless of race or socioeconomic status and that the health care system is set up to serve everyone with equal effectiveness. This approach makes Gwendolyn a victim and blames her for her problems, thereby rendering her culturally invisible. Leadership can be provided here by providing training in which Marie is able to understand and acknowledge the influence of her own cultural roots, beliefs, and behaviors. From this assessment, she can acquire skills to progress toward cultural competence.

Scenario 3

Background Information Itza is a 25-year-old married women from Cuba who presents for prenatal care with a midwifery service located in a community health center. Itza and her husband Rafael have been in the United States seven months. They came to the midwifery service based on a recommendation from her sister-in-law, who recently received labor and birth care from the same group.

The demographics of this health center have changed rather rapidly. When the Hispanic/Latino population at the health center reached 20 percent, the administration applied for Healthy Start funding, with which the center hired two Spanish-speaking midwives, one trained medical assistant, and a case manager. Additionally the entire health center staff, including the administrators, have been involved in a yearlong cultural diversity training that includes developing and participating in community-based health fairs. Itza was made to feel immediately at home as the waiting room has a variety of Spanish literatures. Because Itza and Rafael speak very little English, they have been assured that a Spanish-speaking midwife and doula will support them in labor.

Analysis The midwifery service described in this scenario demonstrates the characteristics of a culturally proficient agency through its commitment to hiring multicultural providers and its active participation in community health promotion projects [2]. Table 3-2 summarizes the characteristics of a culturally competent practitioner.

TABLE 3-2 Characteristics of Culturally Competent Practitioners

- Move from cultural unawareness to an awareness and sensitivity of their own cultural heritage.
- Recognize their own values and biases and are aware of how they may affect clients from other cultures.
- Demonstrate comfort with cultural differences that exist between themselves and clients.
- Know specifics about the particular cultural groups they are working with.
- Understand the historical events that may have caused harm to a particular cultural group.
- Respect and are aware of the unique needs of clients from diverse communities.
- Understand the importance of diversity within as well as between cultures.
- Endeavor to learn more about cultural communities through client interactions, participation in cultural diversity dynamics, and consultations with community experts.
- Make a continuous effort to understand a client's point of view.
- Demonstrate flexibility and tolerance of ambiguity, and are nonjudgmental.
- Maintain a sense of humor and an open mind.
- Demonstrate a willingness to relinquish control in clinical encounters, to risk failure, and to look within for the source of frustration, anger, and resistance.
- Acknowledge that the process is as important as the product.

Conclusion

Eliminating health disparities is a national agenda. Poverty, primary language, and health insurance are among the many factors that affect access to health care as well as health status. Recent national and state data describe the prevalence of the poor health outcomes among women of color. One approach to eliminating racial and ethnic health disparities is to increase the cultural competence of the health care workforce. Becoming a culturally competent provider requires a series of steps. The first is recognizing where one is on the continuum and moving forward. The second is to remain committed to the process. The health care system is very likely going to rely on midwives to provide leadership in the development and implementation of health promotion strategies for women of color across the life span. It is essential that CNMs and CMs deliver culturally competent, comprehensive primary care services for all women. Cultural competence includes being able to recognize and respond to health-related beliefs and cultural values. Examples of culturally competent midwifery care include striving to overcome cultural, language, and communications barriers, and providing an environment in which women and their families from diverse cultural backgrounds feel comfortable discussing their cultural health beliefs and practices in the context of reproductive health. Midwives must be at the forefront in the implementation of cultural competence training programs, which are now considered a key intervention in reducing the health care disparities that disproportionately affect women of color. Integrating traditional healing methods and spiritual beliefs where appropriate into treatment plans is another crucial element toward achieving the goal of cultural competence.

CHAPTER

4

International Midwifery and Safe Motherhood

MARGARET A. MARSHALL, CNM, EdD, FACNM
JOYCE E. THOMPSON, CNM, DrPH, FACNM, FAAN

A 43-year-old Gravida 11 came complaining of severe lower abdominal pain for the past two days. Then she had slight dark bleeding, dizziness, and couldn't walk. Her BP 110/50, pulse 160, and abdomen tender to touch. Lucky for me it was on a Tuesday which is our market day and judging from her age and parity I thought could this be appendicitis. The BP too could not give me a clue as to ectopic. But I gathered courage, did the puncture [an abdominal puncture to rule out ectopic pregnancy], and it was positive. So I referred her immediately to hospital. Luck was not on my side. The only M.O. [medical officer] had traveled to Accra. She was detained according to her [the patient] to give her some tablets to take home the next day.

So they returned to me on a Thursday with a BP of 60/0. I set up Dextrose 5% with hydrocortisone 100 mg IV and arranged for a boat to take her to Kpando Hospital on the Volta River. This patient will prefer to die in my clinic if I won't accompany her to Kpando myself, for fear that if she does not meet any Doctor she won't know what to do; and she believes my company will help give her prompt treatment. So, we got a boat which took 20,000 cedis [approximately one month's salary for a hospital nurse]. Immediately we got there a blood transfusion was arranged for and I gave a pint of blood. I left on the third day for my station. I had lost all confidence as I knew this patient was going to die. But she survived!!!

This rural midwife from the Affron Plains in Ghana was trained in Life-Saving Skills. It took an average of 26 hours to refer a patient to the nearest facility with surgical capability. Travel was by car/truck, boat, bicycle, and again car/truck. During the rainy season, referrals would take up to three days.

Introduction

Midwifery—"an ancient profession reborn in contemporary society" [1]—is by its very nature global. Midwives have been with women for pregnancy and birth since the beginning of civilization. Likewise, for centuries midwives often accompanied women as they migrated to new lands to live and raise their families. Today's focus on international midwifery reflects the continued migration of the professional workforce of midwives.

An international or global focus to midwifery practice is reflected in the expanding network of midwifery associations working in partnership with global agencies, policymakers in governments, and groups—from the World Health Organization and the United Nations, to the White Ribbon Alliance—that share common goals and concerns related to the health of women. The international nature of midwifery, and the work of midwives with women often not of their own race, ethnicity, or culture, also raises daily concerns for cultural competence and respect in the practice of midwifery. The most

compelling reason for understanding the international nature of midwifery is the ever-increasing demand for promoting basic human rights, especially for girls and women—including the right to a safe and secure reproductive life [2, 3].

This chapter will focus on the role of midwives as the key health professional in global efforts to make pregnancy and birth safe throughout the world and to promote the health and well-being of girls and women wherever they reside. Data on the health of women globally are used to set the stage for understanding the work of midwives around the world. The key role of the International Confederation of Midwives (ICM) and its work with midwives and women throughout the world will be featured. In addition, a brief introduction to the World Health Organization as a leader in global health efforts, and other global partners in the Safe Motherhood Initiative will be addressed. The end of the chapter will focus on frequently asked questions about international midwifery derived from decades of working with midwifery students in the United States and other areas of the world.

The Situation Worldwide

> Every minute of every day, somewhere in the world, a woman dies as a result of complications arising during pregnancy and childbirth. The majority of these deaths are avoidable. [4]

Every minute around the world

380 women become pregnant

190 women face unplanned or unwanted pregnancies

110 women experience pregnancy-related complications

40 women have unsafe abortions

1 woman dies

White Ribbon Alliance for Safe Motherhood. *Awareness, Mobilization, and Action for Safe Motherhood: A Field Guide.* Washington, DC: NGO Networks for Health, 2000.

Since 1982, the World Health Organization (WHO) has systematically reviewed indexed medical literature, nonindexed publications, and reports from national and local authorities regarding maternal mortality and maternity care coverage worldwide. Its best estimate in 1987 was that there were in excess of 500,000 pregnancy-related deaths per year, most of them preventable [4]. Subsequent reanalysis of the data revealed that closer to 585,000 women die per year [5]. Of these nearly 600,000 deaths, more than half come from just eight countries: Bangladesh, Ethiopia, India, Indonesia, Nepal, Nigeria, Pakistan, and Uganda. Nepal suffers a maternal death every five minutes, Nigeria every ten minutes.

The worldwide Safe Motherhood Initiative was launched in 1987 in Nairobi, Kenya. The goal of this meeting was to raise awareness, alert the international community to this silent tragedy, and mobilize efforts and resources on the behalf of women. At the 1990 World Summit for Children, 166 nations signed on to the action plan goals, one of which was to reduce maternal mortality by 50 percent by the year 2000 [6]. In September 2000, the United Nations member states adopted the Millennium Development Declaration that reinforced the emphasis on healthy women and safe pregnancies and birth for development in any country. The Millennium Development goals included the reduction of maternal mortality by 75 percent between 1990 and 2015, using the proportion of births attended by skilled personnel as an indicator for this goal [7].

Mortality figures, though difficult to obtain, have been the most sensitive indicator of the health of women. However, in considering maternal mortality, it is important that a far wider scope of pregnancy-related health problems, including maternal trauma, chronic disease, and reduced energy output, which have profound ramifications for the family and the economy, not be overlooked. Maternal mortality represents only the tip of the mountain of health problems for women. The road to maternal death and disability for many women begins at birth, when they are born female. Morbidity has been even more difficult to define and measure. Many women never enter the health care system during pregnancy, even when gravely ill, and therefore their deaths or disabilities are not captured in vital statistics or other records.

A myriad of service factors—from improper care to a lack of supplies, transport to a referral center, surgical capability, blood banks, and money with which to access available care—contribute to maternal mortality in developing countries. These factors most recently have been categorized as the "enabling environment or system of care" as distinct from the person who provides needed care [8].

Cultural factors that limit access to care tend to be less well known and less well documented.

Utilization of faith healers, local herbs, over-the-counter treatments, and "quack" practitioners who claim unearned health credentials can complicate access to appropriate care given in a timely fashion. When disease is believed to be caused by black magic or lack of faith, orthodox medical services based on belief in the germ theory are not seen as offering solutions. Cultural factors also include the existing norms that define the status of women, with the consequence of interfering with a woman's decisions to seek care in a timely manner.

To confront the problems of maternal mortality and morbidity, issues of quality and access must be addressed. They can be analyzed within the framework of the three delays [9]:

1. Delay in recognition that there is a problem
2. Delay in reaching the appropriate level of care once the problem/complication has been recognized
3. Delay in receiving the appropriate care after arrival at the service site

Maternal Death

The World Health Organization defines *maternal mortality* as follows:

> Death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and the site of pregnancy, from any cause related to or aggravated by the pregnancy itself or its management, but not from accidental or incidental causes [10]. Accidental or incidental causes are those that would have caused death irrespective of pregnancy, such as traffic accidents, gunshot wounds, poisonings, and so forth.

Deaths are then divided into two categories:

1. *Direct obstetrical deaths*, resulting from obstetrical complications of the pregnancy state (pregnancy, labor, and puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of the above [10].
2. *Indirect obstetrical deaths*, resulting from previous existing disease or disease that developed during pregnancy, and that were not due to direct causes, but were aggravated by physiologic effects of pregnancy [10].

In developing countries, the five major direct causes of maternal death are (1) hemorrhage, (2) sepsis, (3) pregnancy induced hypertension, (4) unsafe abortion, and (5) obstructed labor.

The patient was a 32-year-old Gravida 3, one live baby, who had been attendant since 12 weeks of pregnancy. She was my friend and came from this very village. The patient came in with labor pains at 9 p.m. onset 4 p.m. P.V. [vaginal examination] done. Os was 2 cms. dilated. Membranes intact. Labor progressed well. Patient delivered spontaneously a live female infant at 4:15 a.m. The placenta appeared to be complete but the membranes was ragged. Patient started bleeding. IV 500 cc set up with pitocin. External bimanual compression done without effect. Manual removal [uterine exploration] done. Only blood clots expelled. Internal bimanual compression done without effect. Another IV 1000 mls set up and the patient was transferred. There were transportation difficulties and the road is very bad. It took us 4 hours 10 minutes to travel a 35 km journey. The patient received 2500 mls of IV fluids but very unfortunately the IV got infiltrated on the way; but due to the bad road I could not get the vein. All attempt to start the IV again failed. The patient expired at the hospital before the Doctor arrived. EBL 2500cc. I collapsed at the hospital. They gave me Valium 20 mgs and put me in a bed. I was not aware for some time. I cried and felt very bad. They talked to me and explained that they sometimes have such women die at their hospital with everything. I did not feel confident and competent. Sometimes when I think about it now I cry.

This rural midwife trained in Life-Saving Skills had organized the TBAs in the seven villages around her to come to her maternity home for continuing education and to refer their patients with problems. Note that once the bad road was graded, travel time was decreased from 4 hours 10 minutes to under an hour and a half.

Ways to Express Mortality

There are three main ways to calculate and express maternal mortality: (1) rate, (2) ratio, and (3) lifetime risk.

Maternal Mortality Rate The maternal mortality rate is expressed as the number of women who die while pregnant or within the first 42 days after pregnancy, from any cause related to or aggravated by preg-

nancy per 100,000 women of reproductive age in a given year [10]. The WHO International Classification of Diseases (Vol. 10, 1997) has revised the definition to include deaths within one full year after the termination of pregnancy. Because this definition is less in use and difficult to obtain, it is important to see how data are reported when making comparisons over time or from one country to another for both maternal mortality rate and ratio [11]. The rate is determined as follows:

$$\frac{\text{Number of maternal deaths in a year}}{\text{100,000 women of reproductive age in the population}}$$

The advantage of using the maternal mortality rate is that it compares maternal deaths with all women at risk in the population. In a society with a reliable system of gathering statistics, this provides a clear way of expressing deaths. However, in most developing countries, the census data are too old or faulty to make it possible to use rates.

Maternal Mortality Ratio The maternal mortality ratio is expressed as the number of women who die while pregnant or within the first 42 days after pregnancy, from any cause related to or aggravated by pregnancy per 100,000 live births in a given year [10].

$$\frac{\text{Number of maternal deaths in a year}}{\text{100,000 live births in a year}}$$

The advantage of using maternal mortality ratio is that the numbers of live births are comparatively easier to count. This is the most commonly used way to express trends within a country and to make cross-country comparisons.

Lifetime Risk of a Maternal Death The lifetime risk of a maternal death is calculated by multiplying the maternal mortality rate by 30 (the number of years of exposure between ages 15 and 44), but the effective duration of exposure can vary widely. The lifetime risk of maternal death can be more simply stated as the risk of an individual woman dying from pregnancy or childbirth during her lifetime. Calculations are based on maternal mortality and fertility rates in the country. A lifetime risk of 1 in 3000 represents a low risk of dying from pregnancy and childbirth, while 1 in 100 is a high risk [12]. Table 4-1 presents regional data on lifetime risk of a woman dying during the childbearing cycle.

The advantage of using lifetime risk of dying a maternal death is that it recognizes that women of high fertility or women lacking in universal access to effective family planning have an extremely high risk of dying as a result of pregnancy or childbirth.

TABLE 4-1 Women's Lifetime Risk by Region

Region	Lifetime Risk of Dying
Africa	1 in 16
Asia	1 in 65
Latin America/Caribbean	1 in 130
All developing countries	1 in 48
All developed countries	1 in 1800

Maternal Morbidity

As difficult as it is to obtain accurate maternal mortality data, morbidity data collection is far more difficult. However, women worldwide are dying during pregnancy of diseases for which we have prevention and treatment strategies. In Nigeria, where a maternal death occurs every ten minutes, 10 percent of maternal deaths are from malaria. Other common causes include maternal tetanus, tuberculosis, and increasingly HIV/AIDS.

One of the huge challenges for this century is improved prevention, recognition, and low-technology treatment for morbid conditions of pregnancy. Currently, there is no global agreement as to definitions of pregnancy-induced hypertension, obstructed labor, and hemorrhage. Definitions are crucial because they dictate what treatment protocol will be used. A practical example of this is hemorrhage, which is defined as 500 cc of blood loss during the birth process. A woman entering labor with a hemoglobin of 12 g can tolerate this blood loss with few symptoms. A woman entering labor with a hemoglobin of 4 g may well go into shock and die with a 300 cc blood loss.

Historically, much time and effort have been invested in the training of traditional birth attendants (TBAs), feeling that this investment would decrease maternal deaths in the community. More than 20 years experience has shown that this has not contributed significantly to a reduction in mortality. Clearly, it is unreasonable to expect that community women, no matter how skilled and loving, can affect great change when working within a system bedeviled with poor transportation, lack of emergency funds, inadequate blood safety, and poor referral institutions. Rendering maternity care is a system problem

requiring multiple levels of preparedness and active community awareness and participation.

Many nations have felt that moving childbirth into institutions was the answer to maternal mortality. Experience has shown that site of delivery is not the critical factor. The linchpin of improved maternal outcomes is introducing skilled providers at every level of care. An important distinction has evolved to differentiate between a *trained* and a *skilled* provider. A trained provider may have as little as a five-day training for TBAs and is not in a position to negotiate and handle emergencies.

Skilled Provider A skilled provider refers exclusively to a person with midwifery skills (for example, a doctor, midwife, or nurse) who has completed a set course of study and can manage normal labor and delivery, recognize the onset of maternal and neonatal complications, perform essential Life-Saving Skills, initiate treatment, and supervise the referral to a higher health care facility.

Source: Family Care International. *Saving Lives: Skilled Attendance at Childbirth*. New York: FCI, in collaboration with Safe Motherhood Inter-Agency Group, 2001, pp. 5–16.

Persons who are skilled providers are referred to as those who have midwifery skills, whether or not they are midwives. At the ten-year anniversary conference in Sri Lanka for the Safe Motherhood Initiative, it was noted that worldwide 75 million births take place annually and 60 million of those births take place without the presence of a skilled attendant.

> The single most critical intervention is to ensure that a health worker with midwifery skills is present at every birth, and transportation is available in case of emergency. A sufficient number of health workers must be trained and provided with essential supplies and equipment especially in poor and rural communities. [13]

Clearly the presence of a skilled provider, though essential, is not sufficient to save women's lives. Providers work within teams with complementary skills and need essential equipment and supplies. Given a supportive environment, skilled providers may render safe, high-quality care in any site: home, maternity home, birth center, health post, district hospital, or referral hospital. The inputs at each level of care play an important role in rendering emergency obstetrical services when required. The levels of obstetric care and personnel providing such care are summarized in Table 4-2.

TABLE 4-2 Levels of Obstetric Care

Comprehensive Emergency Obstetric Care Facilities: 1 per 500,000 people	**District Hospital Providers**
Perform surgery under general anesthesia Perform assisted removal (e.g., D&C) of retained placental pieces Perform manual removal of retained placenta Perform assisted vaginal delivery (e.g., vacuum extraction or forceps delivery) Provide safe blood replacement Administer parenteral (IV or IM) antibiotics Administer parenteral (IV or IM) sedatives Administer parenteral (IV or IM) oxytocics	Physicians, midwives, paramedical and support staff
Basic Emergency Obstetric Care Facilities: 4 per 500,000 people	**Health Center**
Perform manual removal of retained placenta/pieces Perform assisted vaginal delivery (e.g., vacuum extraction) Administer antibiotics, sedatives (e.g., Valium, magnesium sulfate), and oxytocics (ergometrine, Pitocin) IM or IV, and IV fluids.	Physicians and/or midwives, paramedical and support staff
Obstetric First Aid in the Community	**Village/Community Level**
Uterine massage/pressure point May be able to administer sublingual/nasal/IM oxytocics (ergometrine) Provide oral rehydration salts	Junior health staff, traditional birth attendants, local leaders, women's groups, community workers, families

Source: Ross, S. R. *Promoting Quality Maternal and Newborn Care: A Reference Manual for Program Managers*. Washington, DC: Cooperative for Assistance and Relief Everywhere (CARE), 1998, p. 5.55.

The Newborn

The mother/newborn dyad is inseparable. Improving the health of the mother will improve the outcome for the infant. It is likewise crucial to improve the survival of the infant so that women are not exposed to the risks of many pregnancies to ensure that a few children make it to adulthood and are able to care for their aged parents. Repeated pregnancies take a huge toll on a woman's body and increase her lifetime risk of dying a death related to childbearing. Again, the essentials of newborn care are low technology and well within our hands today, as described in Table 4-3.

Approximately 8 million perinatal deaths occur each year. Of these, approximately 85 percent of newborn deaths are from infections, birth asphyxia, and birth injury [14]. More than two-thirds of these newborn deaths occur in fully developed term-sized infants. These infant losses contribute in turn to the cycle of poor birth spacing, excessive fertility, recurring fetal loss, and maternal morbidity and mortality.

The Situation in the United States

For most women in the United States, childbirth is a relatively normal experience and people have come to expect the perfect delivery experience, the perfect newborn, and a mother unharmed by the experience. In fact, from 1990 to 1995, almost 2000 American women died from pregnancy and its complications, even with modern advances in health care (see Figure 4-1).

TABLE 4-3 Essentials of Newborn Care

Care of Future Pregnancies	Special Attention
Improve the health and status of women Improve the nutrition of girls Discourage early marriage and early childbearing	Promote safer sexual practices Provide opportunities for female education
Care During Pregnancy	**Special Attention**
Improve the nutrition of pregnant women Immunize against tetanus Screen and treat infections, especially syphilis and malaria Improve communication and counseling: birth preparedness, awareness of danger signs, and immediate and exclusive breastfeeding	Monitor and treat pregnancy complications such as anemia, preeclampsia, and bleeding Promote voluntary counseling and testing for HIV Reduce the risk of mother-to-child transmission (MTCT) of HIV
Care at Time of Birth	**Special Attention**
Ensure skilled care at delivery Provide for clean delivery, clean hands, clean delivery surface, clean cord cutting, tying and stump care, and clean clothes. Keep the newborn warm; dry and wrap baby immediately, including head cover, or put skin-to-skin with mother and cover Initiate immediate, exclusive breastfeeding, at least within one hour Give prophylactic eye care, as appropriate	Recognize danger signs in both mother and baby and avoid delay in seeking care and referral Recognize and resuscitate asphyxiated babies immediately Pay special attention to warmth, feeding, and hygiene practices with preterm and low birth weight babies.
Care after Birth	**Special Attention**
Ensure early postnatal contact Promote continued exclusive breastfeeding Maintain hygiene to prevent infection; ensure clean cord care and counsel mother on general hygiene practices, such as hand-washing Provide immunizations such as BCG, OPV, and hepatitis B vaccines, as appropriate	Recognize danger signs in both mother and newborn, particularly of infections, and avoid delay in seeking care and referral Support HIV positive mothers to make appropriate, sustainable choices about feeding Continue to pay special attention to warmth, feeding, and hygienic practices for low birth weight babies

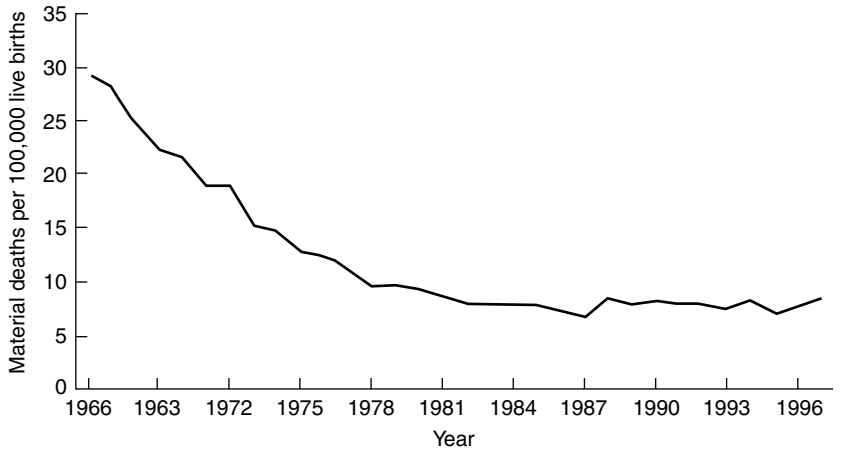

FIGURE 4-1 Maternal mortality in the United States: 1966–1997.

Source: National Center for Health Statistics, Centers for Disease Control and Prevention. *Vital Statistics*, 1998.

According to the National Center for Health Statistics (NCHS), no progress has been made in decreasing maternal deaths since 1982 (see Figure 4-2). Twenty other countries have lower maternal mortality rates than the United States. In 1990, the federal government set a goal to decrease maternal mortality to 3.3 per 100,000 live births by the year 2000. Only three states achieved the goal: Massachusetts, Nebraska, and Washington. Eight other states were able to achieve a maternal mortality rate of less than four. This indicates clearly that there is excess mortality, that decreases can be achieved, and that meeting these goals in other states will be difficult. The Health and Human Services Healthy People objectives for 2010 have again been set at 3.3 maternal deaths per 100,000 live births. The special focus for the 2010 goal is to reduce racial disparities [15].

Early in the twentieth century, the death rate for Black women was twice that of White women. Today, the racial disparity has increased: the death rate of Black women is 4.5 times that of Whites and 1.6 times that of Hispanics. In addition to these

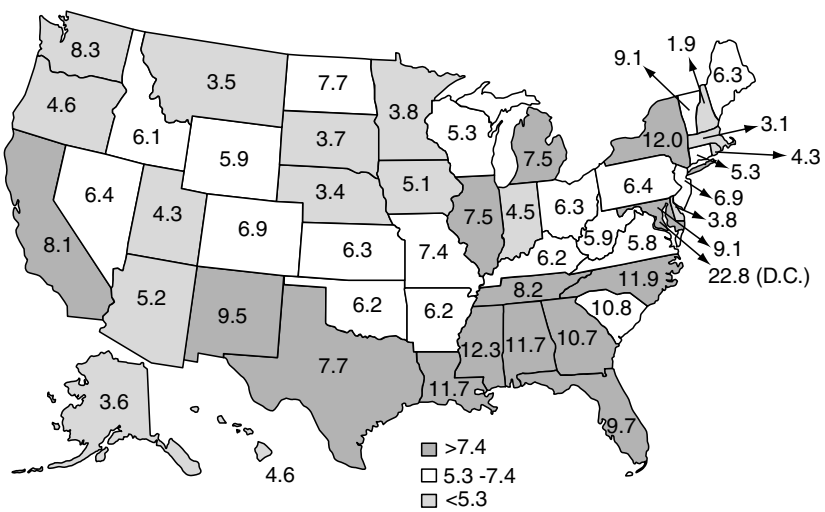

FIGURE 4-2 Maternal mortality ratios: 1987–1996.

Source: National Center for Health Statistics, Centers for Disease Control and Prevention. *Vital Statistics*, 1998.

mostly preventable deaths, many more women (approximately 25 percent) suffer significant complications of pregnancy and childbirth, including infections, hemorrhage, hypertension, depression, and urinary incontinence.

In a federal study of the pregnancy-related mortality ratio between 1991 and 1997, the overall maternal mortality ratio was 7.31. However, the ratios for Hispanic women were 10.3 times that of white women; for Asian/Pacific islanders they were 11.3 times; for American Indians/Alaska Natives they were 12.2 times; and for Black women they were 29.6 times the rate for white women (see Figure 4-3) [16]. During this time frame, 3193 women died during pregnancy or within one year of the end of pregnancy. Some developed countries are moving toward the use of the Pregnancy Related Mortality Rate (PRMR), the feeling being that with the use of current technology, some women are dying after the typical 42 days postpartum time frame that would clearly have died sooner in the absence of the technology [16]. The PRMR captures those pregnancy related deaths that fall after the traditional 42-day cutoff postpartum.

Race and ethnicity are not considered risk factors for maternal mortality, but rather they are indicators of lack of an enabling environment in the areas of the economy, access to the health system, and lack of quality of care.

Accurate reporting of maternal deaths is a problem in the United States as well as in the rest of the world. Underreporting of deaths due to misclassification are estimated to be 1.3 to 3.0 times the numbers of deaths reported through the vital statistics system. Thus the 3086 deaths recorded between 1987 and 1996 may well be closer to 9300.

Global Partners Promoting the Health of Women and Childbearing Families

The International Confederation of Midwives

The International Confederation of Midwives (ICM) is a global federation of midwifery associations, functioning as either independent entities or as autonomous groups within other organizations, such as nursing or physician groups. These midwifery associations choose to join together to promote and strengthen midwifery in order to enhance the health of women and childbearing families throughout the world. The ICM is the only international midwifery association with formal recognition by the United Nations (UN) as a nongovernmental organization (NGO), receiving its first UN accreditation in the early 1960s. The official mission of the ICM as stated in 1993 is to "advance worldwide the aims and aspirations of midwives in the attainment of improved outcomes for women in their childbearing years, their newborns, and their families wherever they reside" [17]. From modest beginnings in the early 1900s, the ICM in 2002 has more than 80 midwifery associations in membership from over 70 countries, representing an estimated 500,000 midwives worldwide [18].

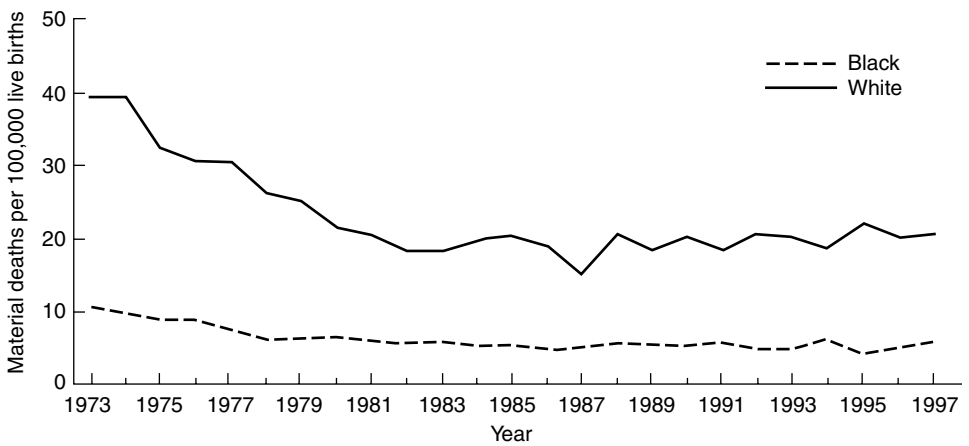

FIGURE 4-3 Maternal mortality ratios in the United States by race: 1973–1997.
Source: National Center for Health Statistics, Centers for Disease Control and Prevention. *Vital Statistics*, 1998.

History Midwives and midwifery practice survived for centuries without formalizing midwifery education, regulation, and standards of practice, or developing an organizational structure at the local, national, or international level. Midwifery was, and continues to be, a vital service provided to women during one of the most vulnerable times of their lives—that of conceiving and bearing children. Until the beginning of the twentieth century, however, only a few countries (among them, Finland, France, Germany, Holland, and Sweden) had sophisticated educational programs for midwives and regulated the practice of midwifery. Most other countries "were content to leave childbirth to the care of traditional practitioners whose skills were transmitted from generation to generation through some form of apprenticeship" [19].

In the late nineteenth century, industrialized nations became concerned about the high death rates of women and children and their overall poor health. Policymakers, politicians, and public health officials searched for ways to promote the health of women and infants, albeit for a variety of reasons (including hopes for an intelligent workforce, healthy army recruits, etc.) that often failed to recognize the importance of women as human beings beyond their reproductive abilities. At the same time that awareness of the poor health status of childbearing women was being discussed, many midwives realized that they would have to improve their standards of education and working conditions if they were to survive within newly developing systems of health and illness care. European midwifery was strongest and continues to thrive in the twenty-first century. The foundation of the ICM was thus firmly rooted in European midwifery of the early 1900s. In other parts of the world, midwives found their practice limited to their own immigrant group or were pushed aside by the rapid increase in the number and prominence of physicians struggling to gain recognition by denigrating the importance of the midwife in the care of childbearing women [19] (also see Chapter 1).

The rapid institutionalization of childbirth after World War I, falling birth rates, and an ever-growing number of doctors threatened the ancient practice of midwifery in many countries. The need to work together across national and cultural boundaries was compelling, and European midwives formed the International Midwives Union (IMU) in 1919. Meeting every two to three years in Europe, the IMU members debated such timeless issues as the place of birth, expansion of the traditional midwifery role beyond childbearing care, methods of pain relief that could be offered to women safely, and ways to improve the standards of education and practice as well as working conditions for midwives. Wars interrupted the IMU meetings, and many records were lost during World War II [20]. In 1954, the "reborn" International Confederation of Midwives, with headquarters in London (until 2000), reached well beyond Europe. Midwives throughout the world began to realize the value of sharing information and working together to improve conditions for childbearing women and families while strengthening the profession of midwifery [19].

Aims and Objectives The ICM's primary aims are to "improve the standard of care provided to mothers and babies and the family throughout the countries of the world; to support and advise, when required, associations of midwives in liaison with their Governments; to advance the provision of maternity care; and to develop the role of the midwife as a professional practitioner in her own right" [21]. The ICM also represents midwifery to international bodies and agencies, through meetings or consultations, or through direct relationships with the heads or governing bodies of such organizations. All of the ICM's activities are directed toward a single aim: to achieve a reduction in rates of maternal and neonatal mortality and morbidity [20, 21] as well as to promote the health and well-being of young girls and women throughout their lives.

Organization and Structure All members of the ICM are either independent associations of midwives or autonomously governed midwives' groups within other organizations, such as nursing or obstetrical societies. Criteria for association membership in the ICM is delineated in the ICM constitution and bylaws. Membership is based on members of an association meeting the International Definition of the Midwife, including educational preparation as a midwife and legal recognition to practice midwifery. There is no individual midwife membership category within ICM. All midwives who are members of an association having membership status in the ICM are considered members. For example, all members of the American College of Nurse-Midwives (ACNM) are automatically members of ICM and can participate in any of the ICM activities.

The structure of the Confederation is based on four regions with 11 elected representatives, who

also serve as members of the Executive Committee. The regions and number of representatives include Africa (2), Americas (2), Asia-Pacific (2), and Europe (5). The International Council is the governing body of the Confederation, made up of two voting delegates from each member association, 11 named Regional Representatives, the Officers of the Confederation (President, Vice-President, and Immediate Past President), and three elected members of the Board of Management (Director, Deputy Director, and Treasurer). Meetings of the International Council are normally held every three years prior to the ICM Triennial Congress. Terms of office for elected officials are also three years, with provisions for reelection for a total of three consecutive terms in the same office.

The Executive Committee (Regional Representatives and Board of Management) functions as an advisory body to headquarters staff and ICM Council, meeting twice in each three-year period. The Board of Management is charged with implementing the ICM Council policies and activities and provides oversight to ICM staff, meeting at least every three to four months. The Secretary General, based at ICM headquarters, is the chief executive officer of the ICM, appointed by the International Council to manage the day-to-day affairs of the Confederation as directed by the Council and the Board of Management.

Global Vision and Goals The preface to the original statement of the ICM Global Vision and Goals [22], first adopted by the ICM Council in 1993, includes the following statement of purpose:

> In looking forward to the twenty-first century, midwives and women share many of the same concerns and will work toward achieving the vision that empowers both women and midwives to be fully respected as persons who are also productive members of all societies.

This purpose statement reflects the awareness that the growth and development of midwifery and the ICM are inevitably linked to the educational, social, and economic status of the women it serves along with the evolution and promotion of the rights of women in all societies.

Core elements contained in the *Empowering Women . . . Empowering Midwives* ICM Vision Statement focus on a vision for women and their health as well as a vision for the future of midwifery. Much of this content was based on the vision statements of the ACNM [23] and used with permission—an example of the importance of having global midwifery partners working together to share experiences and ideas. These core elements begin and end with respect for women as persons with inherent human rights—whether as the recipient of midwifery care or the midwife, herself [24, 25]. The vision is of a world where "no woman has to fear for her life or the life of her baby when she is pregnant," and "women are educated and empowered to delight in a strong sense of self, to trust their bodies, to plan their pregnancies, and to make wise choices in the health care arena" [22].

Core elements in the *Vision for the Future of Midwifery* [22] include having a world where "midwives provide care in all settings and for all women who need midwifery care" as "autonomous health care providers who value team work in providing for the total needs of women and their families." The vision continues with "Midwives are recognized as the experts in the care of childbearing women and the linchpins in any Safe Motherhood effort" and "midwives play a key role in determining the future of health care, including community-based primary health care for all women and families."

All vision statements must have a companion "strategy" document [26]. The ICM has identified specific strategies to meet their goals: (1) to address women's health globally, (2) to strengthen the midwifery profession, and (3) to promote the organization internationally. The updated 2002 goals include working toward the achievement of Safe Motherhood goals and demonstrating the potential of midwifery actions to reduce maternal and perinatal mortality and morbidity; extending the knowledge of midwifery and the influence of midwives throughout the world in venues where decision making takes place and policies are made about the delivery of maternity care; and working with communities and women's groups to develop their knowledge and awareness of how to attain and maintain health. Other ICM goals relate to strengthening midwifery education and regulatory activities, encouraging and supporting midwifery research, and promoting quality midwifery care. As an organization, ICM is also committed to increasing membership, disseminating information, and securing the financial viability of ICM as well as providing forums such as Triennial Congresses where member associations can share and develop from the experience of others.

International Definition of the Midwife (1972; 1990; 2002) The International Definition of the Midwife (see Chapter 1, p. 3), first developed in 1972, has

been one of the most important documents that the ICM has put forth to the global community. The fact that it was subsequently agreed to by the WHO and then the International Federation of Gynecology and Obstetrics (FIGO) speaks well of ICM's collaborative status with major players in global health, as well as its credibility in defining who the midwife is, what the midwife should be doing, and within what regulatory framework and enabling environment the midwife works. This definition was updated in 1991 and again in 2002, primarily to modernize language and to reflect more clearly the self-governance and autonomy of midwifery.

During 2000 and 2001, a statement of essential competencies for basic midwifery practice was field tested in 22 different countries [27]. A total of 214 individual task statements within six domains (e.g., antepartum, intrapartum) were presented for consideration and comment by midwifery educators, senior midwifery students, practicing midwives, and regulators of midwifery practice. It was during this field-testing that both the type of midwifery education and the scope of midwifery practice were addressed. Of this sample, slightly more than 40 percent of education programs were direct entry, 30 percent were based on nursing first, and 20 percent integrated nursing and midwifery. The scope of practice ranged from care during pregnancy and childbirth only to care for women from adolescence to senescence, with births attended in all settings. The majority of midwifery respondents were salaried employees working primarily in institutional settings, with 75 percent providing antenatal care, 93 percent intrapartal care, and 85.5 percent caring for women during the immediate postpartum period. Only 63 percent of practicing midwives provided care for the newborn. There were some noticeable differences by regions of the world, with midwives in southern tier developing nations having a wider scope of practice than midwives in many developed countries [28].

Key Activities The steady growth and increasing influence of the ICM during the past decade give rise to the increasing need for young midwives to become active in the programs and activities of the ICM. Some of these activities are described below.

Congresses and Conferences The ICM Triennial Congresses bring together midwives from all over the world to share knowledge, ideas, and experience. The congresses have been the primary activity and financial strength of ICM since 1919, with the exception of the world war years. The series of meetings has been uninterrupted since 1954.

Since 1987, when the Safe Motherhood Initiative was launched by the World Health Organization and other global partners following the Nairobi Conference, the ICM has been an active player and leader in global efforts to promote Safe Motherhood. It has educated and supported midwives who live and work in those countries where most maternal deaths occur by organizing workshops to be held either before an ICM Congress, in the same venue, or between venues in regions where the need is greatest. Since 1987, the Pre-Congress Workshops have been a collaborative effort with WHO and with UN agencies such as UNICEF, UNAIDS, and UNFPA. In addition, mid-triennium workshops are held following the Executive Committee meetings in developing countries.

International Day of the Midwife In the mid-1990s, the ICM designated May 5 each year as the International Day of the Midwife. Efforts to gain global recognition of this day are continuing through individual member associations. The ICM Council sets the theme for activities during each triennium within the context of Safe Motherhood and the role of midwives. In 2000, a poster was created by ICM to be used for announcing the Day of the Midwife and the year's theme. Member associations are very active during this annual event and often raise funds to support attendance by midwives from developing countries at ICM conferences and congresses.

Representation As the only international midwifery organization with official recognition by the United Nations, the ICM elects member organizations to represent the ICM by attending meetings of interest to midwives at selected regional and global offices of the United Nations (New York, New Delhi) and the World Health Organization (Geneva). In addition, ICM participates in regional and global committees addressing women's health, Safe Motherhood, and workforce issues. As of 1999, the ICM is a member of the Interagency Group on Safe Motherhood and has taken on the role of co-chair since 2000.

Resources/Tools Key midwifery resources have evolved during the past 50 years, and they are still important to the work of ICM, midwives, and midwifery associations. These include the *International Definition of the Midwife*, Pre-Congress Workshops on Safe Motherhood that have resulted in the WHO Midwifery Modules [29] used

throughout the developing world, the ICM Mission Statement [19], and the *International Code of Ethics for Midwives* [24], which has been used to formulate statements of ethics in individual member associations. Other documents, such as the *ICM Vision and Global Strategy* [22], *Essential Competencies for Basic Midwifery Practice* [27], and *Guidelines for Establishing a Midwifery Educational Programme* [30], along with assorted position and policy statements, have guidelines for their use within a given member association or group.

The ICM Web site was initiated in 1996 and reconfigured in 2001. (See Appendix B at the end of this chapter.) Current ICM documents and activities can be located on the Web site, or by contacting ICM headquarters in the Netherlands.

Publications The major publication of the ICM is *International Midwifery*, published four to six times a year, which contains information on headquarters and Board of Management activities and midwifery association activities as well as individual midwife efforts to make pregnancy and birth safe throughout the world. Individual subscriptions are encouraged and can be made through the ICM Web site. ICM also publishes yearly press releases for the International Day of the Midwife, May 5, and works with the International Council of Nurses (ICN) on joint press releases.

The World Health Organization

The World Health Organization (WHO)—established under Article 57 of the Charter of the United Nations in 1948—is a prime player in the global health arena. It was in this original UN charter that the broad definition of health was codified and reiterated in the constitution of the World Health Organization: "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" [31].

The WHO works diligently to achieve its primary objective—the attainment by all people of the highest possible level of health—by acting as the directing and coordinating authority on international health work; by establishing and maintaining effective collaboration with the United Nations, specialized agencies, governmental health administrations, professional groups, and other organizations, such as NGOs; by furnishing technical assistance when requested by governments; by proposing conventions, agreements, and regulations with respect to international health matters, such as gender discrimination and human rights; by working with specialized agencies, such as the CDC, on the eradication of epidemic, endemic, and other diseases; by establishing and revising as needed the international nomenclatures of diseases, causes of death, and public health practices; and by developing, establishing, and promoting international standards with respect to food, biological, pharmaceutical, and similar products. The WHO also advocates and promotes maternal and child health and welfare, mental health, health services, health personnel preparation and deployment strategies, and conducts research in the field of health in cooperation with member states and designated centers of excellence, such as the WHO Collaborating Centers in Nursing and Midwifery.

Organization and Structure The WHO global headquarters are located in Geneva, with regional and country offices throughout the world. The six WHO regions include Africa (Brazzaville, Republic of the Congo), the Americas (Pan American Health Organization in Washington, DC), Europe (Copenhagen, Denmark), Eastern Mediterranean (Cairo, Egypt), Southeast Asia (New Delhi, India), and Western Pacific (Manila, The Philippines). Each of the WHO regional offices has a post for a nursing/midwifery advisor, although nurses without midwifery credentials often fill these posts.

The WHO consists of "member states"—generally countries with membership in the United Nations who agree to the conditions set forth in the WHO constitution, including the payment of assessed financial dues. Each member state may send up to three official delegates to the World Health Assembly (WHA), the formal policymaking body of the WHO, which meets each May in Geneva. Selected observers may also be admitted, upon approval of the Director General. Such observers may be individuals or organizational representatives from NGOs, such as ICM and ICN, and other health-related groups or alliances. The Executive Board normally meets in January and May to set the agenda for the WHA and consider other business of note that has occurred between the meetings. The WHA selects individual member states each year who then designate a person to serve on the Executive Board. The Director General of the WHO, currently Dr. Gro Harlem Bruntland from Norway, presides over meetings of the board and determines the work of the WHO Secretariat (in Geneva as well as in the regional offices), including the proposed work for each year.

WHO Programme of Work The strategic directions adopted in the *General Programme of Work 2002–2005* to focus WHO's technical work are as follows [32]:

1. Reduce excess mortality, morbidity and disability, especially in poor and marginalized populations.
2. Promote healthy lifestyles and reduce risk factors to human health that arise from environmental, economic, social and behavioral causes.
3. Develop health systems that equitably improve health outcomes, respond to people's legitimate demands, and are financially fair.
4. Frame an enabling policy, create an institutional environment for the health sector, and promote an effective health dimension to social, economic, environmental and development policy.

In order for the WHO to respond effectively to a changing international context, new ways of working have been identified and are being implemented. These include adopting a broader approach to health within the context of human development, humanitarian action, equity between men and women, and the establishment of human rights, with a particular focus on the links between health and poverty reduction. This change of approach places the WHO at the forefront in several areas: establishing wider national and international consensus on health policy, strategies, and standards through the generation and management of effective interventions from research and expertise; triggering more effective action to promote and improve health and to decrease inequities in health outcomes using carefully negotiated partnerships; and creating a responsive organizational culture [32].

Each year the WHO sets overall organization-wide priorities to shape technical advice, policy, and use of budgetary allotments. For example, the 2002–2003 organization-wide priorities include the following: (1) malaria, tuberculosis, and HIV/AIDS; (2) cancer, cardiovascular disease, and diabetes; (3) tobacco; (4) maternal health; (5) food safety; (6) mental health; (7) safe blood; (8) health systems; and (9) investing in change in WHO. The various departments within WHO Geneva are charged with carrying out the plan of work and providing needed technical expertise to governments and member states.

Role in Making Pregnancy Safer The WHO overall organization-wide priorities since 1987 have included an emphasis on maternal health, beginning with the launch of the global Safe Motherhood Initiative in Nairobi in 1987. Resources such as videos, *Why Did Mrs. X Die?* and *Opening the Gates to Life* (see Appendix B), manuals such as the *Mother-Baby Package* [33], and educational standards such as the *Midwifery Modules* [29] have all come from the technical arm of WHO, the Division of Reproductive Health. In 1998, World Health Day was dedicated to Safe Motherhood, and maternal health received global attention in a new way.

In 1999, WHO, UNFPA, UNICEF, and the World Bank issued a joint statement for reducing maternal mortality. The new emphasis in this document was acknowledgement that Safe Motherhood can be achieved by the promotion and support of basic human rights, including empowering women to make choices in their reproductive lives with the support of their families and communities, and ensuring access to quality maternal health services, with birth attended by skilled personnel with midwifery skills, along with timely access to emergency obstetric care should severe complications arise [4].

In 2000, WHO's renewed commitment to the health components of the Safe Motherhood Initiative took the form of a program entitled Making Pregnancy Safer (MPS)—a health sector strategy for reducing maternal and perinatal morbidity and mortality [34]. Specific goals include improving national capacity to reduce maternal and perinatal ill health, standard setting and the development of tools to use in the field, research and development of the best practices for reducing maternal death and disability, and monitoring and evaluating such practice for replication in areas of the world in greatest need. In addition, other divisions and clusters within and outside the WHO continue work on other aspects of the Safe Motherhood Initiative, including human rights, women's empowerment, education of young girls and women, and socioeconomic development of women.

Key messages of the MPS strategy, which mirror those of SMI-USA and the White Ribbon Alliance, include the following: (1) every pregnancy should be wanted; (2) all pregnant women and their infants should be able to access skilled care; and (3) all women should be able to reach a functioning health facility to obtain appropriate care for themselves or their newborns when complications arise [34]. The need for greater collaboration in the global effort to ensure healthy outcomes for all childbearing women and their newborns is the cur-

rent theme of WHO, ICM, FIGO, IAG, and the White Ribbon Alliance—key organizations interested in making maternal and newborn health a top priority for all governments and nations. For without healthy women, we will never have healthy children. And without healthy children, no nation will achieve its highest potential for health and development. Midwives are therefore crucial to the development of healthy nations.

Role of Midwives and Midwifery in WHO The WHO has long recognized the value of a well-trained midwife in reducing maternal death and disability [35]. The 1999 joint statement noted above more fully recognized the fact that midwifery can make a difference in promoting safe pregnancy and birth for women and newborns. Midwives have held key positions within WHO Geneva as technical experts in the Safe Motherhood programme of work, and they have worked with ICM, ICN, and FIGO on the development of training materials for midwives and physicians. An example of a productive partnership between the WHO and the ICM was the development of the WHO midwifery modules based on the outcomes of the 1990 and 1993 ICM Collaborative Pre-Congress Workshops. Midwives are vital partners in any Safe Motherhood strategy. Indeed, as Dr. Barbara Kwast, a Dutch midwife, noted in the early 1990s, midwives are the linchpin in any effort to make pregnancy safe for women and newborns [36].

World Health Assembly Resolutions on Strengthening Nursing and Midwifery Since 1948, the World Health Assembly (WHA) has adopted a series of 11 resolutions aimed at strengthening nursing and midwifery in order to achieve health for all [37]. The resolution in May 2001 expressed concern for the global shortage of nurses and midwives, and recognized the importance of "nursing services and midwifery services being the core of any health system and in national health" [38]. The resolution urged member states "to pursue health sector reform by involving nurses and midwives in the framing, planning, and implementation of health policy at all levels" [38] and was an important step in acknowledging the policy role that midwives and nurses must play in designing responsive health services and systems. Other aspects of the resolution addressed competency-based education of nurses and midwives, facilitative regulatory frameworks for nursing and midwifery practice, and the development and maintenance of healthy work environments. The WHO Web site (see appendix B) under WHA resolutions provides details of recent resolutions. This and other WHO activities recognize the valuable role that professional midwives play in any effort to improve the health of women, especially childbearing women.

The International Federation of Gynecology and Obstetrics (FIGO)

One of the health professional groups with a keen interest and expertise in women's health is the global organization of obstetricians and gynecologists (FIGO). FIGO is the only worldwide organization that groups obstetricians and gynecologists from national societies together in membership. FIGO was founded in 1954 with 42 national societies, and as of 2000, there were 102 national societies in membership representing OB/GYNs in more than 100 countries.

Mission and Governance The mission of FIGO is to promote the well-being of women and to raise the standard of practice in obstetrics and gynecology [39]. The Executive Board is composed of six officers and 24 representatives from national societies. It determines policy and is responsible for administration of the society, meeting once a year, with the officers meeting at least twice a year. The General Assembly meets every three years at the time of the triennial World Congress of Gynecology and Obstetrics to receive reports, approve financial accounts, and elect the officers and new members of the Executive Board for three-year terms.

Save the Mothers Fund Project One of the major activities related to Safe Motherhood is the organization and administration of the FIGO Save the Mothers Fund Project. Designed to reduce maternal mortality in developing countries, this project works primarily through the "twinning" of developed country OB/GYN societies with developing country societies. FIGO also awards social action grants to societies involved in the organization of national workshops related to Safe Motherhood and the reduction of maternal mortality. In 1999, FIGO joined the Safe Motherhood Interagency Group along with the ICM. Since 2000, the ICM Secretary General has sat on the board of the Save the Mothers Fund Project—two important examples of global partnerships for Safe Motherhood.

Other Activities and Resources FIGO publishes the monthly peer-reviewed *International Journal of Gynecology and Obstetrics* (*IJGO*), as well as the

FIGO Newsletter. Through the work of four committees and 21 advisory panels, FIGO extends its efforts to many aspects of obstetrics and gynecology, including oncology, STDs/AIDS, perinatal health, education, medical terminology, the pathology of the breast, and ethics. Of great interest to midwives is FIGO's *World Report on Women's Health*, published every three years to coincide with the World Congresses. This supplement to the *International Journal of Gynecology and Obstetrics* represents a comprehensive overview of issues in women's health. The FIGO Web site provides updated information on activities and resources (see Appendix B).

Safe Motherhood Interagency Group/Global Partnership for Safe Motherhood and Newborn Health

History The Safe Motherhood Interagency Group (IAG) was formed in 1987 at the launch of the Global Safe Motherhood Initiative in Nairobi, which gathered 130 participants to draw attention to maternal mortality and to mobilize action at the international and national levels. The founding members of IAG included the World Health Organization, UNICEF, UNFPA, the World Bank, the Population Council, and the International Planned Parenthood Federation. In 1999, a decision was made to add the two major health professional groups involved in Safe Motherhood—the International Confederation of Midwives (ICM) and the International Federation of Gynecology and Obstetrics (FIGO)—as well as two regional Safe Motherhood groups—the Regional Prevention of Maternal Mortality Network (Africa) and the Safe Motherhood Network of Nepal. The Secretariat for the IAG is Family Care International (FCI) in New York City.

Aims and Objectives The primary objectives of the IAG are to mobilize and inform governments and others on the continuing problem of maternal mortality and disability in many areas of the world, to offer strategic directions for intervention to promote Safe Motherhood based on expert technical advice, and to provide a variety of informational tools and resources, such as fact sheets and briefing cards, which can be used to promote Safe Motherhood throughout the world.

Summary of Activities 1987–2002 Notable among the activities during the past 15 years were regional and national workshops held between 1989 and 1994 to mobilize and inform government and non-governmental organization (NGO) leaders around the issue of maternal death and disability in areas of the world where maternal death is highest. One of the capstone events was the tenth anniversary (1997–1998) of the global Safe Motherhood Initiative (SMI), with a technical consultation held in Colombo, Sri Lanka. The focus of this meeting was to identify those interventions that had been successful in reducing maternal death and disability, to define needs and priorities including cost-effective strategies, and to determine future action needed to promote safer pregnancy and birth in the world (see Table 4-4).

These action messages have been used to focus subsequent IAG activities since 1997, beginning with an emphasis on skilled attendance at birth (1999–2002) and adding an emphasis on the prevention of unsafe abortion in 2001. The process followed for each message includes the preparation of a "review of evidence" paper, technical consultation, an international and/or regional conference for advocacy of the specific approach defined by the experts, and the completion and dissemination of a set of materials, such as a policy booklet, briefing cards, country case studies, and conference reports.

Family Care International, as the Secretariat for the IAG, serves as an information clearinghouse on Safe Motherhood, including the development of an annotated bibliography of Safe Motherhood publications, responding to individual requests for information and materials, and launching the Safe Motherhood Partners Listserv in 2000 to improve coordination and collaboration among a range of organizations who share the commitment to make pregnancy and birth safe for all women and new-

TABLE 4-4 Ten Action Messages from the Sri Lanka Meeting on Safe Motherhood Intiatives

1. Advance Safe Motherhood through human rights.
2. Empower women, ensure choices.
3. Safe Motherhood is a vital social and economic investment.
4. Delay marriage and first birth.
5. Every pregnancy faces risks.
6. Ensure skilled attendance at delivery.
7. Improve access to quality maternal health services.
8. Prevent unwanted pregnancy and address unsafe abortion.
9. Measure progress.
10. Power of partnership.

Family Care International. *The Safe Motherhood Action Agenda: Priorities for the Next Decade*, 1998.

borns. The Web site for reviewing and ordering Safe Motherhood materials at FCI is listed in Appendix B at the end of this chapter.

In 2001, a decision was made to review the objectives and structure of the Safe Motherhood IAG in order to become a more inclusive organization and to mobilize significant financial resources directed toward the improvement of the health and well-being of childbearing women and their newborns. In January 2002, an expanded partnership for Safe Motherhood and Newborn Health met in London to determine the future of global efforts to promote Safe Motherhood in the world. The draft mission statement is "to mobilize and monitor political will, global resources, and effective interventions in support of health systems and communities to improve survival and well-being of women and newborns. This mission will be achieved in the context of global efforts toward poverty reduction, equity, and human rights." The group includes all former IAG members, in addition to representatives from the U.S. Agency for International Development (USAID), Department for International Development (DFID), Save the Children, Initiative for Maternal Mortality Programme Assessment (IMMPACT), White Ribbon Alliance, UN Foundation, Asian Development Bank, Norwegian Ministry of Foreign Affairs, and the Maternal Newborn Health (MNH) project of Johns Hopkins University. The future of Safe Motherhood will be much stronger with the combination of major donors, bilateral agencies, and universities, as well as international provider groups.

American College of Nurse-Midwives

The American College of Nurse-Midwives (ACNM) has had a strong international orientation since its inception. Founders came from primarily European midwifery traditions. Early midwifery graduates often served as missionaries worldwide. A significant percentage of ACNM members have overseas work experience and foreign language ability.

Concern for international health is found in the official documents of the ACNM as well. Among its goals is "to establish the ACNM as a national and international leader in promoting optimal health care for mothers and children" [40]. The ACNM has also had a long history of active involvement in the International Confederation of Midwives, frequently providing leadership by filling the roles of Regional Representatives or Board of Management officers.

In the late 1970s Bonnie Pedersen, a visionary CNM, was concerned that midwives were not strengthening the practice of midwifery worldwide by assisting one another. In her quest to have "midwives help midwives," she sought a home for the conduct of international projects, which became the ACNM in 1981. The first funding was for the International Project for Traditional Birth Attendants (TBA) in 1982.

During the first five years, Pedersen was joined by Deborah Armbruster and Gilberte Vansintejan and their group conducted extensive needs assessments, training of TBAs, and the development of training materials in multiple languages. As funded projects expanded to include midwifery continuing education and preservice midwifery education, the name was changed to the ACNM Special Projects Section to reflect the enlarged scope of work undertaken. Much work was done to integrate family planning into the practice of West African midwives who had come from an educational tradition with no family planning.

In the early 1990s, following the conduct of two maternal mortality studies by Margaret Marshall in Ghana, the Special Projects Section began to move into an era of a number of Safe Motherhood projects. *The Life-Saving Skills Manual for Midwives* [41] was developed, piloted in Ghana, and then taught in Nigeria, Uganda, Indonesia, Vietnam, and ultimately other countries through the ACNM and other agencies. It has also been translated into multiple languages.

The 1990s also brought a number of exciting opportunities to work with sister midwifery associations working on institution strengthening and continuing education for members. Significant multiyear relationships developed with the national midwifery associations in Ghana, Uganda, and Indonesia. Through skills-building efforts, these associations are now in a position to accept multiple donor projects and to serve their own memberships in policy development, continuing education, and the creation of model service delivery projects.

In the mid-1990s, the ACNM expanded into the domestic arena with a project to address continuing education needs of ACNM members on domestic violence. As this expansion into domestic projects progressed and to better portray the work of the ACNM, the Special Projects Section changed its name in 2000 to the ACNM Division of Global Outreach. Today, the work of Global Outreach is approximately 80 percent international and 20 percent domestic, with international projects including training in Life-Saving Skills, home-based Life-Saving Skills, postpartum and post-abortion care, midwifery association development, family planning, maternal-to-child HIV transmission, family-centered maternity care, and domestic violence. In

its first 20 years of work, ACNM efforts have involved more than 30 countries, employment of approximately 20 CNMs on staff, and more than 40 CNMs working as consultants. The vision of "midwives helping midwives" has been realized [42].

Safe Motherhood Initiative–USA

In May 1996, the voting members at the ACNM annual business meeting unanimously endorsed the establishment of a Task Force on Safe Motherhood to focus on maternal death and disability in the United States. ACNM President Joyce Roberts appointed Drs. Joyce Thompson and Margaret Marshall to cochair this Task Force. The first meeting of the Task Force was in December 1996, following the charge to submit a tentative plan of action to the ACNM Board of Directors in 1997.

From this early endeavor, the Safe Motherhood Initiative–USA was born on October 25, 1997, on the tenth anniversary of the International Safe Motherhood Initiative. The founding partners included ACNM, Midwives Alliance of North America, American College of Obstetricians and Gynecologists, March of Dimes, the National Black Women's Health Project, and the National Coalition of Hispanic Health and Human Services Organization. Technical support and expertise were contributed by the Centers for Disease Control and Prevention and the Maternal-Child Health Bureau of the U.S. Department of Health and Human Services. New partners have been added since 1997, including the Asian Women's Health Network, and the American Public Health Association. The SMI–USA Web site provides updated information (see Appendix B).

Definition of Safe Motherhood The original definition of Safe Motherhood adopted within the Task Force and founding partners was as follows:

> Safe Motherhood in the USA means that no woman should die or be harmed by pregnancy or birth. Safe Motherhood begins with having it safe to be a girl and a woman in our society. Safe Motherhood–USA is founded on freedom from discrimination of any form and freedom from the exaggerated fear of childbirth. Safe Motherhood is a state of well-being in which a woman approaches childbirth with confidence in her abilities to birth and nurture her newborn. Safe Motherhood values the girl child, respects the freedom to choose when and whether to have children, and encourages active participation during health care. Safe Motherhood implies the availability, acceptability, and easy access to health care for a woman's prenatal, birth, postpartum, family planning, and gynecological needs. Safe Motherhood demands the ethical use of technology. It also requires involvement and commitment from each community and the nation to fairly allocate resources that promote the health of all women. [43]

Each of these statements in the definition of Safe Motherhood have been further defined within the SMI–USA brochure as part of the group's effort to educate the public on the nature and need for SMI activities in the United States.

Vision for Safe Motherhood in the United States The vision of SMI–USA agreed to by the founding and subsequent partners is that:

All pregnancies are intended.

All women will complete childbirth strengthened.

No woman will die or be harmed as a result of being pregnant.

The rationale for such a vision was based on the fact that every day at least one to four women die from pregnancy-related causes in the United States, with most of these deaths preventable. In addition, no improvement has been made since 1982 in the maternal mortality rate in the United States. Among the most tragic statistics is the fact that black women are four times more likely than white women to die from pregnancy-related causes (see Appendix B, CDC Web site).

Selected Priorities for SMI–USA After much discussion and deliberation among the SMI–USA partners, it was agreed that there would be three priorities to be addressed during the next few years. These include access to quality childbearing care for all women and behavioral changes among health professionals and pregnant women that result in first trimester pregnancy care in a woman-centered service that promotes self-esteem, confidence, and positive health outcomes for mothers and babies. Beginning in 1999, model programs that exemplify the Safe Motherhood Vision have been selected, publicized for replication in other communities, and held up as examples of what can be done to promote safe pregnancy and birth for women and newborns.

SMI–USA is a unique opportunity for midwifery students and new midwives to become active players in the political action needed to make all pregnancies safer in the United States.

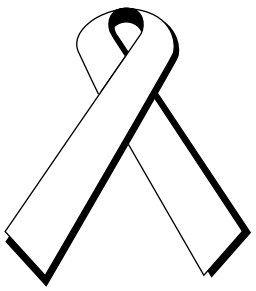

FIGURE 4-4 The white ribbon is a symbol dedicated to the memory of women who have died during pregnancy or childbirth.

Source: White Ribbon Alliance for Safe Motherhood. *Awareness, Mobilization, and Action for Safe Motherhood: A Field Guide.* Washington, DC: NGO Networks for Health, 2000.

The White Ribbon Alliance

The goal of the White Ribbon Alliance (WRA) is to raise awareness of the need to make pregnancy and childbirth safe for all women in both developed and developing countries. The WRA envisions broad-based, collaborative efforts among international non-governmental organizations (INGOs), government agencies, NGOs, and community-based organizations in developing countries to decrease maternal mortality through shared resources and experiences [44].

The organization members attempt to assist in the development of coalitions, usually called Safe Motherhood Initiatives or White Ribbon Alliances, in all countries of the world. The group encourages the largest membership possible from all sectors of society. Activities undertaken to date include provision of advice and technical assistance to groups in developing countries wishing to start their own WRA, an electronic newsletter to share experiences and lessons learned, development of a social mobilization field guide on how to start a Safe Motherhood coalition, and awarding annual prizes in conjunction with the Global Health Council, a U.S.-based NGO working on international health issues, to those groups making a substantial contribution to the health of childbearing women through their own national alliances. Members include NGOs, governments, and interested persons.

Frequently Asked Questions About International Midwifery

The following are a few of the frequently asked questions related to international midwifery and Safe Motherhood.

1. What do I need to do in order to work as a midwife in another country? Midwives desiring to practice midwifery in a country where they did not complete their basic education as a midwife need to investigate such issues as reciprocity of education, recognition of licensure or other regulatory conditions, and the ability to obtain a permit to work in that country. The U.S. system of basic or first-level midwifery education meeting criteria specified by the ACNM Division of Accreditation is very specific to midwifery practice in the United States. In most countries, basic midwifery education and/or licensure is rarely transferable to another country without some type of negotiation with the regulatory body in the new country. In some cases, presentation of evidence of graduation from an ACNM accredited nurse-midwifery or midwifery education program, successful completion of the ACC Certification Examination, and a notarized copy of one's license to practice midwifery in a given state will meet the regulatory requirements to be registered or licensed as a midwife in another country. In other cases, presentation of these documents will obviate the need to take another examination for entry into midwifery practice, though a period of observation by supervisor midwives may be required before a permit to practice is issued.

If you are thinking about practicing midwifery in another country, it is wise to learn as much as possible about the status of maternity care and women's health, the scope of midwifery practice, and any particular regulatory and reimbursement patterns under which midwives work. Beginning your exploration of almost any country is made easy through the Internet. Finding out the details about the vital health indicators (e.g., maternal and infant mortality and morbidity rates and/or ratios) can often be done through the World Health Organization or other agencies of the United Nations in addition to the U.S. Centers for Disease Control and Prevention. Several Web sites are listed at the end of this chapter (Appendix B) to facilitate this investigation of health indicators.

Discovering the details about midwives and midwifery practice in a given country is often difficult, especially in those developing countries where access to electronic media is still quite limited. The International Confederation of Midwives (ICM) is a good place to begin for contacts with individual member associations that might become your contact for a discussion of midwifery work in that country. However, not all countries of the world have midwifery associations, and there are some

midwifery associations that are not yet members of the ICM. In these cases, you might talk with individuals or agencies that work in such countries, including staff of the ACNM Division of Global Outreach, Save the Children—Saving Newborn Lives, and Family Care International.

Obtaining a global perspective on midwifery education, regulation, and practice is essential for all midwives as women throughout the world need the services provided by well-prepared midwives, and global migration of health workers is a reality. A note of caution is warranted: any new midwifery graduate often needs time to become confident with all the midwifery skills, management decisions, and adjustment to the autonomous role of the licensed midwife. It is often easier for new graduates to attain this level of confident practice in their own country before learning a new health system and pattern of midwifery practice in another country. Take time to make good decisions about your career and how to advance it to include international midwifery service.

2. What do I need before applying for international consultation positions in midwifery? International midwifery experience is often a prerequisite to becoming eligible for international consulting positions in midwifery—whether short- or long-term. In many ways, it becomes a catch-22 situation: in order to be employed in international midwifery, you have to have had international midwifery experience—and yet it is difficult to obtain international midwifery experience if you have never worked in another country. However, many midwives gain such international experience through volunteering—either with a church-related organization, the Peace Corps, emergency relief agencies, or other volunteer agencies. Sometimes the international experience required does not have to relate to midwifery; at other times international midwifery experience is vital.

Among the most important criteria for international consultation in midwifery is excellence in both practice and teaching. Be the best midwife you can be prior to thinking about sharing your experience with others. Hone your teaching skills with individuals and with groups. Remember, expertise takes time and is built upon one's ongoing midwifery experience—it does not come quickly or without effort, including learning from your mistakes. Effective consultation also requires expert communication skills, cultural sensitivity and competence, and insight into and awareness of the impact of your values and value-biases on how you view the world—especially when that world is very different from your own. We all view the world through our own "value lens"—and must understand that though there are some universal values, such as respect for human dignity, there are many values that are not shared from one culture to another, from one country to another, or from one person to another in the same country. The person with unexamined values can be a menace to others, for lack of insight into oneself often means the unconscious imposition of one's personal values on others—often inappropriately.

It is important to have a working ability in at least one language other than English. The effort involved in learning another language (or more) is an important element of becoming culturally competent. Multiple language ability is an extra bonus for those interested in international midwifery consultation. English, Spanish, and French are the major languages of the United Nations, the World Health Organization, the International Confederation of Midwives, and other international agencies. With these languages, a midwife can work successfully in almost all areas of the world. Taking time to learn the dominant language of the country where you plan to work is not only valuable for working with in-country colleagues, but also expresses your respect for their language. Consultants assigned on a short-term basis (working for a few days or weeks) often do not have the luxury of time to learn a local language, such as Chichewa, Urdu, Hindi, or Polish, and therefore need to know how to work through interpreters. Long-term consultants working for several months or years will need to learn the local language and will need to have time provided to study in the country if the language is not among those taught in colleges and universities in their home country. While working in the language of the host country is not always mandatory, having the ability to do this demonstrates exceptional commitment to the host colleagues and their culture.

The primary role of the consultant is to offer advice after learning about the country and background on issues to be addressed during the consultation, sharing experiences from other areas of the world that might be useful in the given situation, or offering suggestions as to how these experiences might be adapted to the country or situation. Above all, a consultant is a guest in the country and needs to act in a way that preserves the integrity of the host country. A large measure of humility is vital to international consultants—for a consultant must al-

ways remember that the host country needs to make the final decisions on any advice or suggestions given. This is yet another example of the midwifery model of care that empowers others to care for/decide for themselves what is best for them.

It is a good idea and often fun to spend time talking with midwives who have spent a good portion of their career as international midwifery consultants. These are very wise and worldly individuals, and they can offer insight into what works and what does not work in the international arena relative to midwifery, women's health, family planning, public health, or primary care—to name a few of the areas of consultation needed in the world. International midwifery consultants work with a variety of levels of health workers—from the revered Traditional Birth Attendant (TBA) to physicians needing midwifery skills. They may provide educational consultation at universities and colleges for preservice (basic) or postbasic (degree) midwifery education, hands-on training in Life-Saving Skills (LSS) or upgrading of general midwifery skills (on-going education). They may provide consultation to governments, Ministries of Health, and policymakers on the health needs of women and childbearing families. They may work with in-country midwives to begin and/or strengthen local midwifery associations. They may also work with regulatory agencies, such as nurses' and midwives' councils, to provide for strong self-governance and regulation of midwifery practice in the country. There is a great need for strengthening midwives and midwifery throughout the world, and ACC certified nurse-midwives and midwives have a strong educational base on which to build the needed skills to become an effective international midwifery consultant. Clinical and teaching expertise, cultural competence, known personal values, and a minimum of a second language joined together with a passionate commitment to women's health and quality midwifery care can result in an effective career as an international midwifery consultant.

3. Where can I find information on topics such as Safe Motherhood, violence against women, female genital cutting (mutilation), positive and negative traditions (practices) surrounding pregnancy and birth in a variety of cultures, and gender discrimination? As more and more midwives are guided into international midwifery—whether by faculty when they are students or through personal interests—searching for the best sources of information on selected international topics in women's health becomes very important. Every midwife should fully understand the global efforts to make childbearing safe for all women and should remember that pregnancy is a condition that was never intended to result in the death of the woman or infant. However, hundreds of thousands of women still die during childbearing, and many of their newborns also die.

As Rebecca Cook noted several years ago [2], the global tragedy of maternal death and disability is one of the most poignant reminders that women's rights are being disregarded in many areas of the world. Human rights for girls and women are another key topic of interest among midwives, as the nature of midwifery is working with women—wherever they are and in whatever condition midwives find them [28]. Violence against women, female genital cutting, the continued low status of women, and other forms of gender discrimination are all evidence of the persistent denial of the basic human rights of young girls and women throughout the world. Key sources of information on human rights and the status of women can be located in the Web sites of the World Health Organization, and UN agencies such as the United Nations Fund for Women (UNIFEM), UNICEF, and UNFPA.

Some of the most interesting topics surrounding pregnancy, birth, and the immediate postnatal periods involve cultural rituals and taboos for the woman. These range from what can be eaten or not eaten, to what the woman can see or do. Selecting an area of the world to read about, explore, and discuss with members of that society can be a mind-expanding activity for the midwifery student or new graduate. As you will discover when working in the international arena, the goal of midwifery care is to support those cultural traditions that promote the health and well-being of women or are harmless, and to work to eliminate those rituals and taboos that are harmful to women and infants. Books on these topics abound, beginning with some of the early writings of Margaret Mead and other cultural anthropologists. A literature search will result in some very interesting reading, and will help you to understand the culture of birth, including the culture in the United States, more fully.

4. What are the various educational pathways to midwifery practice throughout the world? There are a variety of educational pathways to becoming a professional midwife throughout the world in keeping with the ICM/WHO/FIGO International Definition of the Midwife. These can be captured in two main categories: (1) midwifery education built

upon or within nursing, and (2) midwifery education entered directly without a health background. In each of these two pathways, there are a variety of educational levels that are prerequisite to entering midwifery education. Within developed nations, the majority of midwifery education is built upon a minimum of a high school education, although the actual midwifery education may or may not lead to a college degree. In developing nations, midwifery education is generally built upon a minimum of a tenth grade secondary education.

It is estimated that approximately one-half of the world's professional midwives are also nurses, constituting dual professional qualification. Many nations require dual qualification in nursing and midwifery to meet the growing need for professional health workers working in community-based primary care facilities. In other areas of the world, direct-entry midwifery is encouraged to meet the demand for childbearing services of high quality. And in several nations, both types of professional midwives are prepared. Whatever the pathway to midwifery education, it is the competencies of the individual midwife that are most important.

5. How can I become active in the International Confederation of Midwives? Any individual midwife who is a member of a midwifery association that is a member of the International Confederation of Midwives (ICM) is considered an active member of the ICM. As noted earlier in this chapter, ICM depends on the volunteer efforts of midwives throughout the world to carry out its mission, vision, and global strategy. Midwifery students, new graduates, and experienced midwives are encouraged to take an active role within the ICM. This role may be working with officers of the Confederation on individual projects, such as the evolving international midwifery competencies and standards of practice, the development of the ICM Web site, or on mid-triennium conferences and Triennial Congresses held in their area of the world. Anyone interested in becoming active in the ICM should contact the Secretary General at ICM headquarters to volunteer their time and talents.

Future Trends and Challenges in International Midwifery

Historically the evolution of midwifery practice internationally has undergone a series of major changes. A profession that started out with just attending the labor and delivery and providing several days postpartum care has added on a full range of services, including antenatal care, newborn care, family planning, minor gynecological care, preconception care, care of the menopausal woman, and care of some medical conditions. These services have always been delivered in a variety of worksites—home, clinic, and hospital.

The challenges for the midwife in addressing Safe Motherhood today and in the future can be discussed in several areas: involvement in policy, clinical practice, and community-based approaches to social mobilization.

Policy

Midwifery associations in various countries have made huge gains over the past 20 years by being at the table in policy development. It will be critical that we build on the gains of midwifery pioneers and do not slide into the expectation that others will recognize our value or what we have to share. Volunteerism is difficult as we live busy lives with competing priorities. But without it, we cannot serve the compelling needs of mothers and newborns around the world.

Clinical Practice

Historically, midwifery clinical practice has always been undergoing change. As painful as it may be for those of us who are comfortable with our current scope of practice, we must remain flexible in order to embrace changing conditions and priorities. Expanded emergency skills as well as dealing with all areas of AIDS prevention and care, displaced populations, post-trauma war survivors, environmental hazards, terrorism, and war all challenge our creativity, stamina, fund-raising skills, and multiyear commitment.

Community Based Approaches to Safe Motherhood

One of the ongoing challenges for midwives dealing with Safe Motherhood is how to better address community issues. If we stay in clinical facilities, we will miss a majority of maternal complications and deaths. We must develop improved strategies for addressing delay in recognition of complications and delay in reaching the appropriate level of care. Midwives need skills in advocacy, social mobilization, participatory learning methodologies, utilization of positive deviance approaches, and other strategies. Advocacy can address policy issues. Social mobilization brings community awareness to what are the barriers to safer pregnancy

(communication, emergency transportation, emergency funds, permission to seek medical care, etc.) and development of community solutions to community problems. This local solution means that solutions are within the means of the community and therefore have potential for sustainability. Participatory learning activities (PLA) are techniques developed by agricultural workers to involve community members in examining all sides of an issue and seeing how multiple inputs can help bring a solution. The goal is to encourage various levels and groupings of stakeholders to contribute in practical ways. Positive deviance is a strategy that analyzes how positive behavior has survived in the face of cultural and family pressures. For example, if a few families in a village have resisted the pressure to have their daughters circumcised, studying how they have succeeded in a pressured environment yields helpful information in developing a strategy to eliminate female genital mutilation. Applying strategies such as PLA and positive deviance helps bring about profound changes at the community level.

As a midwife, you will have the power to make a profound impact on the survival of mothers and infants globally. Begin with the best educational preparation, maintain competence, listen to women and respond to their needs, and never become complacent about maternal mortality and morbidity. Women and families are counting on you!

CHAPTER

5

Preconception Care

By the time a woman misses her menses, has a positive home pregnancy test, and schedules a prenatal appointment, organogenesis is nearing completion. The fetal heart is formed and functioning, the spinal canal has closed, eyes are formed, limbs are moving actively, and the genitalia are recognizable. All of this has happened while morning sickness has just begun in full swing. For those with good intentions to change lifestyle issues—from smoking to using alcohol or illicit drugs—and to increase exercise or improve nutrition, it is too late to prevent fetal exposure. Any genetic risks or teratogenic effects of medication or environmental hazards have already been expressed in the fetus.

During the 1980s and 1990s, there was great emphasis on preventing poor pregnancy outcomes with quality prenatal care. To some extent, this has been helpful. Improved management of diabetes in pregnancy, preterm labor, cardiac disease and hypertensive disorders have improved both maternal and neonatal outcomes. Expanded knowledge of human inheritance has led to greater opportunities for genetic counseling, preconception identification of risk factors, and prenatal genetic diagnosis. However, as prenatal care has been critically evaluated, it has become more obvious that the time to prevent complications of pregnancy is often before a woman conceives.

In 1989, the U.S. Public Health Service Expert Panel on the Content of Prenatal Care declared that preconception care "should be standard care" [1], and among the goals outlined in the Public Health Service's 1991 publication *Healthy People 2000* was the provision of age-appropriate preconception care and counseling by a majority of primary care providers [2]. These goals are restated and strengthened in the *Healthy People 2010* guidelines [3]. Emphasis is on prevention of pregnancy in adolescent populations as well as changes in lifestyle prior to conception. Reproductive risks should be considered a part of primary care for all persons (male and female).

As part of its ongoing goals of improving maternal and child health, the Centers for Disease Control and Prevention (CDC) has formed a partnership with other organizations to safeguard the health of mothers. They have established multiple programs to reduce pregnancy complications, to conduct research, and to gather and disseminate information to improve the overall health and health care for mothers. They state, "Safe motherhood begins before conception with proper nutrition and a healthy lifestyle" [4]. Preconception care is care provided prior to pregnancy with the goal of facilitating the efforts of a woman to be healthy before she conceives. Clearly, a healthy pregnant woman has a greater probability of having a healthy baby.

As providers of primary health care for women from puberty through senescence, midwives know that every contact with a woman of childbearing age is a time for preconception care. The dedication of midwives to health promotion, education, and preventive care makes midwives ideal providers of preconception care. Midwives practice in a variety of settings that offer the opportunity—and, indeed, give the responsibility—to midwives to provide preconception care and counseling. Settings include

family planning clinics, occupational health clinics, health fairs and workplace health promotion programs, school-based clinics, homeless shelters, halfway houses, college and university health care services, substance abuse treatment centers, women's shelters, detention centers and prisons, women's health centers, and abortion clinics. Every visit—from family planning, annual Pap smears, or pregnancy tests and sexually transmitted disease screenings, to postpartum or postabortion visits—provides opportunities for counseling. The personal, individualized care that midwives provide creates the perfect environment for preconception care.

A few couples will come to the midwife seeking a preconception health assessment and anticipatory guidance. The majority, however, will present for midwifery care for many purposes, and it is left to the midwife to be proactive in providing relevant information. This chapter covers a wide range of possible topics to be considered for preconception care, more than is reasonable to discuss with every woman at every visit. Therefore, the midwife must use the opportunity for targeting teaching. For example, at an annual visit, a woman's nutritional status and exercise habits may be emphasized and recommendation made to have adequate folic acid intake daily. Another woman may be encouraged to stop smoking for general health benefits and to avoid smoking-related problems in pregnancy. A negative pregnancy test visit is an excellent time to ask if pregnancy was being attempted and to screen for HIV, rubella, or varicella. An STD (sexually transmitted disease) visit gives the opportunity to relate the dangers of STDs to the developing fetus. Individualizing the information shared with each woman will improve the likelihood of her being able to incorporate this into her daily life without taking a lot of time during the clinical visit.

In an ideal world, all pregnancies would be planned and every infant conceived in a healthy environment. But, of the 6 million pregnancies in the United States each year, the majority are unplanned. The CDC's Pregnancy Risk Assessment Monitoring System (PRAMS), states that more than half of all pregnancies are unintended [5]. The exact numbers are not known, however, in 1999, the prevalence of unintended pregnancy for women who continued their pregnancy to a live birth was 32 to 52 percent in the states sampled [5]. It has been found that of all unintended pregnancies, about half are electively terminated [5, 6]. Therefore, the overall rate of unintended pregnancy is quite high.

Many couples are unaware of the risks to which they may be exposing their unborn children. Education is the best tool available to encourage individuals to maximize their health and minimize the risk of unintended fetal exposure. It is important for midwives to be considering this risk at all health care encounters with women of childbearing age. The information must be offered without women (and their partners) specifically seeking it out, as most people do not seek information regarding pregnancy-related issues until they are already pregnant.

The benefits of preconception care are many and varied: It allows identification of medical illness; assessment of psychological, financial, and life goal readiness; and discussion of workplace and environmental hazards. In addition, a woman's or a couple's genetic makeup and habits that might negatively affect the fetus can be evaluated and possibly corrected before conception. In some women the risk can be eliminated; in others, risk can be assessed and appropriate measures can be taken to minimize its impact on the future developing fetus. On occasion, the result of preconception care may be a decision not to have children—for example, if a woman discovers she or her partner has a devastating genetic pedigree. For the majority of women and their partners, preconception care will help to identify ways to make positive changes in their lifestyle to improve their overall health as well as the potential to have a healthy baby. Preconception care provides the woman and the couple with information to make informed decisions about their childbearing.

The risk factors for potential obstetric complications are quite varied, and they are present in a large percentage of women. Figure 5-1 shows the results of a preconception survey that was performed at the time of a negative pregnancy test when women were screened for preconception risk factors. This survey demonstrates the scope of issues that may be considered at any visit with a woman of childbearing age [7]. Other research has demonstrated that when women were educated about the need for preconception alterations in their lifestyle, they were more likely to make those changes when they anticipated pregnancy [8].

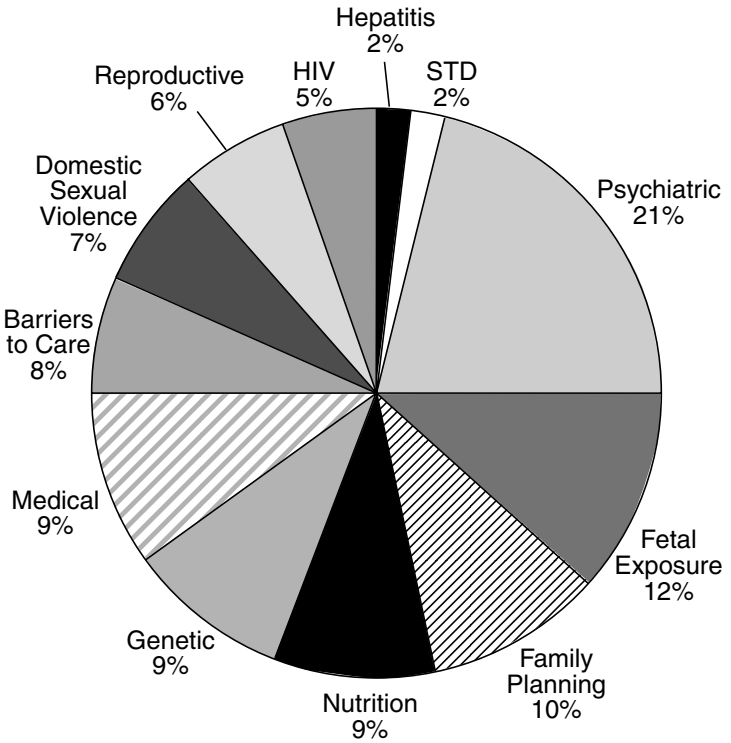

FIGURE 5-1 Preconception risk factors as a percentage of total risks at the time of a negative pregnancy test.

Source: Reprinted with permission from Jack, B. W., Culpepper, L., Babcock, J., Kogan, M. D., and Weismiller, D. Addressing preconception risks identified at the time of a negative pregnancy test: A randomized trial. *J. Fam. Pract.* 1998;47(1):33–38, Dowden Health Media.

Health and Risk Assessment

If a woman and her partner present requesting a comprehensive preconception assessment, the following database should be collected. As previously stated, for most women, the midwife will identify specific components of preconception care as a plan of management is individualized.

Baseline Data

The baseline history, physical and pelvic examination, laboratory tests, and adjunctive studies for a comprehensive health assessment were outlined in Chapter 2. One suggestion for a history form is to use a prenatal history and physical form as this covers the areas of specific importance to pregnancy. The following information pertinent to preconception care can be drawn from this database:

1. Need for treatment of any medical illness
2. Need for treatment of any mental illness
3. Need for counseling/treatment for sexually transmitted diseases
4. Need for HIV testing/counseling
5. Need for discussion of treatment programs for substance abuse:
   - **a.** tobacco
   - **b.** alcohol
   - **c.** prescription medications
   - **d.** illicit drugs
6. Need for self-evaluation of lifestyle, coping skills, and stress reduction
7. Need for psychological, social, or economic support in the presence of
   - **a.** depression or other mental health issues
   - **b.** domestic abuse
   - **c.** homelessness
   - **d.** lack of resources for basic needs

8. Need for nutritional counseling in the presence of
   a. underweight/malnutrition
   b. obesity
   c. inadequate dietary intake of any major food/nutritional source
   d. bulimia
   e. anorexia
   f. hypervitaminosis
9. Need for fitness and exercise counseling/training
10. Need for immunizations/vaccinations
11. Need for genetic screening based on race, ethnicity, or family history
12. Need for a family planning method that is in accord with the woman's or the couple's childbearing plans

Additional Data to Be Obtained

1. Need for vitamin/mineral supplements
2. History of pica
3. Need for specific genetic screening/counseling regarding the following:
   a. sickle cell anemia (African Americans, those of Mediterranean descent)
   b. Tay-Sachs disease (Ashkenazi Jews from Central or Eastern Europe)
   c. thalassemia (Greeks, Italians, Southeast Asians, Filipinos)
   d. familial patterns (fetal/neonatal loss, disease, or abnormality)
   e. hemophilia
   f. Duchenne muscular dystrophy
   g. G6PD (those of Mediterranean descent)
   h. cystic fibrosis
   i. fragile X
4. Exposure to household lead (lead poisoning)
5. Occupational and environmental hazards (teratogens)
6. Involvement of the father-to-be, other family support
7. Readiness for childbearing: psychological, financial, life goals (career, education)
8. Need for dental care
9. Need for mammography (for women over age 40 or who have a family history indicating need for early mammography)
10. Need for special preparation in the presence of specific chronic illness
11. Need for referral for further health assessment, social work assistance, mental health assessment/therapy

Counseling Specific to Preconception Care

The counseling addressed in this section is in addition to any counseling the midwife might provide during or as a result of the comprehensive health assessment. As a midwife you need to remember that you may be providing preconception counseling to single women or lesbian couples as well as to married women or heterosexual partners. Single women and lesbian couples may require further counseling specific to their unique issues (see Chapter 11).

Preconception counseling begins with discussion of the woman's or the couple's psychological readiness to bear and raise children. This discussion includes topics such as whether there is room in the relationship for children, rationale for childbearing, stability of the woman and/or the couple emotionally and financially, and expectations of the experience of childbearing and parenting. Previous assessment of existing or potential physical, sexual, or emotional abuse in the relationship should be reevaluated, as such abuse often begins or escalates with pregnancy [5, 9].

The timing of childbearing as it relates to the woman's or the couple's efforts to complete an education or begin a career, as well as the separate and combined stresses of these activities, should be explored. With adolescents, a discussion of completing high school and their plans for college or vocational training, along with provision of a reliable birth control method, may provide an alternative to early childbearing.

When to Stop Contraceptive Methods

Talk of planning a family should include a discussion of timing a pregnancy in relation to discontinuing a family planning method and how this is done, as it varies from method to method (see Chapters 16 through 20). The importance of keeping track of menstrual periods should be emphasized, as it is critical for dating a pregnancy. Encouraging a woman to keep a menstrual calendar is a good practice. Birth spacing should be discussed, and the importance of early and continuing prenatal care should be mentioned at every opportunity.

Common questions include how long it is necessary to be "off the pill" before attempting to conceive. It is generally recommended that a woman not get pregnant during the first month after stopping oral contraceptives. After she has had one

menstrual cycle, she has most likely resumed spontaneous ovulation. It is important to emphasize that this recommendation is related to optimizing dating of a pregnancy; there is not a concern about teratogenic effects of oral contraceptives.

If a woman has been using long-term hormonal methods such as injections or implants, she should be advised that it may take several months before regular ovulation occurs. She and her partner should be encouraged to prevent conception with a barrier method until she has regular menses in order to date the pregnancy accurately. Again, no harmful effects to the fetus would be anticipated if conception occurred soon after cessation of these methods.

For women who have irregular menses, predicting ovulation timing and therefore dating of a pregnancy may be difficult. For these women, basal body temperature charting or ovulation predictor kits may be useful. They may also benefit from evaluation by a fertility specialist if pregnancy does not occur within 12 months of unprotected intercourse.

Nutrition

Maintaining good nutritional status before becoming pregnant is an essential preconception care topic. Achieving ideal body weight, controlling eating disorders and pica, and developing nutritionally balanced dietary habits are all important preparation for growing a healthy baby and the prevention of low birth weight. Identification of nutritional concerns may lead to education by the midwife regarding minor dietary changes. Referral to a nutritionist may be necessary for women dealing with major nutritional deficits or obesity. For women who may be dealing with an eating disorder, psychologic evaluation is advisable, and the woman should be encouraged to delay pregnancy until she is in care and consuming a healthy diet.

Special consideration should be given to the recommendation from the Centers for Disease Control and Prevention (CDC) in 1992 that all women of childbearing age take folic acid supplements to ensure a consumption of at least 0.4 mg a day in order to reduce the risk of having a baby with spina bifida or other neural tube defects [10, 11]. Most over-the-counter multivitamins have 0.4 mg of folic acid in them, so there is no need for expensive vitamin supplements; generic preparations are sufficient. Prescriptive prenatal vitamins are usually formulated with 1.0 g of folic acid. Some women like the idea of using a prenatal supplement during the preconception period, which is well accepted. Because ingesting a consistently adequate quantity from food sources is difficult, supplementation is required. If a woman is highly motivated to consume the folic acid from more natural sources, she may be encouraged to do so. Dietary sources of folic acid are identified in Chapter 6, p. 112.

For those women who have previously had an infant with a neural tube defect, the recommended dosage of folic acid is 4.0 grams daily for at least 1 month prior to conception and through 12 weeks of pregnancy. The CDC cautions against a total folate consumption of more than 1 mg per day for women who do not have this specific increased requirement [10]. The midwife should assess any other vitamin pills or multivitamin pills the woman takes to determine folic acid content and to ascertain hypervitaminosis.

Genetic Screening

The baseline history should have revealed any specific need for genetic screening/counseling based on race, ethnicity, and family history. In all genetic counseling the key is to determine the chance that any one baby born to a particular woman and a particular man will have a genetic disease. Therefore it is essential to involve the father-to-be. If a specific risk factor is identified, or if the future parents have serious concerns, referral to a genetic counselor is recommended.

Dental Care

The woman should be advised to take care of any needed dental work that requires radiation exposure, sedation, anesthesia, or gum surgery prior to pregnancy. Research has demonstrated an increase in preterm labor and birth when women have significant periodontal disease [12]. The increased blood volume during pregnancy and resulting hyperemia in the gums will cause excessive bleeding if gum surgery is required when she is pregnant. If a woman plans to breastfeed, the elapsed time from conception to weaning will likely extend well beyond a year. Therefore, dental work other than routine preventive care is best done prior to pregnancy.

Medical Risk Factors

Medications

For women with epilepsy, chronic hypertension, psychoses, malaria, and other diseases treated with drugs that are teratogenic to the fetus, the midwife's pre-

TABLE 5-1	FDA Labeling Criteria for Drugs During Pregnancy

A Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and the possibility of fetal harm appears remote.

B Animal studies do not indicate a risk to the fetus; there are no controlled human studies, or animal studies do show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.

C Studies have shown the drug to have animal teratogenic or embryocidal effects, but no controlled studies are available in women, or no studies are available in either animals or women.

D Positive evidence of human fetal risk exists, but benefits in certain situations (e.g., life-threatening situations or serious diseases for which safer drugs cannot be used or are ineffective) may make use of the drug acceptable despite its risks.

X Studies in animals or humans have demonstrated fetal abnormalities, or evidence demonstrates fetal risk based on human experience, or both, and the risk clearly outweighs any possible benefit.

conception care should include collaboration with the physician who is treating the disease regarding the risk to the fetus and whether other nonteratogenic drugs exist for treatment [13]. In addition, the possible teratogenic effect of any medications taken during pregnancy is always a concern [14]. Both prescription and over-the-counter medications a woman may be taking should be evaluated for potential teratogenic effects, and the continuing need for the medication should be assessed. It is very important that women do not just stop taking medication because they are pregnant as this may negatively effect their medical or mental health [15]. Many medications are safe during pregnancy. For others, the risk/benefit ratio of medication use and pregnancy should be discussed prior to conception whenever possible. Therefore, a plan must be in place for use of any specific medication in the preconception period and during the early stages of organogenesis [16]. The Food and Drug Administration (FDA) has identified five labeling categories for use in pregnancy (Table 5-1) that assist in determining the risk of harm from specific medications. Table 5-2 identifies medications that are known teratogens that should be avoided during pregnancy.

Diabetes

When blood glucose levels are consistently elevated at the time of conception and early organogenesis, there is a significantly increased risk for development of major congenital anomalies. Therefore, women with Type I or Type II diabetes mellitus are prime candidates for preconception counseling [17, 18]. Their plan of care should focus on achieving and maintaining good control of their glucose levels in order to reduce the incidence of congenital malformations and low birth weight babies. If the woman is currently diet controlled or using an oral hypoglycemic agent, she should anticipate using insulin during pregnancy [18]. The woman with diabetes should have her preconception visit with a high-risk obstetrician or endocrinologist who will manage the diabetes during her pregnancy.

In addition to stabilizing blood sugar levels, the preconception period is an optimal time to have a full health assessment in order to identify any high-risk factors that may be related to diabetes. This usually includes physical assessment for diabetic retinopathy, nephropathy, coronary artery disease, and hypertension [18].

Women with a history of gestational diabetes should be informed that they are at increased risk for abnormal carbohydrate metabolism during future pregnancies. Adherence to a balanced diet and a moderate plan of exercise prior to and throughout the pregnancy may minimize the risk of gestational diabetes or at least decrease the complications [18].

Cardiac Disease

The woman with known or suspected cardiac disease should be strongly counseled to plan the timing of pregnancy with a cardiologist and obstetrician. Cardiac disease may represent a minimal risk such as with mitral valve prolapse, or may be a life-threatening risk, such as that caused by pulmonary hypertension. During the preconception period, the woman's cardiac status must be assessed and she and her family appraised of the implications that pregnancy may carry. Risk is based on three main factors: (1) the cardiac lesion, (2) the baseline functional compromise, and (3) the possibility of complications during pregnancy [19]. For a few cardiac lesions, the risk of maternal mortality is so high that termination of the pregnancy would be recommended for the mother's sake. Pulmonary hypertension, dilated cardiomyopathy, Marfan's syndrome, and any uncorrectable cardiac lesion in functional classes III or IV refractory to medical management are examples of cardiac diseases that have a serious risk of maternal mortality during pregnancy. Certainly, advance planning to avoid pregnancy would be preferable to facing the dilemma of risking both the mother's and the baby's life.

For many women with cardiac disease, the possibility of multiple office and hospital visits as well

TABLE 5-2 Medications That Have Moderate to High Teratogenicity

Drug (Class)	Generic (Trade) Names	FDA Pregnancy Category	Trimester When Most Teratogenic	Fetal/Infant Effects
Androgen	Danazol (Danocrine)	X	2nd, 3rd	Virilization of females and ambiguous genitalia
Angiotensin-converting enzyme (ACE) inhibitors	Captopril (Capoten) Enalapril (Vasotec)	C	All	Fetal hypotension syndrome, fetal kidney hypoperfusion, anuria, oligohydramnios, pulmonary hypoplasia
Angiotensin II receptor blockers	Candesartan Cilexetil (Atacand) Irbesartan (Avapro)	D	2nd, 3rd	Fetal and neonatal hypotension, skull hypoplasia, anuria, renal failure and death
Antibiotics	Aminoglycosides: Spectinomycin Gentamicin Streptomycin	D	All	8th nerve toxicity, discoloration of teeth, altered bone growth
	Tetracycline	D		Bone and teeth staining
Anticoagulants	Warfarin (Coumadin)	X	All	Hypoplastic nasal bridge (1st trimester) CNS malformations (2nd trimester) Risk of bleeding (3rd trimester)
Anticonvulsant	Carbamazepine	C	1st	Neural tube defects
	Phenytoin	D		Hydantoin syndrome
	Trimethadione	D		
	Valproic acid	D		
Anti-infective	Iodine	D	All	Congenital goiter, transient hypothyroidism
Antineoplastic	Aminopterin	X	1st	Multiple unspecified malformations and low birth weight
	Busulfan	D	1st	
	Cyclophosphamide	D	1st	
	Cytarabine	D	1st	
	Methotrexate	D	All	
	Tamoxifen	D	All	
Antituberculosis therapy	Isoniazid	C	All	Shown to have an embryocidal effect in rats and rabbits when given in pregnancy; no well-controlled studies in pregnant women
	Rifamycin	C	All	CNS abnormalities with chronic use
Antiviral (HIV)	Efavirenz (Sustiva)	C	All	Teratogenic in primate lab animals; no well-controlled human data
Benzodiazepine	Lorazepam (Ativan)	D	3rd	Neonatal dependence with chronic use
	Clonazepam (Klonopin)	C		
	Chlordiazepoxide (Librium)	D		
	Oxazepam (Serax)	D		
	Diazepam (Valium)	D		
Chelating agent	Penicillamine	D	1st	Cutis laxa, other congenital anomalies
Dermatologic preparation	Minoxidil	C	2nd, 3rd	Newborn hirsutism
Hallucinogen	Phencyclidine	X	All	Abnormal neurologic exam, including poor suck reflex and poor feeding
Hypoglycemic agents	Chlorpropamide	C	All	Prolonged neonatal hypoglycemia

TABLE 5-2 Medications That Have Moderate to High Teratogenicity (*continued*)

Drug (Class)	Generic (Trade) Names	FDA Pregnancy Category	Trimester When Most Teratogenic	Fetal/Infant Effects
Prostaglandin analog	Misoprostol (Cytotec)	X	All	Embryocidal in early pregnancy; may cause preterm labor and birth
Retinoid, systemic	Isotretinoin (Accutane)	X	All	CNS, cardioaortic, ear, and clefting defects; microtia, anotia, thymic aplasia, brachial arch and aortic arch abnormalities; certain congenital heart malformations
Retinoid, topical	Tretinoin (Retin-A)	C	All	Very unlikely to attain therapeutic topical exposure to retinoids
Sedative	Thalidomide	X	1st, 2nd	Phocomelia, limb reduction
Thyroid drugs	Propylthiouracil	D	All	Goiter
	Methimazole	D	All	Aplastic cutis

Source: Adapted from Reynolds, H. D. Preconception care: an integral part of primary care for women. *J. Nurse-Midwifery* 43(6):452.

as close medical scrutiny should be anticipated. Therefore, advance planning for workplace issues, health insurance, child care for other children as well as for medical care will help to optimize the outcome of pregnancy for both mother and infant.

Genetic issues may also come into play for women with cardiac disease as some disorders may be the result of inherited heart disease [16]. Therefore, genetic counseling may be indicated as part of the preconception assessment.

Seizure Disorder

The preconception care of a woman with a seizure disorder includes detailed history taking regarding her frequency of seizures and the medications being used. This is another area where physician consultation is required to assess the woman's risk for pregnancy complications and to evaluate medical therapy. The most commonly used medications for control of seizures are teratogenic to the fetus. If she has not had seizures in several years, there may be an opportunity to decrease the overall dose of medications, at least for the early pregnancy period. Whenever possible, the use of a single medical therapy is advocated [20]. If seizures are frequent or not well controlled, however, there should be strong emphasis on seizure control prior to pregnancy as this may worsen during gestation. This is also a diagnosis that requires detailed counseling of the parents-to-be regarding risks to mother and infant. In addition to evaluation of the seizure disorder, it is recommended that women with neurologic disorders such as epilepsy increase their dose of folic acid to 1 mg daily [11].

Hypertension

Most women with chronic hypertension can anticipate the birth of a normal, health baby. The primary goals in the preconception period are avoiding use of ACE inhibitors and angiotensin II receptor antagonists (see Table 5-2). Women should also be educated about their risk for preeclampsia and fetal growth restriction.

Thyroid disorders

Because hyperthyroidism is known to be associated with congenital malformations, adequate treatment must be undertaken prior to conception. Similarly, hypothyroidism is associated with dwarfism and other anomalies. For both hypothyroidism and hyperthyroidism, the goal is for the woman to be euthyroid prior to pregnancy. Medical consultation and follow-up is indicated in order to establish a plan for assessment of thyroid levels and potential medications during pregnancy. If a woman is taking propylthiouracil or methimazole prior to pregnancy, medication changes are recommended as both drugs are rated as Category D (see Table 5-2). For most women with thyroid disorders, midwifery care is quite appropriate with consultation.

Infectious Diseases

The preconception period is an ideal time to assess women for infectious diseases (see Chapters 8, 15

and 24). For rubella and varicella, a nonimmune lab result can easily be handled with vaccine prior to pregnancy, thereby eliminating any risk during pregnancy (and thoughout life). Toxoplasmosis and cytomegalovirus can be screened for. In this case, a positive titer, indicating previous exposure, allows for reassurance of minimal risk, and a negative titer gives the opportunity to give appropriate warnings. Hepatitis B vaccine can be offered. HIV screening and other STD testing can also be completed. If a woman becomes pregnant within 3 months following this testing, there may not be a need to repeat the STD screens at the first prenatal visit.

For women with a history of genital herpes, counseling can be done regarding the approach to this infection during pregnancy. Women at risk for tuberculosis may be screened with PPD. If they have previously had a positive PPD, or BCG vaccine, a chest x-ray can be done if indicated.

Phenylketonuria

For a woman with phenylketonuria (PKU), the best chance of protecting her child from the effects of her disease (over 90 percent of such children exhibit mental retardation and over 70 percent exhibit microcephaly) lies in going back on dietary therapy before conception and continuing on the diet throughout pregnancy [21]. Many of these women have abandoned or are not in strict compliance with their dietary plan. Nutritional assistance as well as a comprehensive medical evaluation is advisable.

Previous Obstetric Complications

A woman who has been pregnant before may have concerns about the potential for recurrence of complications associated with a previous pregnancy. The best predictor for preterm birth is a previous preterm birth. Other risk factors that may repeat in subsequent pregnancies include gestational diabetes, hypertensive disorders, placenta previa, dysfunctional labor, and low birth weight. Complications such as an incompetent cervix, large uterine fibroids, or a previous eclampsia may indicate a need to plan for appropriate intervention in another pregnancy to help ensure the best outcome.

In addition to medical/obstetric risk factors, women may have concerns from previous birth experiences regarding vaginal versus cesarean birth, use of analgesia, positions for giving birth, support of care providers, and many other issues regarding the birthing process. It is important to question the woman and help her determine if there are ways to increase her satisfaction with the birth process. Conversely, she may have had an excellent experience and want assistance in ensuring a similarly positive outcome in future pregnancies.

Advanced Maternal Age

A woman who has delayed childbearing or who is having additional children after age 35 may have age-related concerns. The preconception period is the best time to answer questions and address concerns. The issues after age 35 certainly include an increased risk of genetic disorders [22]. In addition, as women age, their risk for gestational diabetes, hypertension, and other chronic diseases increases. Therefore, genetic counseling and a comprehensive medical assessment are important.

For the woman planning her first pregnancy after the age of 35, infertility may be a greater concern. Major changes in an established lifestyle also occur for couples of advanced age, a topic that may need to be addressed by the midwife.

Environmental and Workplace Issues

Exposure to teratogens at home, in the environment, and in the workplace is a major concern. Lead poisoning from lead paint in the home should be investigated. The woman may be exposed to a myriad of chemicals, temperature extremes, heavy metals, radiation, infectious agents, and stress factors in the home or workplace that may negatively affect a developing fetus and cause congenital anomalies. Preconception care includes counseling a woman to identify such risks and ascertain their teratogenic potential prior to pregnancy.

The presence of lead in the home can be the cause of lower IQs in children. This is a preventable public health concern [23]. Table 5-3 lists screening questions to assess the risk of lead-based products in the home environment.

The workplace may be the route of exposure to harmful chemicals, irradiation, or biologic risks such as viruses [24]. These may directly effect the worker, and they can be transmitted to other members of their family. For instance, lead in the workplace may be carried on one's clothing, skin, or hair and cause lead toxicity to a sexual partner or children. Exposure to viral illnesses may result in transmission to family members. Tables 5-4 and 5-5 summarize the lists of potential workplace exposures that have been published by the CDC.

TABLE 5-3 Assessing the Risk of High-Dose Exposure to Lead

Do you—

Live in or regularly visit a house with peeling or chipping paint built before 1960?
Live in or regularly visit a house built before 1960 with recent, ongoing, or planned renovation or remodeling?
Have a child being followed or treated for lead poisoning (that is, blood lead ≥15 μg/dL)?
Have a job or hobby that involves exposure to lead?
Live near an active lead smelter, battery recycling plant, or other industry likely to release lead?

TABLE 5-4 Chemical and Physical Agents That Are Reproductive Hazards for Women in the Workplace

Agent	Observed Effects	Potentially Exposed Workers
Cancer treatment drugs (e.g., methotrexate)	Infertility, miscarriage, birth defects, low birth weight	Health care workers, pharmacists
Certain ethylene glycol ethers such as 2-ethoxyethanol (2EE) and 2-methoxyethanol (2ME)	Miscarriages	Electronic and semiconductor workers
Carbon disulfide (CS2)	Menstrual cycle changes	Vicose rayon workers
Lead	Infertility, miscarriages, low birth weight, developmental disorders	Battery makers, solderers, welders, radiator repairers, bridge painters, firing range workers, home remodelers
Ionizing radiation (e.g., x-rays and gamma rays)	Infertility, miscarriages, birth defects, low birth weight, developmental disorders, childhood cancers	Health care workers, dental personnel, atomic workers
Strenuous physical labor (e.g., prolonged standing or heavy lifting)	Late pregnancy miscarriage, premature delivery	Many types of workers

Source: From Centers for Disease Control and Prevention/National Institute for Occupational Safety and Health. *The Effects of Workplace Hazards on Female Reproductive Health*. Pub. No. 90-104. February 1999.

TABLE 5-5 Disease-Causing Agents That Are Reproductive Hazards for Women in the Workplace

Agent	Observed Effects	Potentially Exposed Workers	Preventive Measures
Cytomegalovirus (CMV)	Birth defects, low birth weight, developmental disorders	Health care workers, workers in contact with infants and children	Good hygienic practices such as hand washing
Hepatitis B virus	Low birth weight	Health care workers	Vaccination
Human immunodeficiency virus (HIV)	Low birth weight, childhood cancers	Health care workers	Practice universal precautions
Human parvovirus (B19)	Miscarriage	Health care workers, workers in contact with infants, children	Good hygienic practices such as hand washing
Rubella (German measles)	Birth defects, low birth weight	Health care workers, workers in contact with infants, children	Vaccination before pregnancy if no prior immunity
Toxoplasmosis	Miscarriage, birth defects, developmental disorders	Animal care workers, veterinarians	Good hygienic practices such as hand washing
Varicella-zoster virus (chicken pox)	Birth defects, low birth weight	Health care workers, workers in contact with infants, children	Vaccination before pregnancy if no prior immunity

Carbon disulfide				X
2,4-Dichlorophenoxy acetic acid (2,4-D)		X	X	

* Studies to date show that some men experience the health effects listed here from workplace exposures. However, these effects may not occur in every worker. The amount of time a worker is exposed, the amount of hazard to which he is exposed, and other personal factors may all determine whether an individual is affected.

† Workers were exposed to high levels as a result of a workplace accident.

Preconception Issues for Men

Data regarding male influences on the health of their infants are still limited. The most current information regards the role of genetics. For any man with a personal or family history of a genetic disorder, there may be an increased risk of transmission to a child. Genetic counseling prior to pregnancy can allow a man and his partner to be aware of the risk for him individually and the two of them as a couple to have a child with a chromosomal abnormality.

There is also information that links alcoholism and cigarette smoking of fathers with low birth weight infants [25, 26]. Older men have an increased risk of children with Down syndrome and other age-related chromosomal anomalies. Both sperm production and motility can be decreased by smoking, use of alcohol, illicit drugs, and some pharmaceuticals, thereby diminishing fertility [26].

In addition to lifestyle issues and genetic risk factors, some chronic diseases—most frequently diabetes, hypertension, and autoimmune disorders—may affect a man's fertility. Other medical factors such as previous trauma, sexually transmitted diseases, chemotherapy, or radiation therapy may also affect fertility. A thorough physical assessment is recommended for a man with any concerns. The issue of reproductive risks should be specifically raised with his primary care physician.

Workplace or environmental exposure may be of concern to some men [27]. Table 5-6 summarizes the possible risks and suggestions for dealing with them. Psychosocial issues are also important but often overlooked for men. Any history of depressive symptoms, anxiety, or other mental health issues should also be considered when planning for a family. Men often bear responsibility for financial stability in families and find this to be quite stressful when anticipating the birth of a child. An opportunity for open discussion of this and relationship changes and demands during pregnancy may reveal a need for assistance prior to conception.

For men, the preconception period is an ideal time for routine screening for HIV and other STDs as well as screening for sickle cell trait/disease or other known inheritable diseases. Identification of

medical and genetic risk factors as well as unhealthy habits are important and obvious applications of preconception care.

Other Considerations

The preconception period is also an ideal time for women/couples to consider their access to and availability of health care. This pertains to a range of issues such as selecting a health care provider—do they wish to see a midwife, general OB/GYN, family practice physician, or a maternal-fetal medicine specialist? It is a time to encourage evaluation of risk factors (or lack of), personal philosophy of birth, desire for personal involvement and decision-making as well as an understanding of the differences between potential providers [28].

The choice of birth place is important, and often not considered until pregnancy is established. However, this factor as well as the payment for the provider may be controlled by the insurance carrier. If couples investigate these options preconceptually, they may be able to make the arrangements for the birth provider and environment they need and prefer.

Recognition of the scope of practice and advantages of midwifery care is often still a well-kept secret from the public. Preconception classes can be a good opportunity to provide information to couples who seek it as well as to gain exposure as a knowledgeable health care provider. Table 5-7 outlines a class based on the Public Health Service Consensus Panel [1]. This class can be presented in a two- to three-hour format with time allowed for questions and discussion. This is an excellent opportunity to market your practice in particular and midwifery in general.

Intervention

Intervention includes providing the means to meet the needs identified during the health and risk assessment and providing counseling specific to preconception care. During the course of this assessment and counseling, the potential for education of the woman and couple is immense. Information about

TABLE 5-7 Expecting the Best: A Preconception Class

1. Assessing psychological readiness
   - a. the choice to bear children
   - b. alternatives to pregnancy
   - c. the timing of pregnancy
   - d. assessing and coping with psychosocial risks
2. Assessing physical readiness
   - a. achieving/maintaining ideal weight
   - b. initiating/continuing regular exercise
   - c. evaluation of medical problems
   - d. routine screening for all women
     - (1) hemoglobin or hematocrit
     - (2) Rh factor
     - (3) rubella titer
     - (4) urine dipstick for protein and sugar
     - (5) Pap smear
     - (6) gonococcal culture
     - (7) syphilis
     - (8) hepatitis B
     - (9) HIV (offer)
     - (10) illicit drug screen (offer)
   - e. additional screening for some women
     - (1) tuberculosis skin test
     - (2) chlamydia culture or rapid screen
     - (3) toxoplasmosis

the woman's body and how to care for it for best health and the correction of misconceptions are basic components of preconception care education. The midwife can also provide the woman or couple with recommendations for positive health behaviors and suggest lifestyle changes if indicated. The midwife needs to be knowledgeable about and have established contacts with a variety of treatment and counseling resources (primary care providers, mental health centers, genetic counseling centers, drug treatment centers, smoking cessation programs, outreach programs, support groups, fitness and exercise centers, nutritional counseling services, women's shelters, to name a few) and be ready to make the necessary referrals. The provision of preconception care is a natural bridge between the well-woman gynecologic care encompassed in the primary care of women and midwifery care during pregnancy. Information about the course of pregnancy from the preconception preparations the couple makes to birth represents the ultimate in "early childbearing education."

CHAPTER

6

Nutrition in Women's Health

JENIFER O. FAHEY, CNM, MSN, MPH

Proper nutrition is essential to human growth, development, and well-being. It is in fact impossible to separate health and nutrition. Four of the ten top leading causes of death among American women—coronary heart disease, certain types of cancer, stroke, and diabetes—have dietary factors associated with them [1]. Furthermore, the prevalence of osteoporosis and extremes in body weight continues to increase and have reached epidemic proportions. It is projected that overweight and obesity will soon replace smoking as the leading contributors to morbidity and mortality in the United States [2]. Measures to reduce this disease burden are relatively simple and well researched: maintaining a healthy weight; eating a well-balanced, nutritious diet; not smoking; and exercising regularly. However, survey data from the American Dietetic Association (ADA) reveal that while women seem to recognize the relationship between diet and health, only about one-third of them actually implement dietary strategies to reduce their risk of nutritionally related progressive chronic disease [3].

It is essential that midwives incorporate the promotion of healthy nutrition into their clinical and preventive health visits as well as their treatment plans for diseases that have dietary factors associated with them. This must be done in a clear manner that avoids conflicting messages and that provides clients with specific steps that can realistically be incorporated into their everyday lives. In order to do this, midwives must have an understanding of basic nutrition principles and of nutritional concerns specific to their client population. Midwives must then be able to translate this knowledge into effective educational messages and nutritional recommendations and interventions.

This chapter will facilitate these efforts by providing an overview of the basic principles of nutrition with an increased focus on health concerns and nutrients that are of particular relevance to women's health, including nutrition and reproductive health, nutrition and disease, overweight and obesity, and eating disorders. Also included are recommendations on nutritionally related preventive health screening and general guidelines on nutritional evaluation and nutritional counseling. This chapter does not address nutrition during pregnancy or lactation, topics to be addressed in depth in other chapters.

Principles of Nutrition

Nutrients are the chemical components of food. Humans need over 40 different nutrients for good health. These nutrients are grouped into five major classes: (1) proteins, (2) fats, (3) carbohydrates, (4) vitamins, and (5) minerals. Water is also a necessary nutrient, but it does not fit into any of the above categories. Protein, fat, carbohydrates, and water are referred to as macronutrients while vitamins and minerals are referred to as micronutrients. Protein, fat, and carbohydrates contain calories and are the energy-providing nutrients for the human body. Water, vitamins, and minerals provide no calories but are necessary, among other things, for the body to be able to utilize the energy provided by fat, carbohydrates, and protein.

Humans should obtain both macronutrients and micronutrients from a diet composed of a vari-

ety of foods rather than from nutritional supplements. This diet must be balanced in a way that prevents nutritional deficiencies and excesses. Variety is essential both to guarantee proper intake of all necessary nutrients and in order to benefit from the protective effects of certain dietary components against diseases such as cancer and heart disease, which research suggests are due to combinations of substances in foods and food groups rather than to the effect of a single substance [4]. The sections that follow review intake recommendations for major nutrients, which can be used as a guide in the planning of a balanced diet, and describe in detail the five major nutrient classes.

Recommended Nutrient Intake

The federal government has issued a series of recommendations based on research data to guide health professionals and the American public in the task of designing a diet that provides adequate and well-balanced intake of the nutrients discussed above. These guidelines include Recommended Dietary Allowances (RDAs), U.S. Recommended Daily Allowances (U.S. RDAs), Reference Daily Intakes (RDIs), Daily Reference Values (DRVs), and Daily Values (DVs). This alphabet soup of recommendations can be quite difficult for patients to decipher and translate into food choices. The midwife should, therefore, have a basic understanding of these terms in order to assist clients in determining with what frequency and in what quantities each nutrient should be consumed.

The Recommended Dietary Allowances (RDAs) are guides for estimating nutritional needs for all people of similar age and gender. They were established in the 1940s by the first Food and Nutrition Board of the National Academy of Sciences and are updated every four to five years. Less than half of the over 40 necessary nutrients have an established RDA. It should be noted that RDAs are not daily allowances. Our bodies store most nutrients for later use, and it is normal that our intake of specific nutrients will vary from meal to meal and day to day based on the foods consumed. The RDA for a specific nutrient, therefore, should be the average intake over a 3- to 7-day period. It should also be kept in mind that RDAs were designed to apply to groups (initially to American soldiers during World War II) rather than to individuals, and they are therefore meant for meal planning for healthy groups of people, such as elementary school or college students eating in a school cafeteria. The RDAs are set quite high so as to meet the needs of almost all (97 to 98 percent) of individuals in a group, and thus may be too high for individual needs.

The Food and Drug Administration (FDA) used the RDAs to create the U.S. Recommended Daily Allowances (U.S. RDAs) in 1973. Designed as nutrient standards for use on nutrition labels on foods and on vitamin and mineral supplements, calculation of the U.S. RDAs were based on the highest 1968 RDA value for each nutrient in the appropriate age and gender category. Until the National Labeling Education Act of 1990 was passed, food labeling using U.S. RDAs was voluntary. With passage of that legislation, however, the government increased regulation of food labels and also called for a reexamination of the U.S. RDAs.

Partly due to the need to eliminate the longstanding confusion created by the similarity in the two terms (RDA and U.S. RDA), and also in order to set recommended levels for nutrients not covered by the U.S. RDA, the FDA in 1993 decided both to change the name of the U.S. RDA to Reference Daily Intakes (RDIs) and to create new reference values for nutrients that did not have an RDA. Daily Reference Values (DRVs) set standard levels for sodium, carbohydrate, fat, and dietary fiber intake. Initially, the RDIs for all the nutrients except protein remained the same as the U.S. RDA, but since 1993 the values for certain nutrients have been revised and updated.

The RDIs and DRVs are currently used to calculate Daily Values (DVs). Starting in 1994, Daily Values must appear on the labels of FDA-regulated products (including vitamin and mineral supplements) and are meant to help consumers use the food label information to plan a healthy diet. Using Daily Values, they can determine what percentage of recommended nutrient intake a particular food provides (based, unless otherwise stated, on a diet of 2000 calories). For example, the DV for fat (based on a 2000-calorie diet) is 65 grams. A food item that contains 10 grams of fat, therefore, provides approximately 15 percent Daily Value for fat. DVs also help set upper or lower limits for descriptive terms such as "low fat" that are often used on food labels. It must be noted that DVs are not meant to set levels of nutrients to be consumed every day, but rather to help determine how particular foods fit in to an overall healthy diet.

The Institute of Medicine's Food and Nutrition Board developed Dietary Reference Intakes (DRIs), a new set of standards that refer collectively to three reference values developed by the Board using the latest available research knowledge on the role of

nutrients in human health: (1) the Estimated Average Requirement (EAR), (2) the Recommended Dietary Allowance (RDA), and (3) the Tolerable Upper Intake Level (UL). The EAR is the intake value that is estimated to meet the requirement defined by a specified indicator of adequacy in 50 percent of an age- and gender-specific group. At this level of intake, the remaining 50 percent of the specified group would not have its needs met. The RDA is the dietary intake level that is sufficient to meet the nutrient requirements of nearly all individuals in the group. The UL is the maximum level of daily nutrient intake that is unlikely to pose risks of adverse health effects to almost all of the individuals in the group for whom it is designed. An important characteristic of the DRIs is that they not only aim at determining minimum nutrient intake levels necessary to prevent nutritional deficiencies, but they also strive to set standards to decrease chronic diseases such as osteoporosis and cancer. (See Tables 6-1–6-3.)

The standards outlined above are used by a range of agencies and individuals for a variety of purposes—from meal planning for military forces and determining eligibility for federal programs such as food stamps and WIC, to creating food labels and educational materials on nutrition such as the food pyramid, and determining the need for fortification of food products. Midwives should understand how to appropriately use these standards in clinical practice when conducting nutritional education, evaluation, and interventions both for groups of women and for individual patients. It is of foremost importance for the midwife to remember that these standards are guidelines derived from group data and that they were not created to serve as the sole guideline in determining individual daily nutritional needs. Midwives conducting an assessment of a woman's diet must elicit information on the types of foods in her diet; on dietary patterns (which include religious, socioeconomic and cultural factors that impact food choice); on lifestyle practices such as drug and tobacco use and exercise or activity level; on anthropometric data such as weight, height, and blood pressure; and on coexisting diseases or disease risks. Using this information in conjunction with the standards outlined above and guidelines on ideal body weight (see the section on weight and body fat measurements below), the midwife will be able to assist a woman in adjusting her diet in a manner that avoids caloric and nutritional deficiencies and/or excesses and that promotes wellness and disease prevention.

TABLE 6-1 Daily Values

Daily Values (DVs) are made up of two sets of dietary guidelines:

1. **Daily Reference Values (DRVs)**—guidelines for intake of the following nutrients:
   - Fat (including saturated fat)*
     No more than 30% of total daily calories; saturated fat should comprise no more than 10% of daily calories**
   - *Cholesterol*
     No more than 300 mg per day
   - *Carbohydrates**
     60% of daily calories
   - *Protein**
     10% of daily calories (for adults and children over the age of 4)
   - *Fiber**
     11.5 g per 1000 daily calories
   - *Sodium*
     No more than 2400 mg per day
   - *Potassium*
     No more than 3500 mg per day
2. **Recommended Daily Intakes (RDIs)**—guidelines for intake of certain essential vitamins and minerals (independent of total caloric intake):
   - *Vitamin A:* 5000 International Units (IU)
   - *Vitamin C:* 60 mg
   - *Thiamin (vitamin B_1):* 1.5 mg
   - *Riboflavin (vitamin B_2):* 1.7 mg
   - *Niacin (vitamin B_3):* 20 mg
   - *Calcium:* 1000 mg (1.0 g)
   - *Iron:* 18 mg
   - *Vitamin D*
   - *Vitamin E:* 30 IU
   - *Vitamin B_6:* 2.0 mg
   - *Folic acid:* 0.4 mg (400 mcg)
   - *Vitamin B_{12}:* 6 mcg
   - *Phosphorus:* 1000 mg (1.0 g)
   - *Iodine:* 150 mcg
   - *Magnesium:* 400 mg
   - *Zinc:* 15 mg
   - *Copper:* 2 mg
   - *Biotin:* 0.3 mg (300 mcg)
   - *Pantothenic acid:* 10 mg

* These DRVs depend upon total caloric intake. Please refer to Table 6-2 on calculating DRVs based on caloric intake.

** The National Cholesterol Program of the National Institutes of Health (NIH) now considers 7% to be the cutoff for the maximum number of calories that should come from saturated fat.

Source: Institute of Medicine Food and Nutrition Board.

TABLE 6-2 Calculating Caloric-Dependent DRVs (Fat, Carbohydrates, Protein, Fiber)

To calculate DRVs based on total caloric intake, the following conversion factors are used:

- *Fat:* 9 calories per g
- *Carbohydrate:* 4 calories per g
- *Protein:* 4 calories per g

Sample calculation for carbohydrates in a 2000 calorie diet:

Recommended DRV for carbohydrates is 60% of daily caloric intake (from Table 6-1).

2000 calories × 60% = 1200 calories.

1200 calories ÷ 4 calories per g = 300 g of carbohydrates per day.

Source: Institute of Medicine Food and Nutrition Board.

TABLE 6-3 Dietary Reference Intakes

- *Estimated Average Requirement (EAR):* Intake value that is estimated to meet the requirement defined by a specified indicator of adequacy in 50% of an age- and gender-specific group.
- *Recommended Dietary Allowance (RDA):* Dietary intake level that is sufficient to meet the nutrient requirements of nearly all individuals in the group.
- *Tolerable Upper Intake Level (UL):* Maximum level of daily nutrient intake that is unlikely to pose risks of adverse health effects to almost all of the individuals in the group for whom it is designed.

Source: Institute of Medicine Food and Nutrition Board.

Protein

Protein is the basic component of cells and is needed for cellular growth, replacement, and repair. Enzymes—the substances responsible for controlling the processes that keep the human body functioning—are composed of protein. Hormones, hemoglobin, and antibodies are also composed partially or entirely of protein. Protein is in turn composed of organic compounds known as amino acids. The different arrangements of amino acids into proteins determine the particular properties of the protein.

There are approximately 20 amino acids that are necessary for human growth and metabolism. The body is able to produce the majority of these necessary amino acids. There are, however, approximately nine amino acids that must be provided by foods. These are known as the essential amino acids. Foods of animal origin such as meat, fish, eggs, and dairy products provide all of these essential amino acids and are known as complete proteins. Proteins derived from plants such as legumes, nuts, and grains are known as incomplete proteins because they lack certain essential amino acids. It is possible, however, with proper meal planning to combine different plant foods to obtain all the essential amino acids from a vegetarian diet.

Proteins cannot be stored in the body and must therefore be consumed daily in order to avoid the body breaking down nonessential tissue such as muscle to supply proteins vital for survival. While protein intake deficiencies are common in the developing world, most Americans consume quantities of protein well in excess of the RDA. The average American woman, for example, consumes approximately 70 grams of protein per day [5], which is much more than the RDA for protein for most nonpregnant, nonlactating women 25 to 51 years of age.

There are two ways to estimate desirable protein intake for healthy, nonpregnant, nonlactating adult women:

1. Approximately 10 percent of total caloric intake should be from protein (Daily Reference Value).
2. Women should consume 0.8 grams of protein per kilogram of ideal body weight (Recommended Dietary Allowance).

Table 6-4 contains a list of foods rich in complete and incomplete proteins.

Carbohydrates

Carbohydrates, which can be found in grains, vegetables, fruits, and sugars, are the major dietary source of energy. They are also necessary for the digestion of proteins and for certain brain functions. Sugars are known as the simple carbohydrates, and starches and fiber as the complex carbohydrates (including glycogen, the animal starch that serves as a storage molecule for glucose). Sugars may be single molecules (monosaccharides) such as glucose, fructose, and galactose or double molecules (disaccharides) such as sucrose, maltose, and lactose. Glucose, a monosaccharide, is the body's main energy source. These simple carbohydrates provide a readily available source of energy for the body. Starches—found in potatoes, whole-grain bread, corn, brown rice, and pasta—and fiber found in grains, vegetables, and fruits are polysaccharides composed of long straight chains or branched chains of monosaccharide units.

TABLE 6-4 Food Sources of Protein

Food	Quantity	Amount of Protein (grams)
Complete Proteins		
Lentils	1 cup (cooked)	30
Beef, chuck, roasted	3 oz	28
Pork, center loin	3 oz	27
Turkey	3 oz	27
Chicken breast	3 oz	26
Flounder	3 oz	25
Tuna, canned	3 oz	24
Beef, lean ground	3 oz	22
Scallops	3 oz	16
Cottage cheese	1/2 cup	15
Ham	3 oz	15
Eggs	2 large	12
Shrimp	3 oz	11
Yogurt	1 cup	8
Milk, any type	8 oz	8
Cheddar cheese	1 oz	7
Incomplete Proteins		
Tofu	1/2 cup	10
Green peas	1 cup	9
Peanut butter	2 tbsp	8
Egg noodles	1 cup	7
Brown rice	1 cup	5
White rice	1 cup	4
Bread, whole wheat	1 slice	3

Source: Varney, H., Kriebs, J. M., and Gegor, C. L. *Varney's Pocket Midwife*. Sudbury, MA: Jones and Bartlett Publishers, 1998.

All carbohydrates except insoluble fibers are broken down by the body into the basic sugars and absorbed in the bloodstream. Glucose, galactose, and fructose can be used immediately by the body or can be stored in the liver or muscle tissue in the form of glycogen, which is then converted to glucose whenever there is a need for reserve energy.

Dietary fibers are polysaccharides that are different from starches in that they are joined by chemical links that cannot be digested by the enzymes in the small intestine. These fibers are either soluble or insoluble fibers. Soluble fibers are digested by bacteria in the large intestine, while insoluble fibers are not. The typical American diet is characterized by being low in dietary fiber. Fiber intake among adults in the United States averages about 15 grams. That is about half the recommended amount [6]. Research has revealed that dietary fiber is associated with a decreased risk of heart disease (probably through lowering total cholesterol and LDL levels), diabetes, diverticulitis, and constipation [7, 8]. Although earlier research seemed to suggest that increased fiber intake was protective against colon cancer, more recent data, including evidence from the Nurses' Health Study, indicate that fiber intake is unrelated to colon cancer [9]. The Nurses' Health Study did, however, confirm earlier findings on the role of dietary fiber in reducing the risk of diabetes, heart disease, and diverticular diseases of the colon, thus underscoring the importance of a diet rich in fiber [10].

It is recommended that carbohydrates make up at least 55 to 60 percent of daily caloric intake. Individuals should try to maximize intake of nonstarchy, nonrefined complex carbohydrates, especially fiber, and to minimize intake of the simple sugars and certain starchy foods such as white rice and white potatoes. Simple sugar intake should be 10 to 15 percent of total caloric intake. A desirable intake of fiber is a minimum of 20 to 35 grams per day or 11.5 grams per 1000 calories.

Fats

Fats are also a source of energy and provide more calories per gram than do protein or carbohydrates. Fats are composed of fatty acids and have various roles in the human body. They are involved in the transport and digestion of the fat-soluble vitamins and are part of cell structure. Stored body fat helps in temperature regulation by serving as insulation and helps to protect vital organs by providing a cushioning effect. Excessive dietary fat intake—in particular, high intake of saturated fat—is related to increased rates of chronic disease and increased morbidity and mortality from these diseases.

There are four types of fats in food which differ from each other in the chemical structure of their fatty acids:

1. Cholesterol
2. Saturated fat
3. Monounsaturated fat
4. Polyunsaturated fat

Cholesterol, a fatlike substance, is present in all animal tissue. There are two types of cholesterol: (1) dietary cholesterol, which is found in foods of animal origin such as meat and eggs, and (2) blood cholesterol, which is a waxy, fatlike substance manufactured by the body and stored in the liver. The body uses blood cholesterol to make estrogen, progesterone, and bile. Cholesterol is also an important component of cell membranes. High levels

of cholesterol in the blood, however, promote the production of fatty plaques in arterial walls causing them to lose elasticity and narrow—a disease process known as arteriosclerosis.

Cholesterol cannot be dissolved in the blood and must therefore be carried by fatty proteins called lipoproteins. The main type of this carrier lipoprotein is known as low-density lipoprotein (LDL). An excess of circulating LDL forms fatty plaques in the arteries. Blood LDL-cholesterol level is, therefore, used as a predictor of heart attacks. The type of fats and oils that we consume is an important determinant of LDL levels. Research evidence suggests that high intake of saturated fat is associated with a rise in LDL levels and therefore in the risk for coronary heart disease and heart attacks [11, 12].

High-density lipoprotein (HDL) is another type of carrier molecule of cholesterol in the body. HDL carries excess cholesterol away from the arteries and back to the liver and is thus known as the "good" cholesterol. A high level of HDL appears to have a protective effect against coronary heart disease and heart attacks [13]. In women, unlike in men, it appears that HDL levels may be more predictive of the risk for cardiovascular disease than total cholesterol levels [14]. Exercise is strongly associated with higher levels of HDL in the body and, therefore, of lower risk of cardiovascular disease [15].

The National Institutes of Health (NIH) and the American Heart Foundation recommend that the daily dietary intake of cholesterol should be below 300 milligrams. It is also recommended that total serum cholesterol should be below 200 milligrams per deciliter of blood and that HDL level should be higher than 35 milligrams per 1000 milliliters of blood.

Another way in which fats are transported through the blood to tissues is in the form of triglycerides. The body also uses triglycerides as a means of storing fat. It is still unclear whether a high triglyceride level is an independent cause of heart disease because many individuals with high triglyceride levels also have high LDL cholesterol and low HDL cholesterol, which are known risk factors for heart disease [16]. It does appear, however, that high triglyceride levels are more predictive of cardiovascular disease risk in women than in men [15]. It is recommended that the level of triglycerides in the blood be below 200 milligrams per deciliter of blood although there are no current recommendations for routine screening of triglyceride levels.

Saturated fats come from both animal and plant sources. They are often solid at room temperature and are known to raise the amount of cholesterol in the bloodstream. In fact, research evidence indicates that serum cholesterol level is affected more by intake of dietary fat than by intake of dietary cholesterol. Saturated fats are found in meat fat, butter, whole milk products, coconut oil, palm oil, and palm kernel oil. Of the saturated fats, transfatty acids seem to have the most detrimental effect on blood cholesterol levels [17]. Transfatty acids are formed when food manufacturers partially hydrogenate (saturate) liquid oils in an effort to make the oils stay fresh longer. These acids are most commonly found in deep-fried foods, doughnuts, cookies, pies, shortening, and margarine. The American Heart Association recommends that less than 10 percent of daily caloric intake should be from saturated fats.

Polyunsaturated fats are found mainly in vegetable oils such as safflower, sunflower, corn, soybean, flaxseed, and canola oils in the form of omega-6 fatty acids. They are also the main fats found in seafood in the form of omega-3 fatty acids. Research has shown that eating polyunsaturated fats instead of saturated fats decreases the level of LDL cholesterol in the blood and is therefore protective against heart disease [11].

Monounsaturated fats are also found mainly in vegetable oils such as olive, canola, and peanut oils. Like polyunsaturated fats, research indicates that consumption of monounsaturated fats may also decrease LDL cholesterol when used in the place of saturated fats [11].

In summary, the most recent research on fat suggests that the type of fat consumed is as important if not more important than the quantity of fat intake. As was outlined above, research evidence suggests that replacing saturated and trans unsaturated fats with unhydrogenated monosaturated and polyunsaturated fats is more effective in preventing coronary heart disease than simply reducing total fat intake. It is also important to note that even though a woman's total cholesterol level may not be elevated, her lipid profile may still indicate that she is at high risk for cardiovascular disease. Women with normal or high LDL levels, low HDL levels, and high triglyceride levels seem to be particularly at risk [16].

Tables 6-5 and 6-6 contain summaries of recommended fat and cholesterol intake and recommended blood levels for cholesterol and triglycerides.

TABLE 6-5	Summary of Recommendations on Fat and Cholesterol Intake

- No more than 30% of total calories should be from fat
- 7–10% of total calories from saturated fats
- 10–15% of total calories from monounsaturated fats
- 10% of fats from polyunsaturated fats
- Less than 300 mg of cholesterol

TABLE 6-6	Recommended Blood Levels for Cholesterol and Triglycerides

- Total blood cholesterol less than 200 mg/dl
- HDL cholesterol more than 35 mg/dl
- LDL cholesterol less than 130 mg/dl
- Triglycerides less than 200 mg/dl

Vitamins and Minerals

Vitamins and minerals, which are often referred to as micronutrients, are organic substances used by the body as catalysts for intracellular metabolic reactions. The human body can synthesize some vitamins, but not in sufficient quantities. All necessary vitamins and all minerals must be supplied in essential amounts through daily dietary intake. Vitamins fall into two main categories: (1) fat-soluble and (2) water-soluble vitamins. (Table 6-7 lists each category.) As the body regulates vitamin levels, it stores excess fat-soluble vitamins in body fat and excretes water-soluble vitamins through urine. It is important to remind women that since the body accumulates fat-soluble vitamins, megadoses of these vitamins can lead to potentially dangerous or lethal toxic effects. Vitamin A, for example, is a known teratogen, so pregnant women must be careful not to exceed the recommended intake of this vitamin. Tables 6-8 and 6-9 list Recommended Dietary Intakes for selected vitamins and minerals as well as their function in the body, food sources, and potential toxic effects.

As is discussed in greater detail in the section on nutrient intake guidelines earlier in this chapter, there are recommended levels for micronutrient intake to meet the known nutritional needs of most healthy individuals. It is important to emphasize that these recommendations are calculated to be well over the requirements of most individuals and that most women in normal health can meet most of their micronutrient requirements through eating well-balanced meals without the need for supplements.

TABLE 6-7	Vitamins Categorized by Solubility

Fat-Soluble Vitamins

- Vitamin A
- Vitamin D
- Vitamin E
- Vitamin K

Water-Soluble Vitamins

- Vitamin C
- B vitamins
  - Thiamin (B_1)
  - Riboflavin (B_2)
  - Niacin (B_3)
  - Vitamin B_6
  - Pantothenic acid
  - Vitamin B_{12}
  - Biotin
  - Folic acid (folate)

Essential Minerals

- Calcium
- Chloride
- Chromium
- Copper
- Fluoride
- Iodine
- Iron
- Magnesium
- Manganese
- Molybdenum
- Phosphorus
- Potassium
- Selenium
- Sodium
- Zinc

However, calcium, iron, and folic acid merit special attention in this chapter because women often need them in quantities higher than those provided through the usual American diet. Modifications in diet or supplementation may be necessary therefore to avoid both deficiencies in these micronutrients and the concomitant adverse health effects from these deficiencies. Furthermore, as more research becomes available on the role of micronutrients in disease prevention, it is possible that the recommended levels for other nutrients may be increased to levels higher than those consumed in the average American diet and thus make supplementation of vitamins and

TABLE 6-8 Dietary Reference Intakes for Selected Vitamins for Nonpregnant, Nonlactating Women

Vitamin	Function	RDA/Adequate Intake for Women		Food Sources	Adverse Effects of Excessive Consumption	Other
A Given in retinal activity equivalents (RAEs)	Required for normal vision, gene expression, reproduction, embryonic development, and immune function	9–13 y 14–70 y >70 y	600 mcg/day 900 mcg/day 900 mcg/day	Liver, dairy products, egg yolks, fish, carrots, green leafy vegetables, pumpkins, sweet potatoes	Teratological effects and liver toxicity (from preformed vitamin A only)	Individuals with high alcohol intake are especially susceptible to adverse effects of excess.
D (calciferol) 1 mcg calciferol = 40 IU vitamin D	Maintains serum calcium and phosphorus (important for bone formation and maintenance)	9–50 y 50–70 y >70 y	5 mcg/day 10 mcg/day 15 mcg/day	Fortified dairy products and cereals, fish liver oils, egg yolks	Hypercalcemia, GI distress, anorexia, headache, nausea, vomiting, metallic taste in mouth	Patients on glucocorticoid therapy may need additional vitamin D.
E	Major function appears to be as a nonspecific chain-breaking antioxidant	9–13 y 14–70 y >70 y	11 mg/day 15 mg/day 15 mg/day	Vegetable oils, unprocessed cereal grains, nuts, fruits, vegetables, meats, wheat germ	None reported from vitamin E naturally occurring in foods but hemorrhagic toxicity possible from excess intake of vitamin E in supplements	Patients on anticoagulants need to be monitored when taking vitamin E supplements.
K	Coenzyme during the synthesis of many proteins involved in blood clotting and bone metabolism	9–13 y 14–18 y 19–70 y >70 y	60 mcg/day 75 mcg/day 90 mcg/day 90 mcg/day	Green leafy vegetables, brussels sprouts, cabbage, plant oils, margarine	None identified	Patients on anticoagulant therapy should monitor vitamin K intake.
C (ascorbic acid)	Cofactors for reactions requiring reduced copper or iron metalloenzyme and as a protective antioxidant	9–13 y 14–18 y 19–70 y >70 y	45 mg/day 65 mg/day 75 mg/day 75 mg/day	Citrus fruits, tomatoes, potatoes, broccoli, brussels sprouts, spinach	GI disturbances, kidney stones, excess iron absorption	Smokers and nonsmokers regularly exposed to smoke may require additional vitamin C.
B_6	Coenzyme in the metabolism of amino acids and glycogen	9–13 y 14–18 y 19–50 y 50–70 y >70 y	1.0 mg/day 1.2 mg/day 1.3 mg/day 1.5 mg/day 1.5 mg/day	Fortified cereals, whole grain breads, organ meats, meat, poultry, legumes	No adverse effects from vitamin B_6 in food. Sensory neuropathy has occurred from high intakes from supplement forms.	
B_{12} (cobalamin)	Coenzyme in nucleic acid metabolism; prevents megaloblastic anemia	9–13 y 14–70 y >70y	1.8 mcg/day 2.4 mcg/day 2.4 mcg/day	Fortified cereals, meat, fish, shellfish, poultry, dairy products	None identified	Patients older than 50 may need to supplement dietary sources of vitamin B_{12}.
Folate (folic acid)	Coenzyme in nucleic acid metabolism; prevents megaloblastic anemia	9–13 y 14–70 y >70 y	300 mcg/day 400 mcg/day 400 mcg/day	Enriched cereals, green leafy vegetables, enriched whole grain bread, fortified foods	Masks neurological complications in people with vitamin B_{12} deficiency.	Maternal folate intake is inversely related to the risk of neural tube defects in the fetus.

TABLE 6-9 Dietary Reference Intakes for Selected Minerals for Nonpregnant, Nonlactating Women

Mineral	Function	RDA/Adequate Intake for Women		Food Sources	Adverse Effects of Excessive Consumption	Other
Calcium	Essential role in blood clotting, muscle contraction, nerve transmission, and bone and tooth formation	9–18 y 19–50 y 50–70 y >70 y	1300 mg/day 1000 mg/day 1200 mg/day 1200 mg/day	Milk, cheese, yogurt, corn tortillas, calcium-set tofu, kale, broccoli	Kidney stones, hypercalcemia, renal insufficiency	Amenorrheic women have reduced net calcium absorption.
Iron	Used to make hemoglobin, which transports oxygen to all body tissues	9–13 y 14–18 y 19–50 y 50–70 y >70 y	5 mg/day 10 mg/day 15 mg/day 8 mg/day 8 mg/day	Fortified dairy products and cereals, fish liver oils, egg yolks	Gastrointestinal distress	Recommended intake assumes 75% of iron is from heme iron sources. Those consuming vegetarian diets may need up to twice the suggested iron intake than someone consuming a nonvegetarian diet.
Iodine	Component of thyroid hormones	9–13 y 14–70 y >70 y	120 mcg/day 150 mcg/day 150 mcg/day	Processed food, iodized salt	Elevated thyroid stimulating hormone (TSH concentration)	Individuals with autoimmune thyroid disease, previous iodine deficiency, or nodular goiter are distinctly susceptible to the adverse effects of excess iodine.
Zinc	Component of multiple enzymes and proteins; involved in the regulation of gene expression	9–13 y 14–18 y 19–70 y >70 y	8 mg/day 9 mg/day 8 mg/day 8 mg/day	Fortified cereals, red meats, certain seafood	Reduced copper status	Zinc absorption is lower for those consuming vegetarian diets than for those eating nonvegetarian diets.

Washington, DC: National Academy Press.

minerals necessary for certain women. In June of 2002, the American Medical Association released a statement saying that pending strong evidence from randomized trials, "it appears prudent for all adults to take vitamin supplements" to reduce the risk of chronic diseases. Please refer to the section on supplements later in this chapter for more information and guidelines on vitamin and mineral supplementation.

Calcium

Calcium is essential for the formation, development, and maintenance of teeth and bones. Although opinion is divided as to when peak bone mass is achieved, research indicates that the majority of adult bone mass is established by the age of 20 [18]. Maximizing peak bone mass during this time is now believed to be the most important step in the prevention of osteoporosis, a disease characterized by reduced bone mass, increased bone fragility, and subsequent increased susceptibility to fractures. Osteoporosis affects more than 30 million Americans, most of whom are women [19].

A majority of American women do not get enough calcium; furthermore, the prevalence of calcium deficiency, which can be measured indirectly through the prevalence of osteoporosis, has been increasing [20]. A major contributor to this rise in the rates of osteoporosis is inadequate calcium intake during adolescence. A recent national survey indicates that 85 percent of adolescent females do not consume the Recommended Daily Allowance for calcium [21]. This is due in part to a perception that all dairy products are high in fat and to the fact that many teens replace milk with regular or diet soda. The current recommended intake for calcium for adolescent females is 1300 milligrams per day. This reflects an adjustment made in 1997 to the RDA based on the recommendations made by the National Institutes of Health's Consensus Development Conference on Optimal Calcium Intake. It is crucial for midwives to educate all women, but in particular adolescents, on the importance of adequate calcium intake during childhood and throughout adolescence.

Appropriate calcium intake by postmenopausal women may also be important in protecting against osteoporosis. Calcium supplementation and high intake of dietary calcium among postmenopausal women have been shown in certain studies to increase bone mass density (BMD), reduce bone loss, and decrease the number of fractures [22]. More recent results from the Nurses' Health Study cast some doubt on the true effect of dietary calcium intake on the rate of bone fractures in women [23]. However, although calcium alone may not be able to treat or prevent osteoporosis, it is nonetheless an important component of overall bone health, and women do need to ensure adequate intake of calcium throughout the life cycle to help protect against osteoporosis. Adequate vitamin D is also important for bone health because it allows calcium to be absorbed from the intestine and made available in the circulation for bone formation.

Without any interventions, postmenopausal women can lose 10 to 40 percent of their bone mass between the ages of 50 and 60 [22]. Estrogen or hormone replacement therapy (ERT/HRT) has been shown to partially prevent bone loss and has been considered the most effective means to reduce rates of bone loss and fractures in postmenopausal women [20, 24]. Two recent findings should be noted, however: (1) a combination of HRT, exercise, and adequate calcium intake was shown to be more effective than HRT alone in reducing bone loss [25, 26] and (2) data released by the Women's Health Initiative on hormone replacement therapy suggest that the risks of breast cancer, heart disease, stroke, and blood clots from HRT may outweigh its long-term benefits [27]. In the next few years clinicians may significantly alter their recommendations on the use of HRT for the long-term prevention of diseases such as osteoporosis. Alternative prevention measures for osteoporosis, including the important role of regular exercise in reducing the rates of osteoporosis and osteoporosis-related fractures, should be strongly emphasized with women. Some women who are at particularly high risk for either osteoporosis or osteoporosis-related fractures may benefit from medications other than HRT to prevent and/or treat osteoporosis. Chapter 13, which discusses midlife health, includes more detailed information both on osteoporosis and on hormone replacement therapy.

Recommendations for calcium intake for females of all ages can be found in Table 6-9. The preferred source of calcium is from dietary sources, such as those listed in Table 6-10.

Dairy products are an important source of calcium and, in a typical American diet, their use may constitute the difference between getting enough calcium or not [20]. It should be kept in mind, however, that many dairy products are high in fat and can contribute to cardiovascular disease. Clinicians should thus exercise caution when recommending an increase in these foods. Nonfat and low-fat dairy products that are now readily available in most grocery stores are excellent choices that help reduce fat intake while helping to ensure adequate intake of

TABLE 6-10 Food Sources of Calcium

Food	Quantity	Amount of Calcium (mg)
Ricotta cheese	1 cup	669
Sardines	3 1/2 oz	437
Yogurt, low-fat plain	1 cup	415
Yogurt, low-fat fruit varieties	1 cup	350
Collard greens	1 cup	357
Milk, low-fat 1%	8 oz	300
Tums E-X	1 tab	300
Milk, whole	8 oz	288
Spinach, cooked	1 cup	278
Molasses, blackstrap	2 tbsp	274
Tofu, firm made with calcium sulfate	4 oz	250–265
Cheese, Swiss	1 oz	272
Cheese, provolone	1 oz	214
Cheese, cheddar	1 oz	204
Cheese, mozzarella	1 oz	185
Sesame seeds	2 tbsp	176
Ice cream, vanilla, 16% fat	1 cup	151
Salmon, canned with bones	3 oz	133
Cheese, American	1 oz	124
Tofu, regular made with calcium sulfate	4 oz	120–392
Tofu made with nijare	4 oz	80–146
Cottage cheese	4 oz	70
Hummus	1/2 cup	62
Almonds, blanched	1 oz	50
Chickpeas	1/2 cup	40
Broccoli	1/2 cup	36

calcium and vitamin D as well as other nutrients necessary for bone health. It is also possible for women to get enough calcium from non-dairy food sources and from supplements. Adequate consumption of calcium and dairy products has been shown to have benefits beyond bone health, possibly lowering the risk of high blood pressure [28] as well as colon cancer [29, 30]. While the blood pressure benefits appear fairly small, the protection against colon cancer seems somewhat larger, and most of the benefit comes from having just one glass of milk per day. Getting more than this amount, however, does not seem to further lower risk.

For individuals who do not or cannot obtain enough calcium from dairy products—for example, vegetarians or vegans or those who are lactose intolerant or who choose to avoid dairy products due to their high-fat content—calcium-fortified foods or calcium supplements may be indicated. Those individuals with lactose intolerance can obtain much of their calcium through aged hard cheeses or fermented milk products such as yogurt, which have very low or negligible amounts of lactose.

If calcium supplementation is necessary or desired, the amount of calcium from supplements should be determined based on the amount of dietary intake of calcium. In other words, the baseline amount of dietary calcium intake should be calculated and the rest of necessary calcium intake should come from supplementation. If more than 500 milligrams of supplemental calcium are necessary, the total dosage should be split into 250 to 500 milligram increments. Research suggests that the absorption of calcium from supplements is increased if the supplements, except for calcium carbonate, are taken between meals [31]. The total amount of calcium supplemented should not exceed 1000 milligrams daily because iron and zinc absorption may be inhibited. Doses of up to 2000 milligrams, however, are believed to be safe in most individuals. Excessive calcium intake is associated with kidney stones, hypercalcemia, and renal insufficiency.

It is important for midwives to assess calcium intake among their client population, particularly among their adolescent, pregnant, lactating, and postmenopausal patients. Midwives can elicit infor-

mation on daily consumption of dairy products as a quick means of determining whether calcium intake is appropriate. A more detailed diet history is warranted if dairy product consumption is low or absent, for it most likely signals insufficient calcium intake. For women whose calcium intake is inadequate and for those who are choosing to reduce their fat intake by reducing or eliminating their intake of dairy products, focused nutritional counseling should be conducted and calcium supplements may be necessary. The midwife should provide advice on the proper type and dosage of these supplements. Table 6-11 shows the amount of elemental calcium in common supplements.

Iron

Iron is a metallic element that is used by the body primarily to make hemoglobin, the component in red blood cells responsible for the transport of oxygen to all body tissues. Iron deficiency can lead to anemia—a reduction in the number of circulating red blood cells to the extent that the hemoglobin content of blood is less than that required to meet the oxygen needs of the body. (For additional discussions of anemia, see Chapters 7 and 24.) It must be noted that iron deficiency is only one cause of anemia and that treatment for anemia must be specific to its cause.

Women of reproductive age (from menarche through menopause) whether pregnant or not are at higher risk than men for iron deficiency and iron deficiency anemia. Nonpregnant women of childbearing age are at increased risk due to iron loss during menstruation, particularly if coupled with inadequate dietary intake of iron [20]. Pregnant women are also at increased risk for iron deficiency due to the increased iron requirements of pregnancy as well as to inadequate dietary intake of iron. Iron requirements in pregnancy and anemia in pregnancy are discussed in depth in Chapter 24; the section below is meant to address iron needs in nonpregnant, nonlactating women.

TABLE 6-11 Amount of Elemental Calcium in Common Supplements

Calcium carbonate	40%
Calcium citrate	24%
Calcium lactate	14%
Calcium gluconate	9%

At 40% elemental calcium, a 500-mg tablet yields 200 mg of calcium.

Research indicates that only one-fourth of all females of reproductive age meet the recommendations for dietary iron intake [20]. Due to adaptive mechanisms of the body, this deficiency may not translate into iron deficiency anemia. For example, while an estimated 15 to 20 percent of menstruating women are deficient in iron [32], research data reveal that the prevalence of iron deficiency anemia among females 12 to 49 years old is only about 4 percent [33].

In cases where either iron deficiency or iron deficiency anemia is suspected, a complete blood count (CBC) and iron indices should be ordered. The following changes are consistent with an iron deficiency anemia:

- Decreased hemoglobin
- Decreased hematocrit
- Decreased red blood cells (RBC)
- Decreased mean cell volume (MCV)
- Normal or decreased mean cell hemoglobin (MCH)
- Normal mean cell hemoglobin concentration (MCHC)
- Normal or decreased reticulocyte counts
- Decreased iron/ferritin
- Less than 15% transferrin saturation

Iron depletion, which precedes and is more common than iron deficiency anemia, may be evident in the lab results before any anemia develops.

Both iron depletion and iron deficiency anemia should be addressed through interventions aimed at correcting the deficiency and replenishing stores [33]. Iron depletion and iron deficiency anemia can both be addressed through diet and/or iron supplementation. Before initiating therapy, however, it may be necessary for the midwife to refer a client to a nutritionist for a full evaluation, including a thorough diet history and counseling or, in the case of profound anemias or anemias refractory to diet or iron supplementation, to a physician.

Because iron is best absorbed in dietary form and because iron supplements are associated with gastrointestinal distress, it is preferable if possible to address inadequate iron intake through dietary modification rather than through supplementation. Iron is present in two forms in foods: (1) heme iron and (2) nonheme iron. Heme iron is found in animal products and is absorbed by the body more efficiently than nonheme iron, which is primarily derived from plant products. Tables 6-12 and 6-13 list good dietary sources of heme and nonheme iron.

TABLE 6-12 Food Sources of Heme Iron

Food	Quantity	Amount of Iron (mg)
Clams	3 oz	24
Oysters	3 oz	11
Chicken liver, cooked	3 oz	7
Beef liver, cooked	3 oz	6
Mussels	3 oz	6
Beef, chuck, braised	3 oz	3
Beef, tenderloin, roasted	3 oz	3
Turkey, dark meat, roasted	3 oz	2
Beef, eye of round, roasted	3 oz	2
Turkey, light meat, roasted	3 oz	1
Tuna, fresh bluefin, cooked, dry heat	3 oz	1
Chicken, leg, meat only, roasted	3 oz	1
Crab, blue crab, flaked and pieces, cooked, moist heat	1 cup	1
Chicken, breast, roasted	3 oz	1
Halibut, cooked, dry heat	3 oz	0.9
Pork, loin, meat only, broiled	3 oz	0.8
Tuna, white, canned in water	3 oz	0.8

TABLE 6-13 Food Sources of Nonheme Iron

Food	Quantity	Amount of Iron (mg)
Ready-to-eat cereal, 100% fortified	3/4 cup	18.0
Ready-to-eat cereal, 50% fortified	3/4 cup	9.0
Soybeans, mature, cooked, boiled	1 cup	8
Lentils, cooked, boiled	1 cup	6
Molasses, blackstrap	2 tbsp	6
Kidney beans, cooked, boiled	1 cup	5
Pinto beans, cooked, boiled	1 cup	5
Lima beans, cooked, boiled	1 cup	4
Navy beans, cooked, boiled	1 cup	4
Black beans, cooked, boiled	1 cup	4
Oatmeal, instant, fortified	1/2 cup	4
Prunes, dried	6 oz	4
Prune juice	8 oz	3
Spinach, cooked, boiled	1/2 cup	3
Tofu, firm	1/2 cup	2
Black-eyed peas, cooked, boiled	1 cup	2
Spinach, frozen, cooked, boiled	1/2 cup	1
Whole wheat bread	1 slice	1
White bread, enriched	1 slice	1

Iron supplementation may be necessary in cases where there is a profound anemia or where adequate dietary intake is not feasible. If iron supplementation is to be undertaken, the midwife should provide proper education to ensure the maximum benefit from the supplements and to avoid or minimize side effects. Women should be reminded that iron poisoning is the most common type of poisoning among children; therefore, iron supplements must be kept out of reach of children. The amount of iron supplement necessary will depend on the severity of the anemia. Doses usually range from 30 to 120 mg of elemental iron provided in divided doses. Meat and ascorbic acid–rich (vitamin C) foods such as citrus fruits enhance the absorption of iron; coffee, tea, and milk are iron inhibitors.

Calcium and magnesium also interfere with iron absorption. Therefore, supplemental iron should preferably be taken between meals with a glass of orange juice and not at the same time that a multivitamin supplement is taken. Side effects of iron supplementation—including nausea, constipation, diarrhea, abdominal cramping, and black or tarry stools—should be discussed with women as should ways to minimize and cope with them.

Folic Acid

Folic acid, also known as folate or folacin, is a coenzyme in the metabolism of nucleic and amino acids. Research has demonstrated that inadequate folate intake is strongly linked with neural tube defects in a developing fetus. Due to the fact that formation of the neural tube occurs in the earliest stages of pregnancy, often before a woman is even aware of a pregnancy, it is recommended that all women who are of childbearing age and capable of becoming pregnant consume 400 micrograms of folic acid daily, either in the form of supplements or through folate-fortified foods in addition to their usual intake of dietary folate. If a woman is already pregnant, the RDI for folic acid is 600 micrograms. This intake should continue at least through the sixth to eighth week of pregnancy, but preferably throughout pregnancy. Women who have had a child with a neural tube defect should consume 4 mg of folic acid daily starting at least one month prior to conception and continuing through the first three months of pregnancy [34].

Since January 1998, the FDA has required U.S. food manufacturers to fortify certain food with folate in order to facilitate adequate intakes of this nutrient by women of reproductive age. The foods required to be fortified are enriched bread, rolls, and buns; all enriched flour including bromated and self-rising flours; enriched corn grits and cornmeals; enriched farina and rice; and all enriched macaroni and noodle products, including vegetable macaroni, vegetable noodle, and nonfat milk macaroni products. In addition, breakfast cereals can add folic acid up to 400 micrograms per serving. It should be kept in mind that, with the exception of women with a history of a fetus or child with a neural tube defect, total daily intake of folic acid from all sources should be below 1 milligram. Intakes above that amount may mask symptoms of pernicious anemia, a form of vitamin B_{12} deficiency that left untreated can lead to severe permanent nerve damage.

Weight and Body Fat Measurements and Overweight and Obesity

One of the most important steps a woman can take to maintain her health and prevent chronic disease is to maintain a healthy weight. Obesity has been linked with increased incidence of dyslipidemia, hypertension, Type II diabetes, coronary artery disease, stroke, gallbladder disease, gout, osteoarthritis, sleep apnea, and colon cancer [35]. Women who are obese are also at increased risk of poor pregnancy outcomes, miscarriage, polycystic ovarian syndrome, and breast and endometrial cancers [22, 36].

Recent results from the Centers for Disease Control and Prevention's National Health and Nutrition Examination Survey (NHANES III) indicate that overweight and obesity are on the rise among all age groups in the United States. The same data reveal that 35 percent of American adults of ages 20 to 74 years are overweight and that an additional 27 percent of adults are obese [37]. Women, and in particular minority women, are disproportionately affected by this epidemic and have the highest prevalence of both overweight and obesity across nearly all age groups and income levels. Data show that 33 percent of non-Hispanic whites, 52 percent of non-Hispanic blacks, and 50 percent of Hispanic women are overweight [38].

Although overweight and obesity are often used as interchangeable terms, they do in fact refer to different conditions. The National Center for Chronic Disease Prevention and Health Promotion defines overweight as an excess in body weight in relation to height. Obesity, on the other hand, is defined as an excessively high amount of body fat in relation to lean body mass. Being overweight does not always mean having an excess in body fat. Professional athletes, for example, may have little body fat but may weigh more than others of their same height due to larger muscle mass. In the general population, however, being overweight and having an excess of body fat are usually coexisting conditions.

There are several methods commonly used to determine desirable weights for individuals and to define clinical obesity. One such method, exemplified by the Metropolitan Life Insurance tables, is based on population averages. These tables provide desirable weight ranges for women and men of different height and body frame sizes. The recommended weight ranges are based on weights that have been associated with greater longevity. This

method to determine desirable weight is fraught with problems, including the fact that the data were derived from purchasers of life insurance—not from a random cross-section of the U.S. population—and include the weight of clothes and shoes. Another significant problem with this method is that it does not account for degree of body fat, which is a factor that more accurately predicts propensity for weight-related disease.

The Body Mass Index (BMI), on the other hand, is highly predictive of degree of body fat and is the federally recommended measurement to classify overweight and obesity [39]. Table 6-14 illustrates how to find a person's BMI. BMI is calculated by dividing a person's body weight in kilograms by the square of his or her height in meters (kg/m^2) or by multiplying an individual's weight in pounds by 703 and then dividing by the height in inches squared ($lbs \times 703/in^2$). Table 6-15 shows BMI calculations in pounds and inches. Although exact cutoff values to define overweight and obesity are still being debated, research has clearly demonstrated that in adults, a BMI greater than 25 to 27 is associated with increased morbidity and mortality. At a BMI of 27, for example, the risk for diabetes and hypertension is three times greater than normal and the risk for high serum cholesterol level is two times greater than normal [5]. The most recent U.S. federal guidelines define overweight as a BMI of 25 to 29.9 and obesity as a BMI of 30 and above [35]. Table 6-16 provides classifications for BMI that can be used to assist in conjunction with BMI calculation to determine whether or not an individual is at an appropriate weight for his or her height.

A drawback of the BMI measurement is that it yields no information on the distribution of fat in the body, which is also an important determinant of health risk. Upper-body obesity, in which there is an excess of abdominal fat, is associated with increased risk of heart disease, hypertension, and diabetes [35]. This type of obesity is referred to as android obesity. Because progesterone encourages fat to accumulate preferentially in the lower body, women are less likely than men to develop upper-body obesity. This does not mean, however, that women are immune to upper-body obesity. There are two ways to assess excess abdominal fat. One is to perform a measurement of waist circumference. To do this, the clinician should use a tape measure to measure the distance around the smallest area below the rib cage and above the umbilicus. For women, a waist measurement greater than 35 inches (88 centimeters) is considered a predictor of risk factors and ailments associated with obesity [35]. Waist-to-hip ratio (WHR) is another way of assessing fat distribution. It is determined by dividing waist circumference by hip circumference. Hip circumference is obtained by measuring the distance around the largest extension of the buttocks. A WHR of 1.0 or greater is considered to be associated with an increased risk of adverse health consequences [40]. It should be noted that overall obesity is more closely related to increased risk of morbidity and mortality than either increased waist circumference or increased waist-to-hip ratio. These measurements should therefore be used in conjunction with BMI to evaluate an individual's risk for overweight and obesity related diseases. Furthermore, in individuals with a BMI ≥ 35 kg/m^2, waist circumference and waist-to-hip ratio add little to no predictive power for disease risk.

The National Institutes of Health recommends a ten-step approach for primary care providers in treating overweight and obesity:

1. Measure height and weight.
2. Measure waist circumference.
3. Assess comorbidities.
4. Determine whether a patient needs treatment.
5. Assess whether a patient is ready and motivated to lose weight.
6. Determine which diet should be recommended.
7. Determine and discuss a physical activity goal.
8. Review a weekly food and activity diary.
9. Provide the patient with literature on physical activity, behavioral change, and diet modification. Provide guidelines for food and activity diary.
10. Record the goals that have been set with the patient and follow up to assess progress on a regular basis.

These steps include body weight, height, and BMI assessments as well as an assessment of risk status and of daily food intake and physical activity. Behavioral, exercise, diet, pharmacological, and surgical interventions are then outlined based on an individual's risk profile and degree of overweight and/or obesity.

Much focus has been placed in the media and among the general population on the concept of calorie counting. Calories, kcalories, or kilocalories are a measure of the energy content in foods. One kilocalorie is the heat needed to raise the temperature of one kilogram of water by one degree Celsius. In general, caloric intake should be the same as

TABLE 6-14 Body Mass Index Chart

To calculate Body Mass Index (BMI), find the appropriate height in the column labeled "Height," then move across to a given weight. The number at the top of the column is the BMI at that height and weight. Pounds have been rounded off.

caloric output. Table 6-17 contains the general guidelines for caloric intake for moderately active women. It should be kept in mind that these recommendations are based on averages and are not the best indicator of individual caloric needs. Body frame size and amount of average physical daily activity are two of the many factors that can affect caloric needs (see Table 6-18). Dietary therapy, the cornerstone of treatment of overweight and obesity, aims at a moderate reduction in caloric intake to achieve a slow, progressive, weight loss of one to two pounds per week as well as modification in the composition of the client's diet to minimize risk factors for disease. A reduction in caloric intake of 500 to 1000 calories per day from a woman's current level is usually sufficient to achieve the desired weight loss. Moderate caloric reduction is usually all that is necessary although in some cases more marked reduction may be necessary. During the period of active weight loss, it may be necessary to drop daily caloric intake to a level that is lower than what will be needed to maintain desired weight level. For women, this usually means a diet containing 1000 to 1200 kcal/day. The level of caloric intake should not be too low (less than 800 kcal/day is too low), and the overall goal should be to aim for the target caloric intake that will be required to maintain weight at a desired level. Individuals planning to start calorie-cutting diets should first consult with a dietician to assess caloric needs and to determine what level of calorie restriction is safe. Practitioners should keep in mind that women who are pregnant, lactating, or acutely ill should not be placed on diets that restrict calories.

TABLE 6-17 General Guidelines for Caloric Intake for Moderately Active Females

- 11 to 18 years of age: 2200 calories/day
- 19 to 24 years of age: 2100 calories/day
- 25 to 50 years of age: 2300 calories/day
- 51 years of age or older: 1900 calories/day
- Pregnant women (second and third trimesters): Add 300 calories/day
- Nursing mothers: Add 500 calories/day

TABLE 6-18 Factors Affecting Necessary Caloric Intake

- Body size
- Age
- Height
- Weight
- Activity level/Base Metabolic Rate (BMR)
- Pregnancy status
- Lactation status

In addition to diet therapy, a woman will need a physical activity regimen, behavioral therapy, and sometimes pharmacotherapy or surgery to achieve the necessary weight loss. The midwife who determines that a woman needs to be placed on a low calorie diet or on medications for weight loss should consult with or refer the woman to a dietician or physician. Consultation or referral is always indicated in the case of women who are extremely obese, those who need a very low calorie diet, or those who have untreated or uncontrolled comorbidities such as hypertension or diabetes.

Cardiovascular Disease

Coronary heart disease (CHD) and stroke, the two leading causes of death among American women, kill more women than all forms of cancer combined [22, 41]. Nonetheless, a U.S. Gallup poll found that only 4 percent of women perceive heart disease as a major health threat while 46 percent perceived that breast cancer posed the most significant threat to their health [42]. Midwives should educate women about the fact that coronary heart disease and stroke are important women's health issues and help their clients, particularly those at higher risk

for these diseases, learn ways to prevent these conditions from developing.

It has been demonstrated that lifestyle changes, including changes in diet, can significantly reduce the risk of developing coronary heart disease or complications from the same. Nutritional interventions, along with smoking cessation, exercise, and treatment of hypertension, hypercholesterolemia, and diabetes, form the cornerstone of CHD prevention [43]. As was detailed in earlier sections of this chapter, research data have demonstrated that upper body obesity, elevated serum triglycerides, and low levels of high-density lipoproteins (HDLs) are all strongly associated with increased risk of heart disease in women. Recent studies also suggest that the type of fat consumed may have a larger effect on risk of CHD than the amount of fat consumed. In particular, the Nurses' Health Study found that replacing saturated and transunsaturated fats with unhydrogenated monounsaturated and polyunsaturated fats is more effective in preventing CHD than reducing overall total fat intake [11]. Transfatty acids are believed to have a particularly negative impact on serum lipid profile by raising bad cholesterol and lowering the good cholesterol. Findings from the Nurses' Health Study also support earlier research evidence that a high intake of whole grains especially soluble fiber reduces blood lipids and the risk of heart disease [44]. Other nutrients that have shown some promise in reducing the risk of heart disease include vitamin E, omega-3 fatty acids found in certain fish, folate, and vitamins B_6 and B_{12} [22].

Menopause, specifically the loss of estrogen, causes negative changes in a woman's serum lipid profile (elevation in LDLs and triglycerides and lowering of HDL). These findings led many clinicians to recommend hormone replacement therapy (HRT) to women in order to prevent coronary heart disease. Results from the Women's Health Initiative (WHI) study on estrogen/progestin replacement, the largest randomized controlled study on the subject, suggests that, contrary to what was previously thought, HRT does not reduce nonfatal heart attacks or coronary heart disease–related deaths [27]. While WHI researchers did not find an increase in the number of cardiovascular-related deaths among women using HRT, there was an increase in the rates of coronary heart disease, breast cancer, stroke, and pulmonary embolism in the group receiving HRT as compared to the group receiving a placebo. HRT, therefore, is currently no longer recommended for the purpose of secondary prevention of CHD.

In summary, there are several ways in which nutrition is related to cardiovascular disease risk. Certain nutrients seem to have a direct effect on the risk of heart disease by causing alterations in lipid profiles and by serving as antisclerotic and antioxidizing agents. Proper nutrition also helps to reduce the rates of obesity and diabetes, both of which are risk factors for cardiovascular disease. In conjunction with smoking cessation and exercise, proper nutrition is a key component of cardiovascular health in both men and women.

Cancer

Cancer is the second leading cause of death among American women, with lung cancer ranking as the main cause of cancer-related mortality in women, followed by breast and colorectal cancers [1]. Smoking cessation is the single most important step to reduce lung cancer, which is therefore not considered a nutritionally related cancer. However, research has implicated diet in the etiology of both breast and colorectal cancers.

Breast Cancer

Although it has been established that a family history of breast cancer, early menarche, late menopause, and nulliparity are risk factors for the development of breast cancer, the role of nutrition in the etiology of breast cancer is not as clear. There are a series of nutritionally mediated factors that are believed to increase risk of breast cancer but for which the data are inconclusive. There has been significant controversy, for example, on whether high fat intake and breast cancer are related. The most recent studies on the subject from the Nurses' Health Study did not find a direct correlation between high fat intake or type of fat intake and breast cancer rates [45, 46]. However, among the same women, fat intake—in particular, fat from meats—was found to be strongly associated with colon cancer, suggesting that fat is indeed a carcinogen [47, 48]. It appears, however, that although there may not be a direct link between dietary fat and breast cancer, there may be an indirect effect of fat on breast cancer rates through an increase in body weight. It appears that among premenopausal women there exists an inverse relation between obesity and breast cancer, while in

postmenopausal women, higher BMI is associated with increased risk of breast cancer [49]. This is likely due to the fact that in postmenopausal women, estrogens, which are associated with development and progression of breast cancer, are synthesized from androgens in adipose tissue. In fact, when obesity and fat intake were considered together in one study, there was an association between obesity and breast cancer that was independent of fat intake [50].

While the exact relationship between dietary fat and breast cancer risk remains unclear, it has been clearly demonstrated that diets high in fruits and vegetables are protective against breast cancer. Although it is not yet possible to say with absolute certainty what specific chemicals in fruits and vegetables offer this protective effect, research evidence points to vitamins and vitamin precursors such as carotenoid [51, 52]. Fruits and vegetables also contain fiber, which is believed to offer protection against breast cancer by binding estrogen in the intestine and removing it from circulation [53]. Studies have also demonstrated that women with greater dietary intakes of vitamins A, C, and E, as well as fiber, have a reduced risk of premenopausal breast cancer [54]. It should be noted, however, that a large intake of these vitamins as supplements does not appear to protect against breast cancer in women whose requirements of these vitamins are met through an appropriate diet.

Alcohol intake is also thought to increase the risk of breast cancer. A meta-analysis of research data on the subject has revealed a 30 to 40 percent higher risk of breast cancer in women who consumed 30 grams of alcohol daily (the equivalent of 1.5 ounces of spirits, 1.5 glasses of wine, or 2 cans of beer) than in those who are nondrinkers [55].

Colorectal Cancer

As discussed in the section on carbohydrates earlier in this chapter, recent studies suggest that dietary fiber may not offer the protection against colorectal cancer once believed [9]. However, diets rich in fruits, vegetables, and fibers should nonetheless be encouraged because substances other than fiber found in these foods such as alpha and beta-carotene, terpineol, and lycopene are believed to offer protection against colorectal cancer [56]. Folate and fish oils may also be protective against colorectal cancer. Conversely, high intakes of fat and saturated fat, especially those found in meats, have been found to increase the risk of cancer of the large intestine [57, 58]. There is increasing research evidence that alcohol intake also increases the risk of colorectal cancer [59].

Reproductive Tract Cancers

There are several nutritionally related factors believed to be associated with the etiology of cervical, endometrial, and ovarian cancers. In particular, it appears that diets rich in folate, vitamin C, and carotenoids are protective against these gynecological cancers [22]. Studies also suggest that high total fat consumption, especially of animal-derived fat, increases the risk of endometrial cancer, [60] while complex carbohydrates seem to reduce the risk [61, 62]. High fat and low fiber intake also appear to increase the risk of ovarian cancer [63].

Diabetes

Every year, about twice the number of women who die from breast cancer die of complications related to diabetes mellitus. This disease, characterized by abnormal glucose metabolism, is the seventh leading cause of death in the United States [1]. The relationship between diabetes and nutrition is extensive and complex. The risk factors for Type II diabetes, which accounts for 90 to 95 percent of diagnosed cases of diabetes, include obesity, central adiposity, impaired glucose tolerance, and dyslipidemia [64]. Nutritional interventions are therefore key elements of treatment for diabetes, along with exercise and glycemic control through diet and/or medications.

Due to the advent of insulin and oral glucose-lowering medications, the extreme dietary carbohydrate restrictions that have historically characterized nutrition therapy for diabetes are no longer necessary. On the other hand, it is impossible to achieve optimal glycemic control, the main goal of therapy to minimize complications from diabetes, without dietary modifications. It can generally be said that nutritional therapy for diabetes should aim at achieving a healthy weight, controlling total energy intake, and lowering fat intake. Research has demonstrated, however, that blanket recommendations for carbohydrate and fat intake are not as effective in producing tight glycemic control as are guidelines created (preferably by a registered dietician) to meet the individual age, size, weight, physical activity level, cultural, economic, and comorbidity characteristics of each patient [65].

Nutrition, the Menstrual Cycle, and Fertility

Nutrition affects and is affected by the menstrual cycle. Studies suggest that caloric intake varies during the menstrual cycle, peaking once in the luteal phase and once in the follicular phase, and reaching a nadir during ovulation and menses [66]. Average caloric intake during the luteal phase is higher than during the follicular phase [66]. These changes are thought to coincide with cyclical fluxes in a woman's base metabolic rate (BMR).

Extremes in body weight have been shown to reduce fertility. Although threshold levels for weight or percentage body fat above or below which normal menstrual cycling is disrupted have not been clearly identified, various studies have demonstrated that marked weight loss, particularly quick weight loss, often lead to anovulation and amenorrhea. Similarly, women whose body fat percentage is low and who are at less than 80 to 87 percent of Ideal Body Weight (IBW) have been shown to become amenorrheic [67]. It is believed that this dysfunction is related to disruption of normal hypothalamic function, which leads to abnormal secretion of gonadotropin-releasing hormone (GnRH). Obesity (defined as a BMI of 27 or greater) has also been associated with anovulation [68]. This effect is most likely if weight gain occurs quickly. Once more, it is believed that changes in a woman's hormone milieu triggered by obesity, including an increase in androgen levels, lead to hypothalamic dysfunction.

Adolescence

Adolescence (defined here as ages 11 to 21) is a time of such significant increase in the need for energy and nutrients that nutrition issues of adolescence merits its own section in this chapter and the special attention of midwives who care for these young women. Adolescence marks the life-cycle period of highest total nutritional needs and a period of physical growth second only to that which occurs during the first year of life. During the adolescent years, individuals gain 50 percent of their adult body weight and up to 40 percent of their adult skeletal mass [69]. Inadequate nutrition during this time can therefore have long-term consequences by compromising peak bone mass, stunting growth, and delaying sexual maturation. Furthermore, adolescence is a time of increased concern over weight gain and appearance, especially among teenage girls. Independent eating habits develop during this stage as teens spend more time (including more mealtimes) outside the home. During this stage, peers often have a greater influence on eating behavior than do parents. These factors all place teens at a higher risk for developing unhealthy eating habits, including eating disorders.

One issue of particular concern among this population is inadequate intake of minerals and vitamins. National surveys reveal that American adolescent girls consume inadequate amounts of iron, calcium, magnesium, phosphorous, and zinc. These surveys also demonstrated intakes of vitamin A, vitamin E, vitamin B_6, and folate below recommended dietary allowances [21]. The importance of adequate calcium intake during adolescence is addressed earlier in the chapter as is iron deficiency and iron deficiency anemia. In addition to inadequate vitamin and mineral intake, adolescent diets in the United States are also characterized by high total fat consumption, high intake of saturated fats, sodium, cholesterol, and refined sugars and by low intake of fiber, fruits, and vegetables. Of particular significance is the fact that many teenage girls stop drinking milk at the very time that their need for calcium is at its peak [70].

Health professionals should include a nutritional assessment in the care plan of their adolescent patients. This assessment should include body height and weight measurements to determine if a teenager is either suffering from, or is at risk for, either low weight or overweight. Adolescents below the third percentile for height and either below 5 percent or above 85 percent of their normal BMI need further evaluation. The health of skin, nails, hair, and teeth should be assessed—discoloration or brittleness of these body tissues often signal nutritional deficiencies and/or eating disorders. Adolescent females should be screened every five to ten years for iron deficiency anemia, and teenage girls at high risk for anemia (for example, pregnant or substance-abusing teens or those living in a situation of neglect or abuse) should receive yearly screening. The midwife can play a key role in educating teens (and their parents when applicable) about normal growth and about growth measurements and preparing teens for the changes in physical appearance that are

normal and expected during adolescence. The midwife can also provide reassurance to the adolescent client of the normalcy of fat accumulation during adolescence, particularly in the thighs, hips, and buttocks [69].

Healthy eating behaviors should be discussed and encouraged with particular attention to meeting the increased energy and nutrient requirements of adolescence. Teenage girls need to be reminded of the increased need for calcium and iron, and examples of dietary sources of these nutrients should be provided. The importance of physical activity should be reinforced and the harmful effects of tobacco, alcohol, and other substance abuse reviewed. Adolescent females, particularly those who are sexually active, need to be told of the need for adequate folic acid intake to protect against birth defects in the event of pregnancy. The midwife should continuously evaluate teenagers in their care for the signs of unhealthy eating habits and for the signs and symptoms of eating disorders, keeping in mind that the most common ages for onset of eating disorders are 13 to 14 and 17 to 18 years [71]. Pregnancy also puts adolescents at increased nutritional risk, and it is crucial that midwives caring for pregnant adolescents conduct a thorough nutritional evaluation of all pregnant adolescents and/or refer them for a nutrition consult with a registered dietician.

In summary, the midwife who cares for adolescents must conduct an ongoing evaluation of these young women's nutritional status and provide guidance that facilitates the adoption of healthy eating behaviors. The midwife must stress that habits developed during the teenage years are likely to affect lifelong eating practices, and that several nutritionally related disease processes such as obesity, osteoporosis, and arteriosclerosis can start during adolescence. The midwife must then provide teenagers with concrete and realistic examples of how to improve their diets. However, because it is often hard for them to think beyond the here and now, it is especially important when working to change adolescent eating habits to highlight the immediate benefits of a nutritious diet, such as increased ease in maintaining a healthy weight and the healthier appearance of skin, hair, and teeth. Finally, the midwife must make adequate referrals for evaluation by a physician of adolescents suffering from nutritional disorders, including obesity, eating disorders, and profound nutritional deficiencies such as iron deficiency anemia.

Nutrition During Menopause and Beyond

Changes in nutritional needs are among the many changes that accompany aging. Energy requirements decrease with advancing age while, paradoxically, macronutrient needs stay the same or increase. The decrease in energy requirements seen with advancing age is believed to be due mostly to a reduction in the amount of metabolically active tissue in the body, a reduction in general physical activity, and altered hormone production [72].

While prospective studies show that many women experience an increase in weight and in abdominal and total fat as they age, these changes are often wrongly attributed to menopause [73]. Among perimenopausal women, age, genetics, and physical activity appear to be the largest determinants of the total amount of body fat. There is evidence, however, that the estrogen deficiency that accompanies menopause may contribute to redistribution of fat to the abdominal area, a factor that increases the risk for heart disease, diabetes, and hypertension [74, 75]. A diet low in fat and regular participation in physical activity can slow this process.

As was discussed earlier in this chapter, there is a marked decline in bone density and a concomitant vulnerability to osteoporosis among women following menopause. Osteoporosis is defined as a bone mineral density (BMD) value that is more than 2.5 standard deviations below that of an average young adult [76]. While the most important step in preventing osteoporosis is to maximize peak bone mass during adolescence and early adulthood, there is general consensus that adequate calcium intake, especially when coupled with adequate intake of vitamin D and weight-bearing exercise during the postmenopausal years, can help to maintain bone density. Experts recommend 1500 mg of calcium per day for postmenopausal women who are not taking estrogen and 1000 mg per day for those who are. Dietary sources of calcium are preferred, but calcium supplementation is also effective.

In the 1990s, phytoestrogens—plant compounds similar in chemical structure to estrogen—received much attention in the media due to studies that seemed to suggest that these substances could relieve menopausal symptoms and possibly help prevent breast cancer, osteoporosis, and cardiovascular disease in postmenopausal women and could therefore be used as an alternative to hormone replacement therapy (HRT). More recent research, however, challenges many of these earlier findings

and suggests caution when recommending phytoestrogen-rich foods to women at risk for breast cancer [77, 78]. While some research seemed to suggest that isoflavonoids—phytoestrogens found in soy-based foods—were related to reduced breast cancer risk [79], further research seems to suggest that this protective effective may be due to other nutrients, such as fiber, found in the phytoestrogen-rich foods under investigation [80, 81]. Moreover, it has been demonstrated that the phytoestrogens found in soy can cause breast cell hyperplasia and may increase the risk for breast cancer in women at high risk for developing estrogen-sensitive cancers [82]. Until clearer information is available, concentrated phytoestrogens, such as those found in supplements, should be avoided by women with breast cancer, women at high risk for developing breast cancer, and women taking tamoxifen [83]. Furthermore, while a diet that includes a variety of phytoestrogen-rich foods such as legumes, vegetables, and grains should be encouraged, concentrated phytoestrogen supplements are not currently a medically recommended alternative to hormone replacement therapy.

Midwives caring for menopausal and postmenopausal women should include a nutritional assessment as part of their well-woman visits. Special attention must be paid to determining whether there is adequate intake of necessary nutrients and to screen for signs and symptoms of nutrient deficiency—especially of calcium, iron, zinc, and vitamins D, B_6, B_{12}, E, and C. It is important to counsel women on the fact that they cannot rely on supplements to adequately meet their nutrient needs. Midwives must keep in mind other factors, such as illness, social isolation, or medication regimes that may interfere with adequate nutrition among individuals in this population. After assessing the client's nutritional needs, the midwife can then help design a varied diet for these women that avoids foods with "empty" calories—i.e., foods that are calorie rich but nutrient poor. Women with certain nutritionally related medical problems that are more common with increasing age—for example, hypertension, hypercholesterolemia, Type II diabetes, and kidney failure—may benefit from a nutritional consult with a registered dietician. Elderly women—particularly those who are mostly homebound, living alone, or socially isolated—may also need a social work referral so that they can learn about and enroll in special nutrition programs such as home-delivered or congregate meal plans targeted at this population.

Eating Disorders

Eating disorders are complex, nutritionally related psychiatric conditions that disproportionately affect women. Approximately 90 to 95 percent of cases of eating disorders occur among adolescent girls and young adult females [84]. While anorexia nervosa and bulimia nervosa are commonly described as discrete entities, in actuality there is extensive overlap between these conditions. Research suggests, for example, that up to 50 percent of women with a diagnosis of anorexia nervosa will eventually develop bulimic symptoms [5]. The latest edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) recognizes this overlap and categorizes anorexia nervosa and bulimia nervosa (and more recently, binge eating) as subtypes of a larger entity of disordered eating [85]. The term "nervosa" serves to differentiate these disorders from anorexia and bulimia of nonpsychiatric origin.

The DSM-IV also provides diagnostic criteria for both anorexia nervosa and bulimia nervosa that are outlined in Tables 6-19 and 6-20. These clearly delineated diagnostic criteria belie the complex eti-

TABLE 6-19 DSM-IV Criteria for the Diagnosis of Anorexia Nervosa

- Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected body weight gain during period of growth, leading to body weight less than 85% of that expected).
- Intense fear of gaining weight or becoming fat, even though underweight.
- Disturbances in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- In postmenarcheal females, amenorrhea (the absence of at least three consecutive menstrual cycles).

Specific Type

- *Restricting type:* During the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting; misuse of laxatives, diuretics, enemas).
- *Binge eating/purging type:* During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting; misuse of laxatives, diuretics, enemas).

TABLE 6-20 DSM-IV Criteria for the Diagnosis of Bulimia Nervosa

- Recurrent episodes of binge eating. An episode of binge eating is characterized by the following:
  - Eating, in a discrete period of time (e.g., within any two-hour period) an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
  - A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- Binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for three months.
- Self-evaluation unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specific Types

- *Purging type:* The person regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.
- *Nonpurging type:* The person uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not regularly engage in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

ology of these disorders. Disordered eating appears to be a manifestation of an interaction of biologic, sociocultural, and psychological factors. Persons suffering both from anorexia and bulimia nervosa are more likely to have family histories of affective disorders, and they are more likely than individuals from the general population to have first-degree relatives who have also suffered/are suffering from eating disorders [86]. Anorexia nervosa seems to be associated with dysregulation of the hypothalamic-pituitary-adrenal axis. Similarly, bulimia is associated with a dysregulation in the serotonin-mediated satiety regulation. It is unclear, however, whether these imbalances are the cause or the result of these eating disorders. There are similar psychological factors associated with both anorexia and bulimia nervosa. These include low self-esteem, fear of loss of control, perfectionism, and conflict-resolution problems within the family. Finally, sociocultural factors, especially the cultural push for thinness, are cited as etiological factors for eating disorders. A now famous study demonstrated that in the last couple of decades the average bust and hip size of Miss America pageant winners has decreased while the weight of the average American woman has increased by five pounds [87]. All these factors are believed to interact in a manner that predisposes certain individuals to develop dissatisfaction with their body size and begin on a cycle of dietary restraint and eventual eating disorders.

Although these eating disorders can be seen in individuals of all ages and race and in either gender, the most likely "portrait" of the person with an eating disorder is that of a young (usually under 30, although onset is most common during adolescence), white (approximately 90 percent), woman (approximately 95 percent) of normal intelligence. The prevalence of anorexia nervosa is believed to be between 0.7 and 1 percent while prevalence of bulimia nervosa is cited as 4 to 10 percent, with some estimates as high as 20 percent [86].

Due to the extremely complex etiology of eating disorders, successful treatment requires a multidisciplinary effort by a team of health professionals, preferably with special training in the field. Treatment usually includes a correction of nutritional deficits, psychotherapy, and nutritional counseling. The role of the midwife in addressing eating disorders is primarily to be able to recognize the signs and symptoms of these disorders (see Table 6-21) and to make appropriate consultations and referrals for medical management. The referring midwife can serve as the liaison

TABLE 6-21 Signs and Symptoms of Eating Disorders

Anorexia	Bulimia
Severe weight loss, emaciation	Near normal weight in most cases
Acceptance of appearance as normal	Dizziness
Poor sleep habits	Fainting
Cold intolerance	Increased thirst
Constipation	Muscle cramps
Anemia (mild)	Constipation
Restlessness/Sleep disturbance	Tooth damage, loss of enamel
Pale, dry skin	Reflux esophagitis
Loss of scalp and pubic hair and/or lanugo	Petachiae in and around eyes
Brittle, dry nails	
Tooth disease/decay	

between the woman, family, and various health care providers and should also serve as the woman's advocate, but medical consultation is always indicated for confirmed cases of eating disorders.

Nutrition and Vegetarianism

In the last several decades, an increasing number of individuals have adopted vegetarian eating styles. There is a variety of reasons why people choose to become vegetarians, and about as many different styles of vegetarians. Some people believe it is unethical to kill animals for food or clothing. Others believe that animals present an inefficient and environmentally unsound way to meet human protein needs. Still others practice some form of vegetarianism to maintain cultural or religious beliefs. In the United States, many individuals choose to restrict their intake of animal products for health reasons. Regardless of the reason why someone has chosen a vegetarian style of eating, it is important for health care providers to assess whether or not vegetarian clients are meeting all their nutritional needs. Part of this assessment is determining the degree of dietary limitation. Vegans limit their nutritional intake to foods derived from vegetables, fruits, cereal grains, and nuts, avoiding all animal products. Lacto-ovo-vegetarians incorporate eggs and dairy products in their diets [5].

Health care providers often extol the benefits of a diet that limits intake of meat and animal fat without providing proper guidance on how to ensure proper nutrition from a vegetarian diet. The fact that several government nutritional guidelines such as the USDA's Food Pyramid presuppose that individuals are omnivores, makes it especially important for health care professionals to provide clients with ways to healthfully incorporate a diet that is mainly plant-based.

As was detailed in earlier sections of this chapter, reducing or eliminating meat intake reduces the risk of developing many chronic diseases by reducing caloric, fat, cholesterol, and sodium intake. Vegetarian diets are richer in fiber, complex carbohydrates, and substances such as antioxidants that are also believed to reduce the risk of many chronic diseases. It is important, however, for individuals who wish to adopt a vegetarian eating style, especially those who have little knowledge of nutrition, to have guidance in ensuring that their diet meets their nutritional needs. There are certain nutrients that are more likely to be deficient in vegetarian diets. Particular attention needs to be paid to ensure adequate intake of calcium, iron, zinc, and vitamins D and B_{12} [88]. This is especially true for those choosing a vegan eating style, for adolescents, and for women who are pregnant, lactating, elderly, or ill. These individuals also need to pay special attention to maintaining adequate protein intake. Because individual plant foods do not provide complete proteins, special meal planning is necessary to ensure a mix of grains and legumes that will provide the essential amino acids. The assistance of a registered dietician is especially helpful when conducting nutritional assessment or counseling with these women. The midwife can also recommend that vegetarian clients consult vegetarian cookbooks, the Seventh Day Adventist Dietetic Association Guide, or another resource tailored to the needs of vegetarians. In addition to proper meal planning, nutritional supplements or the addition of fortified foods may also be necessary, particularly in times of "nutritional stress" such as illness.

Nutrition and the Female Athlete

Female athletes are another population at higher risk for nutritional deficiencies and eating disorders [89]. Due in great part to rapid weight loss, dietary restrictions, and significant decreases in body fat that often accompany athletic training and competition, these women are also more prone to dehydration, menstrual dysfunction, osteoporosis, and anemia [90]. Yeager et al. coined the term "female athlete triad" to describe the concurrence of disordered eating, amenorrhea, and osteoporosis seen in many female athletes [91]. Midwives might care for these women when they come in for annual exams or for workups of amenorrhea or infertility. It is important, therefore, for midwives to be aware of this triad so that they can recognize clients who may be suffering from or prone to these conditions and take appropriate steps to either prevent these disorders or obtain appropriate treatment for these women.

Individualized nutritional guidance should be provided for female athletes by registered dieticians or by physicians who are knowledgeable in the field. Many women receive nutritional counseling from their coaches and trainers, but this counseling may not always be accurate or given with the best interest of the woman in mind. As with all clients, the midwife must carry out an assessment of the basic nutritional status of women who are athletes, and carry out appropriate referrals or consultations.

Alcohol and Nutrition

Alcohol abuse or alcoholism negatively impacts nutrition in two general ways: (1) by decreasing the quantity and quality of food intake and (2) by interfering with digestion, storage, metabolism, and excretion of essential nutrients. As a result of this combination of poor diet, decreased nutrient absorption, and disruption in liver function, alcoholics may experience deficiencies of thiamin, riboflavin, niacin, and folate as well as vitamins B_6, B_{12}, C, A, D, and K. Wernicke-Korsakoff syndrome, which is characterized by paralysis of the eye muscles, poor muscle coordination, impaired memory, and damaged nerves is common among chronic alcoholics and results from inadequate intake and absorption of thiamin. Heavy drinkers who substitute alcohol for their normal food intake can also suffer from protein-energy malnutrition. Long-term alcohol abuse can lead to cirrhosis of the liver, a progressive disease in which there is fatty infiltration of liver tissue and a resulting disruption in liver function. Approximately 50 percent of those individuals with cirrhosis will eventually die of the disease [92]. While the liver is particularly vulnerable to the toxic effects of alcohol, virtually every body system is also affected. There is a link between chronic alcohol use and increased rates of arthritis; cancers of the liver, pancreas, rectum, breast, mouth, pharynx, larynx, and esophagus; fetal abnormalities; heart disease; hypergylcemia; hypoglycemia; infertility in both men and women; kidney disease; neuropathy; obesity; and depression [93]. There can also be significant adverse consequences of single-episode intoxication or binge drinking, including lethal respiratory depression, coronary artery spasm, and myocardial infarction as well as motor vehicle and other accidents, suicide, homicide, and sexual assault.

Midwives should assess alcohol intake with both their pregnant and nonpregnant clients and educate them about both the short-term and long-term effects of alcohol abuse. Pregnant women should be informed about fetal alcohol syndrome and reminded that there is no level of alcohol consumption that has been determined as safe during pregnancy. In addition to asking women whether or not they consume alcohol and in what frequency and quantity, midwives can use the CAGE Questionnaire (see Table 6-22) or the TWEAK Questionnaire (see Chapter 12) to screen for alcohol dependence. If the midwife suspects or confirms that a woman has an alcohol dependence, arrangements should be made for appropriate treatment and counseling.

TABLE 6-22 CAGE Alcoholism Screening Questionnaire

C Have you ever felt you need to **C**ut down on your drinking?
A Have people **A**nnoyed you by criticizing your drinking?
G Have you ever felt bad or **G**uilty about your drinking?
E Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (**E**ye-opener)?

Source: Mayfield, D., McLeod, B., and Hall, P. The CAGE questionnaire: validation of a new alcoholism instrument. *Am. J. Psych.* 131:1121–1123, 1974.

A positive answer to any one of these questions warrants further investigation and more than one positive answer is highly indicative of an alcohol abuse problem.

Nutritional Guidelines

There are numerous resources that offer nutritional guidelines, however, both midwives and their clients need to be careful not to follow nutritional advice that may not be research-based or medically sound. For example, there are many Web sites that claim to offer nutritional advice but are actually just fronts for private companies peddling the latest fad diet or diet pills and tonics.

In 2000, the Office of Disease Prevention and Health Promotion of the Department of Health and Human Services in conjunction with the USDA's Center for Nutrition Policy and Promotion released the most recent General Dietary Guidelines for Americans. These guidelines have been published since 1980 and are revised every five years by law based on the recommendations from a scientific advisory group composed of 11 nongovernmental experts. These latest guidelines are grouped within three areas called the "ABCs" of good health: (1) *Aiming* for fitness by aiming for a healthy weight and being physically active each day; (2) *Building* a healthy base by using the Food Pyramid (Figure 6-1) to guide food choices, choosing a variety of grains, fruits, and vegetables daily, and by keeping food safe to eat through proper food preparation and storage; and (3) *Choosing* sensibly by choosing a diet that is low in saturated fat and cholesterol and moderate in total fat, choosing beverages and foods to moderate intake of sugars, choosing and

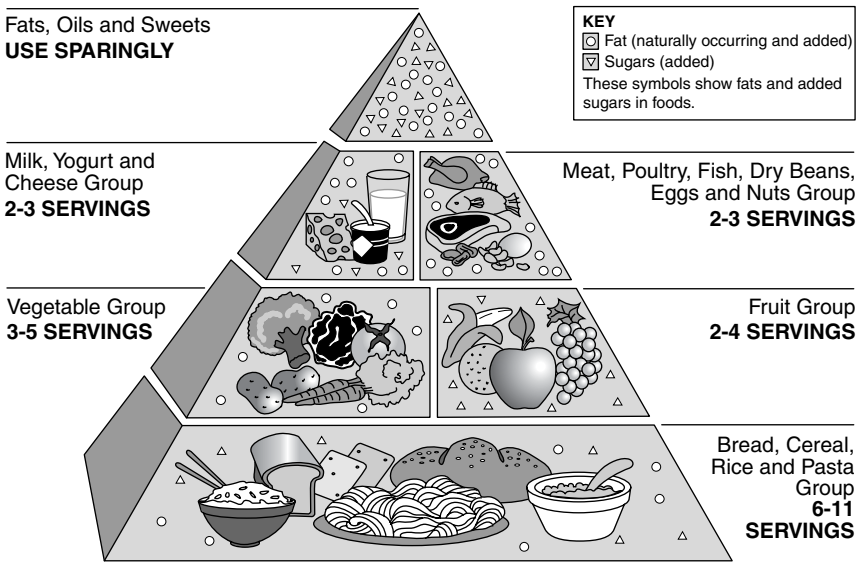

FIGURE 6-1 U.S. Department of Agriculture's Food Pyramid.
Source: USDA and the U.S. Department of Health and Human Services, 1992.

preparing foods with less salt, and moderating intake of alcoholic beverages.

While most components of these guidelines enjoy support from health and nutrition experts, the use of the USDA's Food Pyramid to guide food choice remains controversial. Many health professionals believe that the Food Pyramid, which was released in 1992, is a great improvement over the preexisting model of four food groups of equal weight: (1) meat, poultry, fish; (2) grains; (3) dairy; (4) fruits and vegetables. Some of these same professionals feel, however, that the Food Pyramid is nonetheless still flawed. They argue that the USDA, due to pressure from meat and dairy lobbying groups, still places too high a focus on meat and dairy products [94]. In 1991, the Physicians Committee for Responsible Medicine proposed a redefinition of the main food groups as (1) fruits, (2) grains, (3) vegetables, and (4) legumes. They proposed that meat and dairy be optional and that servings from these two groups should, in any case, be smaller than those proposed by the government. These proposed changes were based on research data that demonstrate that the American diet, which is high in animal fat and protein and low in fiber, increases the risk of obesity, cancer, and heart disease. More recently, Dr. Walter Willett, chair of the Harvard School of Medicine Department of Nutrition and one of the lead researchers for the Nurses' Health Study, has proposed the adoption of a new, research-based food pyramid (Figure 6-2). Dr. Willett argues that the USDA Food Pyramid is flawed in that it treats all fats as equally bad, all complex carbohydrates as equally good, and all proteins as equal in nutritional value. Furthermore, he believes that it promotes too high an intake of dairy products [95].

While the USDA dietary guidelines and approved health claims for food packaging have been continuously updated to incorporate new research findings, the Food Pyramid has not. As a result, some of these guidelines and claims seem to contradict the USDA Food Pyramid. It is not surprising, therefore, that the public is often confused about what foods they should choose to maintain good health. In general, the midwife should help women assess whether their current diet is appropriate to ensure adequate intake of all necessary nutrients while maximizing intake of foods, such as fruits and vegetables, that promote health and minimizing those, such as saturated fats, that promote disease. The section below includes a more detailed summary of research-based dietary guidelines and screening recommendations that can be used by midwives when conducting nutritional evaluation, education, and counseling.

Women should be reminded that proper nutrition begins with exclusive breastfeeding starting, if it is not medically contraindicated, in the first few hours after birth and continuing through five to six months of life before supplemental foods are introduced. It is also essential to stress that healthy eating habits begin in infancy and are reinforced through childhood and adolescence. Parents should

be aware that one of the best ways to ensure that their children eat appropriately is to eat appropriately themselves. This guarantees that the proper foods will be available in the home and that their children have a positive model to imitate. Proper nutrition requires planning and knowledge of what constitutes a healthy diet. Midwives can provide essential education on these topics to their clients both as part of their routine well-woman care visits and their prenatal and postpartum care. Midwives should also provide nutritional advice that will help women prevent nutritionally related disorders and certain chronic diseases. This advice should include the following:

- Eat a variety of foods and strive to obtain most if not all of necessary nutrients from dietary sources rather than from supplements. You can use one of the food pyramids discussed earlier (Figures 6-1 and 6-2) as a guide on what proportions of each food group you should strive to consume daily. Remember that not all foods are of nutritional value. Sugars, sweets (soft drinks, candies, cakes, and cookies), some types of oils, foods high in saturated fats (cream, lard, butter), and alcoholic beverages supply what are often referred to as "empty" calories for they are of little or no nutritional value.
- Eat a diet that provides a healthy balance of nutrients. Regardless of the actual number of calories required by an individual, it is recommended that for a healthy, nonpregnant, and nonlactating woman, approximately 15 percent of total energy intake be in the form of protein, at least 55 percent in the form of carbohydrates, and 30 percent or less in the form of fat. As was mentioned in an earlier section, less than 30 percent of fat intake should be in the form of saturated fats, which should account for less than 10 percent of total caloric intake. It is also recommended that less than 10 to 15 percent of total caloric intake should be in the form of sugars.
- Engage in an exercise program or in regular physical activity beyond that required for activities of daily living, including work.
- Quit smoking. Enrollment in a smoking cessation program can help in this endeavor, as may, in some circumstances, pharmacological agents.
- Maintain a healthy weight. BMI tables are helpful to determine what this weight should be.
- Moderate or eliminate alcohol intake. Women should strive not to drink more than one drink

per day (12 ounces of regular beer, 5 ounces of wine, 1.5 ounces of 80-proof distilled spirits).

- Eat a diet that is low in fat, particularly one that is low in saturated fat and cholesterol. More specifically, your fat intake, which should be no more than 10 percent of your total caloric intake, should include the following:
  - Less saturated fat (found in meat, full-fat dairy products, and tropical oils)
  - More monounsaturated fats (found in olive oil and avocados)
  - More polyunsaturated omega-3 oils (fish, walnuts, and flaxseed and canola oils)
  - Fewer transfatty acids (found in hydrogenated oils)
  - Eat a diet rich in a variety of fruits and vegetables. You should strive to consume at least five servings of fruits and vegetables every day. The majority of these servings should be of fresh fruits and vegetables.
- Eat fish containing omega-3 fatty acids—particularly tuna, salmon, or swordfish—at least once a week. Other good sources of these heart-protective substances are flaxseed oil, canola oil, and English walnuts.
- Maximize your intake of complex carbohydrates and minimize your intake of simple sugars (white sugar, brown sugar, raw sugar, honey, and syrups). Good sources of starches include breads, cereals, pasta, rice, dry beans and peas, and starchy vegetables such as potatoes, corn, and lima beans. Minimize white bread, rice, and potatoes.
- Maximize your intake of good sources of fiber, including whole grain breads and cereals, pasta, and vegetables and fruits with edible skins, such as apples and squash.
- Minimize intake of foods that supply mostly "empty" calories and few necessary nutrients. These include sugars, sweets, fats and oils, and foods high in sugars, fats and oils, and alcoholic beverages.
- Minimize your intake of salt and sodium. Be particularly careful of "hidden" sources of salt and sodium, such as deli meats and canned soups and vegetables.

During all well-woman visits, the midwife should also assess a woman's weight-for-height status and determine if she is underweight, appropriate weight, or overweight. The midwife should also assess abdominal circumference and waist-to-hip ratio as explained earlier in the chapter. Blood pressure measurements should be checked on every woman and the midwife should inquire about dietary practices and exercise habits. Table 6-23 provides a list of questions that can be used to elicit important information regarding a woman's nutrition and eating habits. The midwife can ask the woman to fill out a food and exercise diary for the three days to one week before her well-woman visit to facilitate nutritional counseling. Midwives should also conduct nutritionally related screening tests as indicated (see the following section on screening) and determine the appropriateness of any current dietary supplementation or the need for the initiation of dietary supplementation.

If serious nutritional problems are detected or suspected, the midwife should refer the woman to a registered dietician or other nutrition professional who can conduct the necessary assessment and interventions. It may also be necessary, as in the case of profound anemias or eating disorders, to refer the woman to a physician. Midwives can also refer women as appropriate to WIC or other food programs.

Screening

The Department of Health and Human Service's Public Health Service has created the U.S. Preventive Services Task Force (USPSTF), which conducts ongoing review of research on a variety of health conditions and concerns affecting the U.S. population. This task force periodically issues recommendations on preventive health measures, including screening to help guide clinicians who provide preventive health services to their patients. The nutrition-related screening recommendations made by the USPSTF are summarized below.

Lipid Screening (Cholesterol and Triglycerides) The third, and most recent, USPSTF report recommends that women 45 years old or older have their cholesterol levels tested routinely. The USPSTF does not, however, specify how frequently screening should occur and leaves that to the discretion of health care providers. Midwives should determine if their clients who are 45 years old or older have had a recent (within the last five years) cholesterol screening and order one if necessary. For younger women, screening is recommended if there are risk factors for heart disease, such as smoking, diabetes, high blood pressure, or a family history of heart disease or high cholesterol. In addition to obtaining a total cholesterol level (TC), the level of HDL cholesterol should also be measured. There is currently insufficient evidence, according to the USPSTF, to recommend for or against routinely measuring triglycerides.

TABLE 6-23 Guideline Questions for a Nutritional Assessment

Measure weight, height, and blood pressure and calculate BMI.

Ask the following:

1. Are you currently taking any medications or undergoing treatment for any health problem?
2. Do you smoke? If so, how much do you smoke in one day?
3. Do you drink alcohol at all? If so, how much do you drink in one day? In one week? (Use CAGE Questionnaire if appropriate.)
4. Do you use any street drugs?
5. Do you exercise? If so, how often and for how long? What type of exercise?
6. How many meals do you eat in one day?
7. How often do you snack during the day?
8. How many times do you eat out during one week? (Include all carry-out and fast food.)
9. How many glasses of fluid do you drink in one day? How many glasses of water do you drink in one day?
10. Are you allergic to any foods? If so, what happens when you eat this particular food?
11. Are you on a diet? If so, what kind of diet? How long have you been on it and with what results?
12. Do you take any of the following:
    - Multivitamins
    - Calcium supplement
    - Iron supplement
    - Folic acid supplement
    - Diet pills
    - Laxatives
    - Power drinks/diet drinks (such as Ensure, Slimfast, etc.)
13. Which of the following terms would you use to describe your current weight?
    - High
    - Just right
    - Low
14. Do you or a first-degree family member (mother, father, brothers, or sisters) suffer from any of the following medical conditions?
    - Hypertension (high blood pressure)
    - Diabetes (high blood sugar)
    - Heart disease
    - Kidney disease
    - Liver disease
    - Anemia, sickle cell disease
    - Immune disorder such as lupus or HIV infection
    - Cancer
    - Crohn's disease, irritable bowel syndrome, ulcerative colitis

Ask patient to conduct a three-day diet/exercise recall by doing the following:

1. Write down everything you eat AND drink in one day including all snacks (no matter how small).
2. Write down any physical activity beyond your activities of daily living (for example, include a half-hour walk but do not include housework or walking done during your job).

Plasma Glucose The USPSTF does not make a recommendation for or against the routine screening for non-insulin-dependent diabetes mellitus (NIDDM) in nonpregnant, asymptomatic women. Screening for this condition is up to practitioner discretion; nevertheless, based on the possibility of reducing the risk of complications from hyperglycemia through exercise and diet, screening those at high risk for NIDDM is probably warranted. Individuals at risk for NIDDM include those who are obese (particularly obese clients older than 45), those with a strong family history of diabetes, and those who are Native American, African American, or Hispanic. Fasting plasma glucose is considered the optimal screening test for NIDDM. The frequency of testing is up to the practitioner. The midwife should inquire if clients at risk for NIDDM have been recently screened and order a fasting plasma glucose if indi-

cated. Screening should definitely be conducted in women who are symptomatic.

Hematocrit and Hemoglobin Routine screening of nonpregnant women for anemia is not recommended by the U.S. Preventive Services Task Force. Hemoglobin and hematocrit levels should be drawn for women with signs and/or symptoms of anemia.

Bone Densitometry While the USPSTF recommends that all postmenopausal women be counseled on the risks for osteoporosis and on the importance of smoking cessation, regular exercise and adequate calcium intake, the task force has found that there is insufficient evidence to recommend for or against routine screening for osteoporosis with bone densitometry in postmenopausal women. Women who are at high risk for osteoporosis may desire bone densitometry to help determine whether or not to initiate estrogen prophylaxis and or other pharmacologic interventions aimed at treating or preventing osteoporosis and/or osteoporosis-related fractures.

Supplementation

There is much controversy both within and outside of the health professional community regarding the appropriateness and need for dietary supplements. The debate over vitamin supplementation is made more complicated by the numerous studies that seem to indicate on the one hand that intake of certain vitamins, minerals, or other substances in excess of the recommended dietary allowance may be protective against certain diseases, and the warnings that megadoses of vitamins and minerals can be harmful on the other hand. Most nutrition experts do seem to agree that a balanced diet composed of a variety of foods will provide a healthy, nonpregnant, nonlactating adult woman with all the necessary nutrients. There do appear, however, to be some exceptions to this rule, when even a healthy adult woman may need to supplement her diet. Women of reproductive age, for example, need folic acid in excess of what is consumed in the usual American diet in order to prevent certain birth defects in their infants. Similar cases include women who bleed excessively during menstrual periods who may need additional iron to prevent anemia and vegetarians who may need to supplement nutrients such as calcium, iron, zinc, and vitamin B_{12} that are either more readily or exclusively available from animal products. Other individuals who may need supplements are those with certain illnesses or diseases or on certain medications, like diuretics, that may deplete them of necessary nutrients. Women who are at risk for or already suffering from osteoporosis may need to take supplemental calcium and/or vitamin D.

It is more difficult to make recommendations on supplementing a healthy, well-balanced diet in a healthy adult. As more and more studies are released that suggest that certain vitamins and/or vitamin precursors are linked to a reduction in the risk of diseases such as cancer, women are increasingly likely to seek the advice of health professionals on the need for supplementation. An increasing amount of evidence, for example, seems to suggest that intake of vitamin E in amounts far in excess of the current RDA is protective against heart disease [96]. Based in part on findings such as these, the American Medical Association (AMA) has recently recommended that all adults take one multivitamin daily. They say that this practice is justified "by the known and suspected benefits of supplemental folate and vitamins B_{12}, B_6, and D in preventing cardiovascular disease, cancer, and osteoporosis, and because multivitamins at that dose are safe and inexpensive" [97].

Although the passage in 1994 of the Dietary Supplement Health and Education Act has made it possible for the government to establish standards regarding dietary supplements and for persons on their own or in conjunction with a health care provider to decide whether to supplement their diet, certain factors must be kept in mind. In particular, both clients and health care providers must be careful to avoid overdosing. It is a common misconception that overdosing on vitamins and minerals is difficult if not impossible and that the body will simply eliminate any excess of these substances through the urine. In truth, megadoses of certain vitamins and minerals can be risky. For example, excess intake of vitamin A during the first few months of pregnancy has been found to be associated with birth defects, excess intake of vitamin E can interfere with blood clotting, and very high doses of folic acid can mask symptoms of a vitamin B_{12} deficiency.

In order to properly advise women on the need for supplementation, midwives should try to keep current on changes in RDAs as well as on recommendations made by government agencies or by well-respected professional organizations. Midwives can also use the following guidelines in advising clients regarding dietary supplementation [98]:

- Increasing intake of foods rich in the desired nutrients is the most desirable option. Vitamin and mineral supplements cannot make up for poor eating habits.
- Supplements that contain more than 100 to 150 percent of the U.S. Recommended Dietary Allowance (RDA) for each vitamin and mineral should be avoided.
- To prevent toxicity or mineral and vitamin competition, a moderate and balanced intake of vitamins and minerals is recommended. When calculating intake of vitamins and minerals, all supplemental sources must be taken into account. Remember that "power" drinks often contain vitamin and mineral supplements and that many foods are fortified with vitamins and minerals.
- Women should not take more than one multivitamin daily in any form.
- With the exception of vitamin E, synthetic supplements of vitamins are treated in the same way as supplements derived from natural sources by the body. The only real difference is in price. Natural vitamin E, however, is more potent and absorbed better than its synthetic counterpart.

In summary, it is recommended that clients use nutritional supplements only after seeking the advice and guidance of a health professional who can assess the need for the supplement, guide the person in choosing the proper dose and formulation of the substance to be supplemented, and monitor the person both for success of the supplementation and for possible side effects or interactions with medications or other supplements.

Conclusion

The midwife should have a good working knowledge of the basics of nutrition and on any nutritionally related recommendations (such as the need for adequate folic acid intake in women of reproductive age) that are relevant to the client population she cares for. In addition, the midwife should incorporate a basic nutritional assessment as part of each well-woman visit and should always be vigilant for signs or symptoms of nutritional disorders or diseases, such as diabetes and heart disease that are affected by, and affect, nutritional status. This nutritional assessment should include an inquiry about eating habits; tobacco, alcohol, and illicit drug use; the use of dietary supplements; chronic medical conditions and any medications being taken for the same; and daily activity levels and exercise habits. The midwife should measure blood pressure, weight, and height and make an evaluation of weight for height status. Necessary lab work should be obtained as indicated by responses to inquiries or by preventive health screening recommendations. Finally, the midwife should evaluate all the information and carry out necessary education, counseling, or interventions—including but not limited to referrals to a physician or registered dietician.

CHAPTER

7

Primary Care and Midwifery

In 1992, the American College of Nurse Midwives issued a position statement describing the role of Certified Nurse-Midwives in primary care (Figure 7-1) [1]. The document was in part a response to the increasingly politicized nature of health care in the United States. At the time, direct insurance providers were restricting access to women's health care clinicians and health plans, although there was ample evidence that many women preferred to use such clinicians as their primary contact with the health care system. Many midwives have found themselves in the position of being the only person a woman sees on a regular basis. Furthermore, the recommended periodic screens for women of childbearing age were well within the core competencies of midwifery practice even before the addition of primary care.

Primary Care

But what is primary care? The definition most used today was published in 1996 by the Institute of Medicine. It describes primary care as follows:

> The provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community. [2]

When one thinks of the women who seek their care from midwives, it is obvious that we can function in this role for some, but not all, of our patients. Women with significant illnesses, or the elderly, may have needs that require medical supervision. On the other hand, healthy women may be well served by having as their primary contact with the health care system a midwife focused on health maintenance, age-appropriate screening, and patient education. One commonly used description of primary care providers is that they can provide 80 percent of the care needed by a person on an annual basis.

The most common reasons for ambulatory care visits have been collected and published by the National Center for Health Statistics (see Table 7-1). Between the ages of 18 and 65, women make relatively more visits to physicians than do men, and Whites make more visits (by about 50 percent) than do Blacks. As age increases, so does the use of medical services [3].

Several small studies of obstetricians and midwives have looked at the range of conditions identified and/or managed in the context of routine care, and found that they included many of the most common conditions seen in primary care practices [4–6]. A survey of 327 midwives taken at the 1993 ACNM annual meeting found that primary care problems were commonly addressed during visits to the midwife. Figure 7-2 demonstrates the breadth of primary care conditions identified by these midwives as early as 1993 as being part of their practices. A survey of obstetrician-gynecologists and HMO medical directors found disagreement as to whether gynecologists provided appropriate services to be considered primary care "gatekeepers" providing most patient services. For example, 43 percent of gynecologists provided immunizations, whereas 100 percent of health plans felt that this was the primary care provider's responsibility.

Position Statement

Certified Nurse-Midwives and Certified Midwives as Primary Care Providers/Case Managers

It is the position of the American College of Nurse-Midwives that Certified Nurse-Midwives (CNMs) and Certified Midwives (CMs) are providers of primary health care for women and newborns.

Care by CNMs and CMs incorporates all of the essential factors of primary care and case management that include evaluation, assessment, treatment and referral as required. The model of health care practiced by CNMs and CMs is focused on the ambulatory care of women and newborns and emphasizes health promotion, education and disease prevention and sees the woman as central to the process of providing such care.

Care by CNMs and CMs includes preconception counseling, care during pregnancy and childbirth, provision of gynecological and contraceptive services and care of the peri- and post-menopausal woman. With health education as a major focus, the goals are to prevent problems and to assist women in developing and maintaining healthy habits.

CNMs and CMs are often the initial contact for providing health care to women, and they provide such care on a continuous and comprehensive basis by establishing a plan of management with the woman for her ongoing health care. Such care by the CNMs and CMs is inclusive and integrated with the woman's cultural, socioeconomic and psychological factors that may influence her health status.

*Midwifery as used throughout this document refers to the education and practice of certified nurse-midwives (CNMs) and certified midwives (CMs) who have been certified by the American College of Nurse-Midwives (ACNM) or ACNM Certification Council, Inc. (ACC).

Other areas of discrepancy between expectation and services offered included management of anemia, depression, thyroid dysfunction, and diabetes [7].

Among common reasons for outpatient visits reported to the National Center for Health Statistics are general health examinations, cough, abdominal pain, cramps or spasm, fever, skin rash, hypertension, depression, headache, diabetes, back symptoms, chest pain, and nasal congestion. The most frequent examinations included pelvic and breast examinations. Blood pressure was checked at fewer than half the visits. One-third of all visits included no diagnostic or screening procedures [8].

TABLE 7-1 Common Reasons for Visits to Ambulatory Medical Offices by Women in 2000

Primary Diagnosis	Percentage of All Visits
Essential hypertension	4.2
Acute upper respiratory infection	3.6
Diabetes mellitus	2.4
Arthropathies, related disorders	3.1
Normal pregnancy	4.6
Malignant neoplasms	2.6
General medical examination	2.4
Rheumatism, other than back	2.0
Otitis media and eustachian tube	1.7
Spinal disorders	1.8
Chronic sinusitis	1.6
Ischemic heart disease	1.0
Other heart disease	1.1
Gynecologic examination	1.9
Asthma	1.0
Allergic rhinitis	1.1
Acute pharyngitis	1.1

Source: Adapted from Cherry, D. K., and Woodwell, D. A. National ambulatory medical care survey: 2000 summary. *Advance Data from Vital and Health Statistics*, No. 328. Hyattsville, MD: National Center for Health Statistics, June 5, 2002.

During the Robert Wood Johnson–funded study on care to vulnerable populations, about 80 percent of midwifery visits were obstetric in nature [9, 10]. Midwives are clearly not spending all of their time on primary care. However, pregnant women are also found to be anemic, have respiratory infections, or stomach pain, and in the course of a pregnancy, most clinicians defer to the person managing the pregnancy as being the most qualified to treat these and other conditions. The presence of a second patient in utero somehow changes the equation. Therefore, midwives have an obligation to be informed about primary care, to be able to identify and manage common minor illnesses, and to appropriately refer women to another clinician for more complex health problems.

This chapter is not intended to be a comprehensive survey of primary health care for women; it is an introduction to health problems commonly seen in midwifery practices. For this reason, discussion of medical therapies for serious health problems is limited. When general medical problems significantly affect the course of pregnancy, they will be further discussed in Chapter 24, which focuses on antepartal complications.

The U.S. Department of Health and Human Services has developed guidelines for preventive care visits. (These are periodically updated and can be found at www.ahrq.gov/ppip.) Table 7-2 lists the current recommendations for normal-risk adults ages 18 to 75, as of this writing [11]. Immunization recommendations for adults are available online at http://www.cdc.gov/nip/recs/adult-schedule.pdf.

Reviewing the complete database for a health examination (Chapter 2), the midwife can easily see that a comprehensive history and physical can lead to the identification of complex problems. Even if the midwife will not be managing every condition diagnosed, she should be prepared to offer a con-

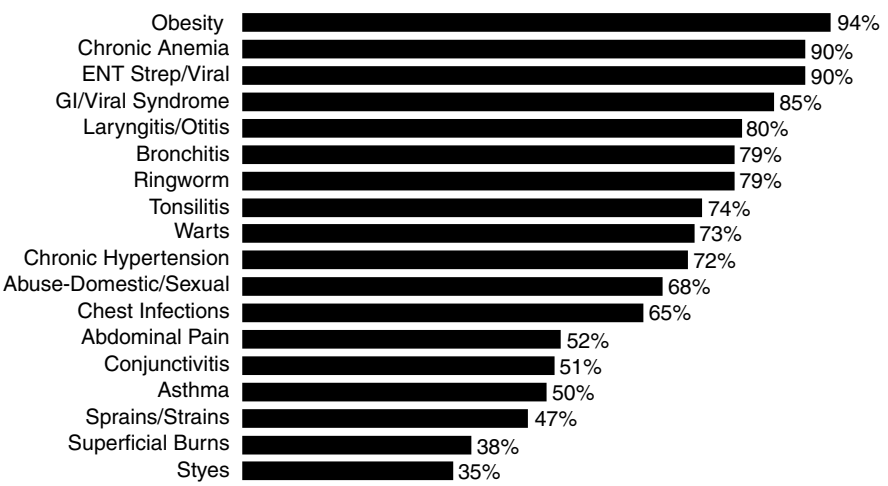

FIGURE 7-2 Percentage of midwives who identify and manage selected health care problems.

TABLE 7-2	Clinical Preventive Services for Normal-Risk Adults, Recommended by the U.S. Preventive Services Task Force

Screening

Blood pressure, height, and weight: Periodically, ages 18–75
Cholesterol: *Men*, every 5 years, ages 35–75
Women, every 5 years, ages 45–75
Pap smear: Women, every 1–3 years, ages 18–65
Chlamydia: Women, periodically, ages 18–25
Mammography: Women, every 1–2 years, ages 40–75
Sigmoidoscopy: Every 5 years, ages 50–75
And/or fecal occult blood: Yearly, ages 50–75
Alcohol use: Periodically, ages 18–75
Vision, hearing: Periodically, ages 65–75

Immunization

Tetanus-diphtheria (Td): Every 10 years, ages 18–75
Varicella (VZV): Susceptibles only, two doses, ages 18–75
Measles, mumps, rubella (MMR): Women of childbearing age, one dose, ages 18–50
Pneumococcal: One dose, ages 65–75
Influenza: Yearly, ages 65–75

Chemoprevention

Aspirin to prevent cardiovascular events:
Men, periodically, ages 40–75
Women, periodically, ages 50–75

Counseling

Calium intake: Women, periodically, ages 18–75
Folic acid: Women of childbearing age, ages 18–50
Tobacco cessation, drug and alcohol use, STDs and HIV, nutrition, physical activity, sun exposure, oral health, injury prevention, and polypharmacy: Periodically, ages 18–75

Source: Clinical Preventive Services for Normal Risk Adults Recommended by the U.S. Preventive Services Task Force. Put Prevention into Practice, Rockville, MD: Agency for Health Care Quality and Research, June 2002.

sultant a complete assessment of a patient's condition. For example, if after a comprehensive history has been taken, the woman reports no problems on a review of systems, and she then walks comfortably into the exam room and is able to undress and position herself for an examination without assistance or physical difficulty, you have a significant amount of information about her general well-being—including sight, hearing, cranial nerve function, memory and orientation, affect, and gait and range of motion. You can use all the information gained through history, review of systems, and observation to target areas of concern during the physical exam and assessment.

The remainder of this chapter addresses specific medical conditions organized by body systems.

Hematologic Conditions

Anemia and Hemoglobinopathies

Among the most common complaints of women seeking care is the familiar "I'm tired all the time, I must be anemic." While there are many causes of fatigue—from anemia to thyroid disease to stress—this one is the first focus of concern for many women. Signs and symptoms associated with anemia are listed in Table 7-3.

In addition to these, the history and review of systems should include an assessment of menstrual flow, even though women's estimation of their flow has been demonstrated to be inaccurate [12]. Prior diagnosis of anemia merits a description of the circumstances. For example, some women may have been treated for pregnancy-related anemia and believe that they will therefore always be anemic.

The diets of most Americans, with the exception of some vegetarians, include about 15 mg of iron daily, and about 10 percent of that is absorbed. Normal daily iron loss through excretion, sweat, and cellular shedding amounts to 1 mg; the menses add an additional monthly loss which, with pregnancy-

TABLE 7-3	Symptoms and Signs Associated with Significant Anemia

Symptoms

Fatigue, drowsiness
Weakness

Splenomegaly
Tachycardia or flow murmur
Tachypnea, dyspnea on exertion

related demands, increases the daily iron need among reproductive age women to 2 to 3 mg/day [13].

A complete blood count (CBC) offers the first level of assessment and will differentiate many of the underlying causes of anemia. Defined as a decrease in red blood cell mass, or more correctly in total hemoglobin, the normal hemoglobin level for menstruating women is 12.0, and for pregnant women it is 11.0 g/dL [14]. However, no adverse effects are expected unless the level is <10.0 g/dL [15]. The U.S. Department of Health and Human Services does not recommend screening for anemia as part of routine health care for adults, except among pregnant women [16].

There are a number of confounding factors. Economic status has an effect, in that lower status translates into higher rates of poor nutrition and thus a higher rate of iron deficiency anemia. Race plays a role; for example, Blacks average about 1 g/dL lower hemoglobin levels than Whites regardless of socioeconomic level. Women who smoke (because of competition for oxygen-binding sites on red blood cells) and women living at high altitudes (because of lower oxygen concentration in the atmosphere) demonstrate higher hemoglobin and hematocrit levels as their bodies adapt to maintain adequate oxygenation (see Tables 7-4 and 7-5) [17].

Identifying the cause of decreased hemoglobin will lead to appropriate therapy and in some cases to referral to a specialist. One way to classify anemias is by the size of the red blood cells. Microcytic anemias include iron deficiency, the thalassemias, and anemia of chronic disease. Macrocytic anemias include folate and vitamin B_{12} deficiency, liver disease, increased reticulocyte production, and some effects from medication—for example, from zidovudine (Retrovir). Normocytic anemias commonly reflect acute blood loss or conditions such as sickle cell disease, hemoglobin C, or G6PD. Aplastic anemia, while normocytic, shows pancytopenia. Table 7-6 presents the laboratory values associated with some common anemias. When the hemoglobin is below 10.0 g/dL, a laboratory panel including the CBC, serum folate, serum iron, ferritin, and total iron binding capacity should be ordered, and a hemoglobin electrophoresis performed. Based on the severity of the anemia and its cause, consultation or referral may be indicated. When the hemoglobin indicates severe anemia (<9.0 g/dL) consultation is always appropriate, even if the anemia is clearly caused by iron deficiency.

TABLE 7-4 Smoking Adjustments for Hemoglobin and Hematocrit Cut-Points for Anemia

Smoking Status	Hemoglobin (g/dL)	Hematocrit (%)
Nonsmoker	0.0	0.0
Smoker (all)	+0.3	+1.0
0.5 < 1 ppd	+0.3	+1.0
1.0–2.0 ppd	+0.5	+1.5
>2.0 ppd	+0.7	+2.0

TABLE 7-6 Laboratory Values in Common Anemias

Laboratory Test	Iron Deficiency	Vitamin B_{12} Deficiency	Folate Deficiency	Thalassemia	Chronic Disease
RBC	low	high	high	normal	normal
Hemoglobin	low	low	low	low	low
MCV	low	high	high	low	normal-low
MCH	low	high	high	low	low
MCHC	low	normal	normal	low	normal-low
Iron	low	high	high	high	low
TIBC	high	normal	normal	normal	low
Ferritin	low	high	high	high	normal-high

Iron Deficiency

The single most common anemia in the United States is iron deficiency, which in most cases is mild and easily reversible. Occult blood loss, excessive menstrual loss, and inadequate nutritional intake are by far the most common causes in adults. In the absence of an identifiable source of bleeding, assessment for gastrointestinal bleeding is warranted; the midwife should inquire about use of aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). Nutritional deficiencies causing significant iron depletion include restrictive vegetarian diets as well as pica, and a careful diet history is part of the workup. Iron supplementation, either nutritional or with oral medications, should be begun in all cases when the hemoglobin is less than 10.0 g/dL. Adding 1.0 mg of folic acid in cases where the serum folate is low or using a vitamin C–enriched product to facilitate absorption may also be useful. Nutritional counseling should stress the importance of including iron-rich foods in the diet—such as green leafy vegetables, collard greens, egg yolks, raisins, prunes, liver, oysters, and some fortified cereals—as well as the elimination of picas, such as eating ice or nonfood starches. When uncomplicated iron deficiency is the cause of the anemia and oral medications are used, any of several iron preparations, including ferrous sulfate, ferrous fumarate, and ferrous gluconate, can be used. The equivalent of 300 mg of ferrous sulfate taken three times a day is standard. Taking iron preparations with meals will decrease absorption, but it will also improve gastrointestinal side effects such as nausea and reflux. After the hemoglobin level has returned to normal, continued supplementation for three months should adequately replenish iron stores in the body.

Thalassemia

Thalassemias are mendelian recessive inherited disorders of the globin chains that form normal adult hemoglobin (hemoglobin A). In alpha thalassemias, decreased hemoglobin α production causes normal proportions of hemoglobins A, A_2, and F. The beta thalassemias show increases in hemoglobins A_2 and F relative to hemoglobin A on electrophoresis. Alpha thalassemia is most common among those of Chinese and Southeast Asian descent. Beta thalassemia is most common among women of Mediterranean origin, less so among Chinese, Asian, and African women. In both cases, the trait will appear as a microcytic anemia in which the mean cell volume (MCV) is markedly low relative to the hemoglobin level [18]. A handy shortcut to identifying these traits is Mentzer's index: MCV/RBC < 13. Nonetheless, a complete anemia panel is justified to rule out a combination of iron deficiency and hemoglobinopathy. When the diagnosis is established, folic acid supplementation may be desirable but iron therapy is inappropriate, as supplementation will not resolve the problem. A woman with a hemoglobinopathy needs to understand her diagnosis to avoid unnecessary testing in the future and to ensure that before she becomes pregnant she and her partner will be evaluated to decrease the risk of bearing a child with severe hemolytic syndromes such as thalassemia major whose risks for the fetus include hydrops fetalis.

Sickle Cell Disease

Sickle cell trait (hemoglobin AS) is found in about 8 percent of African Americans; although the trait itself does not cause severe health complications, identification of those carrying the sickle trait is important to enable couples planning children to obtain appropriate genetic counseling and testing. Midwives can care for women with sickle trait. The primary complication is an increase in urinary tract infections and hematuria.

Sickle cell disease (homozygous SS disease) is a recessive inherited disorder in which hemoglobin S is produced instead of hemoglobin A. Repeatedly stressed red blood cells form a permanent crescent moon or "sickle" shape; they may then clump and block the microvasculature. Sickle cell crises involve acute episodes of severe pain from ischemia and infarction of tissue and organs. The disease has a multiorgan effect and is associated with a shortened life span as a consequence of renal damage, cardiac damage, infection, and acute chest syndrome.

Hemoglobin S may also be present in heterozygous SC disease or sickle thalassemia, conditions that lead to somewhat milder forms of sickle crisis. For all these disease conditions, genetic counseling for couples planning a child is appropriate. Pregnant women with these diseases should be cared for by a midwife only in close collaboration with a physician experienced in the management of sickle cell disease.

G6PD Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked genetic disease seen in those of Mediterranean descent and in African Americans. (Being X-linked, it is far more common among men than women.) Hemolysis occurs when the individ-

ual has an infection or receives oxidative drugs. Certain medications commonly used in pregnancy and women's health care that must not be given to individuals with G6PD deficiency include sulfa and sulfa derivatives, nitrofurantoin, toluidine blue, and methylene blue. Fava beans will also produce hemolysis in those with the Mediterranean variant.

The management of care of women with G6PD deficiency includes avoidance of substances that may cause hemolysis. Prompt diagnosis and treatment of any infection will minimize the risk of hemolysis from infection. Surgery can also precipitate an episode of hemolysis. Therefore, the midwife should remind a woman to notify her surgeon and surgical team prior to any elective or required surgery. Genetic counseling and prenatal diagnostic testing should be offered to all women with G6PD deficiency. When caring for a pregnant woman with G6PD deficiency, the midwife should notify the consulting physician so that appropriate care can be provided in the event an operative delivery is needed or the woman requests postpartum surgical sterilization.

Von Willebrand's Disease

Von Willebrand's disease is an autosomal dominant mutation causing defects in a polymer necessary for platelet adhesion. It is a leading cause of menorrhagia, underlying up to 20 percent of cases, particularly among teenagers [19–21]. Bleeding disorders should be suspected if the history a woman describes includes heavy menstrual bleeding in association with increased bruising, nosebleeds, or a family history of bleeding problems. At that point, the midwife should obtain a platelet count and bleeding time and coagulation studies. If the platelets are normal and the bleeding time is prolonged, von Willebrand's disease is a strong possibility. As with any other bleeding abnormality, the midwife should refer the woman to a hematologist for evaluation, although it would be appropriate for the midwife to continue to provide general care. The woman should be advised to avoid aspirin if a diagnosis of von Willebrand's disease is made [18].

The Cardiovascular System

Assessment of cardiovascular status begins with a history and review of systems that assess for hypertension, cardiac events, and vascular changes in the woman and her immediate family. The current surge in acute cardiac events among relatively young adults—spurred on by elevations of cholesterol, poor dietary habits, a sedentary lifestyle, and increased stress—means that thoughtful questioning should include these factors, which are not always considered during a reproductive health visit. Risk factors for cardiac disease include aging (with 20 percent of women over 65 having some form of heart disease), high blood pressure, dyslipidemia, obesity, lack of physical exercise, and smoking.

If the midwife is acting as the primary provider, assessment of heart sounds and of the pulses during the physical examination is as essential as a correctly taken blood pressure. After taking all data into consideration, the midwife is then able to recommend testing or further evaluation. The New York Heart Association classification system for cardiac disease, based on functional limitation, is widely used to describe severity of cardiac disease (see Table 7-7).

Assessment of Heart Sounds and Murmurs

When assessing heart sounds, the midwife should listen for additional sounds and for alterations such as murmurs or clicks. Some are consistent with functional changes. For example, a third heart sound heard over the apex is normal in pregnancy and is common in healthy young adults. One example commonly heard in young, generally healthy women is the click of mitral valve prolapse. Some murmurs, described as innocent, vary with breathing and position change. More serious murmurs may continue throughout systole, or may be heard during diastole, sound louder, or be associated with palpable vibration of the chest wall. Whenever the midwife identifies abnormal or unexplained cardiac sounds, she should refer the woman for consultation and further evaluation, such as a chest x-ray, electrocardiogram, or echocardiogram. In some set-

TABLE 7-7 New York Heart Association Classification of Heart Disease

Class I	Able to maintain normal physical activity levels without pain, shortness of breath, or other symptoms.
Class II	Some limitation of physical activity; will notice symptoms with normal activity levels.
Class III	Physical activity is limited; symptoms occur with even mild activity.
Class IV	Symptoms of congestive heart failure occur even at rest; physical activity is severely limited.

tings, the midwife may order these tests as part of the report sent to the consultant.

Mitral Valve Prolapse

This common abnormality of the mitral valve, in which the leaflets are thickened or have redundant tissue, is generally asymptomatic and carries a low risk of complications. Estimates of incidence vary widely, but as many as 10 percent of young women are reported to have a mitral valve prolapse. Clinical diagnosis can be confirmed with an echocardiogram. In the absence of insufficiency and regurgitation across the valve, bacterial endocarditis prophylaxis is unnecessary before dental or other surgical procedures [22]. However, women with more serious mitral insufficiency or regurgitation require antibiotic prophylaxis prior to surgeries. While uncomplicated prolapse is not a threatening condition, anyone with an identified cardiac condition needs to be referred to a cardiologist for assessment.

Hypertension

Hypertension—arterial disease characterized by persistent high blood pressure—is more common among men, African Americans, and the elderly. Risk increases into the sixth decade of life, by which time as many as 50 percent of the population may be affected, depending on the definitions used. Among the additional risk factors that tie hypertension to cardiac disease are smoking, dyslipidemia, diabetes, and family history.

Although it does not seem that it should be necessary to mention, many clinicians act on blood pressure results that are not accurate because the technique of assessment is incorrect. Blood pressures should always be taken with the cuff at the level of the heart, using a properly sized cuff, after the woman has had several minutes to sit quietly. She should not have ingested tobacco or caffeine for at least 30 minutes. The classification of blood pressures as presented in the *Sixth Report of the Joint National Committee on Prevention, Detection, and Treatment of High Blood Pressure* is shown in Table 7-8 [23]. Blood pressures that fall within the normal range need reevaluation every two years in healthy adults, while those with high normal values should have their blood pressure checked yearly. Stage 1 hypertension should be reconfirmed within two months. Stage 2 hypertension is reevaluated or referred for care within one month. Stage 3 findings require immediate follow-up.

TABLE 7-8 Blood Pressure Measurement and Clinical Evaluation[a]

Category	Systolic (mm Hg)		Diastolic (mm Hg)
Optimal[b]	<120		<80
Normal	<130		<85
High-normal	130–139	or	85–89
Hypertension[c]			
Stage 1	140–159	or	90–99
Stage 2	160–179	or	100–109
Stage 3	>180	or	>110

[a] Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic blood pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status. In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify presence or absence of target organ disease and additional risk factors. This specificity is important for risk classification and treatment.

[b] Optimal blood pressure with respect to cardiovascular risk is below 120/80 mm Hg. However, unusually low readings should be evaluated for clinical significance.

[c] Based on the average of two or more readings taken at each of two or more visits after an initial screening.

Source: National High Blood Pressure Education Program. *The Sixth Report of the Joint National Committee on Prevention, Detection, and Treatment of High Blood Pressure*. National Institutes of Health, November 1997.

Midwives should provide dietary and lifestyle counseling to promote weight loss and physical fitness among persons with high normal blood pressure; weight loss of as little as 10 pounds may have a salutary effect on blood pressure [24]. When caring for women with hypertensive disease, reinforcing the same information contributes to the effectiveness of medication programs. Appropriate dietary changes include increasing intake of fresh fruits and vegetables and low fat dairy products, and decreasing both total and saturated fats [25]. Additional lifestyle changes include weight loss for those with a BMI greater than 27, increasing aerobic exercise, decreasing dietary sodium to less than 2.4 grams daily, decreasing alcohol, consuming adequate potassium, calcium, and magnesium in the diet, and smoking cessation [23].

Drug therapy for hypertension draws on several categories of medication. The most commonly used as first-line medications include thiazide diuretics, ACE inhibitors (e.g., Lotensin, Zestril), and beta-blockers (e.g., Inderal, Lopressor). Most midwives will refer women who need pharmaceuticals to a physician to initiate treatment or alter medication regimens.

Women with hypertension who are considering a pregnancy need to discuss with their clinicians which medications are safe for use during the childbearing year. Changing therapeutic agents is often necessary and should be undertaken by the person responsible for managing the hypertension (see Chapter 24). In addition, women with preexisting hypertension are at increased risk for superimposed preeclampsia during the pregnancy.

Dyslipidemia

Dyslipidemia—elevated cholesterol—is a major risk factor for cardiac disease, and, often, a preventable one. The epidemic of obesity and high dietary fat intake in the United States is one that can usually be addressed with lifestyle changes. The National Heart, Lung, and Blood Institute (NHLBI) recommends beginning cholesterol screening in healthy adults at age 20. Risk of high cholesterol increases with age; more than 40 percent of women over 55 have elevated cholesterol levels [26]. Other risk factors include cigarette smoking, hypertension, diabetes, hypothyroidism, and a family history of early-onset disease. An excellent tool for estimating risk is available at the NHLBI Web site (www.nhlbi.nih.gov/guidelines). Table 7-9 presents the classification of cholesterol levels.

When the midwife identifies hypercholesterolemia as a risk factor, counseling always includes nutritional changes to decrease total and dietary fat to 25 to 35 percent of total calories, to add dietary fiber, to stop smoking, and to increase exercise levels. Management of obesity and dietary fat is discussed further in Chapter 6. Medication therapy can be deferred while a trial of healthy behaviors is undertaken, as long as there is no family history suggestive of genetic predisposition to coronary artery disease and the LDL cholesterol level is less than 160 for women without other cardiac risk factors.

Pharmacologic therapy is instituted based on LDL level and risk profile. Among the medications used for elevated cholesterol are the statins (e.g., Lipitor, Zocor, Pravachol), bile acid sequestrants (cholestyramine), nicotinic acid (niacin), and fibric acids (e.g., gemfibrozil) [27].

TABLE 7-9 Classification of LDL, Total, and HDL Cholesterol (mg/dL)

LDL Cholesterol
<100 Optimal 100–129 Near optimal/above optimal 130–159 Borderline high 160–189 High >190 Very high
Total Cholesterol
<200 Desirable 200–239 Borderline high >240 High
HDL Cholesterol
<40 Low >60 High

Respiratory Diseases

Upper Respiratory Infections (URI) and Influenza

Commonly viral in nature, colds and influenza produce significant numbers of calls to any medical office, with patients often asking for antibiotics that will not cure the problem. One study has found that 75 percent of antibiotic prescriptions written in the United States were for acute respiratory infections, of which URI is the most common [28]. Overtreatment as well as inappropriate treatment has led to a rapid increase in the presence of resistant *Streptococcus pneumoniae*, a problem with implications for the management of all respiratory disease, as *S. pneumoniae* is the most common bacterial respiratory pathogen [29].

The diagnosis of URI is made based on the presence of nasal congestion and a clear or white discharge, as well as sore throat, muscle aches, headache, and cough. The symptoms of colds and influenza overlap, although high fever and dry cough are more typical of the "flu" than of a cold. Symptomatic management with rest, increased humidity (hot showers, humidifiers), increased fluids, over-the-counter drugs—including antipyretics, analgesics, and cough suppressants or decongestants as needed—will reduce the severity of symptoms. Ipratropium bromide (Atrovent), an anticholinergic nasal spray, has also been shown to relieve rhinorrhea, sneezing, and congestion. Initial use is two sprays in each nostril, three to four times daily [30]. Atrovent is also available in oral inhaler form as a therapy for obstructive pulmonary dis-

ease. In contrast, the use of antihistamines has not been shown to reduce cold symptoms significantly. Kinins, a group of vasoactive peptides, are implicated in rhinitis symptoms, while histamines are not [31]. Resolution of symptoms should be complete within a week.

Many upper respiratory infections can be avoided through the use of simple hygiene techniques, most particularly the practice of hand washing. The use of antibacterial soaps and environmental sprays are, by and large, not necessary in the home.

Several therapies for influenza are available, including rimantidine (Flumantidine) and the neuraminidase inhibitors (Relenza, Tamiflu). When the winter influenza season is in progress, infections suspected of being influenza can be treated within 48 hours of the onset of symptoms to shorten the duration of infection by about one day. Vaccination has been shown to have a preventive benefit as well, although when influenza is defined only by clinical symptoms the benefit is slight [32]. The authors of the Cochrane database review concluded that while vaccination and treatment were beneficial, the most cost-effective approach to managing influenza in the healthy adult was to use supportive measures only [33]. Women with significant exposure risk such as health workers, immunocompromised patients, and older women may receive greater benefit from vaccination.

Sinusitis

Sinus infections are typically bacterial in nature and are frequently found as a superimposed infection when nasal swelling has blocked drainage from one or more sinus cavities. In addition to pain and pressure over the affected sinus, a change from the clear nasal drainage of rhinitis to a green or yellow discharge is commonly found. Toothache near the affected sinus is also predictive. Fever and a cough that worsens when lying down are also characteristic. Therapy includes supportive management with over-the-counter decongestants, increased humidity, and antibiotics. As with colds, antihistamines should not be used unless there is an allergic component to the congestion. Common pathogens in sinusitis include *Streptococcus* species, *Staphylococcus aureus*, and *Haemophilus influenzae*; these can generally be treated for ten days with any of a number of drugs, including mainstays such as ampicillin, trimethoprim/sulfamethoxazole, the cephalosporins, and the macrolides [34]. Table 7-10 summarizes specific therapies.

Because antibiotic resistance is rising, some experts are suggesting the use of symptomatic therapy

TABLE 7-10 Examples of Antibiotics Commonly Used in the Treatment of Respiratory Infections

Class	Dose Range/Duration	Pregnancy Category
Cephalosporins		
Cefaclor (Ceclor)	250 mg q8h × 10 days	B
Cefixime (Suprax)	400 mg po QD × 10 days	B
Cefuroxime Axetil (Ceftin)	250 mg po q12h × 10 days	B
Cephalexin (Keflex)	250 mg po q6h × 10 days	B
	500 mg po q12h × 10 days	B
Macrolides		
Azithromycin (Zithromax)	500 mg po × 1, then 250 mg po QD × 4 days	B
Clarithromycin (Biaxin)	250–500 mg po q12h × 10–14 days	C
Penicillins		
Amoxicillin (e.g., Amoxil)	500 mg po q8h × 10 days 500–875 mg q12h × 10 days	B
Amoxicillin/Clavulanate (Augmentin)	500–875 mg po q12h × 10 days (based on amoxicillin dose)	B
Quinolones		
Ciprofloxacin (Cipro)	500 mg po BID × 10 days	C
Levofloxacin (Levoquin)	500 mg po QD × 10 days	C
Trimethoprim/sulfamethoxazole (Bactrim)	160/800mg po BID × 10 days	C

only in newly presenting uncomplicated infections. Unresolved symptoms after therapy, frequent recurrences or infection, or a finding of periorbital edema require referral to a physician for further evaluation [35].

Bronchitis

Infections of the lower respiratory tract limited to the trachea and bronchi are termed bronchitis. It can appear as an inflammatory response to an otherwise uncomplicated URI. In healthy women of reproductive age, bronchitis is typically a viral syndrome of fever, malaise, fatigue, sore throat, chest pain, and cough. Worsening chest pain with shortness of breath or pain on inspiration suggests pneumonia. The cough may be productive or nonproductive. On auscultation, lung sounds other than over the bronchi should be clear; a chest x-ray, if performed, should not show infiltrates.

In most cases, the infection will clear and the cough resolves within one to two weeks with supportive therapy, which should include the usual regimen of rest, increased fluids, and over-the-counter decongestants or cough suppressants. If cough is the primary symptom, the use of an albuterol inhaler (Proventil, Ventolin) may provide relief [36]. If an inhaler is prescribed, the directions should be for two puffs every four to six hours as needed to relieve symptoms. Greater frequency of use, or prolonged use, suggests the need for referral to a physician.

Antibiotics are not useful in the case of viral bronchitis, but under certain circumstances suspected bacterial infections of the bronchi may require antibiotic therapy (see Table 7-10). Symptoms of such a condition include worsening cough with productive discolored sputum and chronic or recurrent bronchitis with underlying respiratory disease. If the diagnosis is unclear, pneumonia should be ruled out based on examination of the lungs and a chest x-ray. Consultation with the physician is warranted if the midwife is unable to exclude pneumonia.

Community-Acquired Pneumonias

Infections of the lungs are the leading infectious cause of death in the United States. Predisposing factors for pneumonia include damage to the cilia of the respiratory tract from chronic cough, viral infections, or smoking. The most common organisms found are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*, with *S. pneumoniae* causing up to two-thirds of all community-acquired disease. Other bacteria and viruses can also produce pneumonia, as can chlamydia or mycoplasma. The onset of symptoms is usually abrupt, with fever, cough, chest pain, shortness of breath, sweats and chills, generalized aches, headache, and fatigue being common. When the cause is bacterial, high fever and a productive cough are more likely, whereas viral causes will produce a more generalized malaise. Unlike most upper respiratory infections, increases in respiratory rate and pulse are common. The lung fields will have rales and occasional wheezing, and areas of consolidation may produce diminished breath sounds on auscultation. Chest x-ray is indicated to confirm the diagnosis and to identify underlying complications. When feasible, a sputum sample should be obtained to identify the etiologic agent.

Whether patients with pneumonia are treated on an outpatient basis or are hospitalized is a decision with significant consequences in terms of treatment modalities, testing schemes, and costs. Fine and his colleagues reported on the development of a prediction rule that identified patients at low risk of dying or suffering major sequelae [37]. Adults under 50, without existing comorbidity such as liver, kidney, cardiac, cerebrovascular disease, or malignant disease are screened for physical abnormalities: altered mental status, pulse greater than 125 bpm, increased respiratory rate greater than 30, systolic pressure less than 90 mm Hg, or temperature less than 35° C or greater than 40° C. Patients who do not exhibit these signs of severe disease are at low risk of mortality. The authors went on to describe additional criteria for low-risk patients based on laboratory findings and other criteria. Using the findings described above produced a group of women who could be treated without further testing [37]. While uncomplicated pneumonia should be treated promptly with antibiotics and can safely be managed on an outpatient basis in healthy adults, the prudent midwife will consult with a physician if pneumonia is suspected. Common first-line antibiotics for community-acquired pneumonia include the macrolides, doxycycline, and quinolones [38].

Asthma

Asthma is the chronic inflammation of airways—associated with reversible obstruction from spasm, edema, and mucus production—and hyperresponsiveness to stimuli. It is classified into four steps based on severity and frequency of symptoms: (1)

mild intermittent asthma, (2) mild persistent, (3) moderate persistent, and (4) severe persistent (Table 7-11) [41]. Over time, changes in the walls of the airways can lead to irreversible constriction. While most cases of asthma have childhood onset, adults can also develop new disease. Current data suggest that about 14 million U.S. adults have recent asthma symptoms. Being female and African American and having lower family income are all associated with increased risk of developing asthma [39]. An adult presenting with symptoms of wheezing, chest tightness, and shortness of breath should be evaluated for asthma; occasionally a dry nocturnal cough will be the only presenting complaint. The differential diagnosis includes chronic obstructive disease (chronic bronchitis or emphysema), congestive heart failure, pulmonary embolism, drug-related cough, and other causes of airway obstruction. Common triggers for adult asthma attacks include exercise, rhinitis (infectious or allergic), bronchitis, gastroesophageal reflux, and allergies to NSAIDs (such as Motrin), sulfites, or beta-blockers (such as Inderal). Women with asthma should be counseled to avoid triggers, which may also include inhaled allergens such as perfumes and irritants such as environmental smoke or polluted air. Smoking cessation is key for decreasing the severity of the disease among women who smoke. The National Institutes of Health Expert Panel Report on asthma notes that underdiagnosis and undertreatment are the major contributors to morbidity and mortality from asthma [40].

In the office setting, a patient whose lung sounds and symptoms suggest asthma can be asked to use a peak flow meter that measures maximum expiratory breath force before and after the use of a short-acting bronchodilator to establish whether the respiratory difficulty responds to smooth muscle relaxation. Formal spirometry is necessary for an accurate diagnosis, but office evaluation can allow the immediate start of acute therapy. Midwives practicing in areas of high asthma frequency may keep flow meters in their offices either to assist in the presumptive diagnosis of asthma or to assess lung function when asthmatic women present and are symptomatic.

Anyone with persistent asthmatic symptoms needs to be on daily medication, rather than relying solely on a rescue inhaler such as $beta_2$-agonists like albuterol (Ventolin) or metaproterenol (Alupent). Undertreatment limits physical activity, decreases

TABLE 7-11 Classification of Asthma Severity: Clinical Features Before Treatment

	Days with Symptoms	Nights with Symptoms	PEF or FEV_1*	PEF Variability
Step 4 *Severe Persistent*	Continual	Frequent	″60%	>30%
Step 3 *Moderate Persistent*	Daily	≥5/month	>60%–<80%	>30%
Step 2 *Mild Persistent*	3–6/week	3–4/month	≥80%	20–30%
Step 1 *Mild Intermittent*	″2/week	″2/month	≥80%	<20%

* Percent predicted values for forced expiratory volume in 1 second (FEV_1) and percent of personal best for peak expiratory flow (PEF) (relevant for children 6 years old or older who can use these devices).

NOTES

- Patients should be assigned to the most severe step in which *any* feature occurs. Clinical features for individual patients may overlap across steps.
- An individual's classification may change over time.
- Patients at any level of severity of chronic asthma can have mild, moderate, or severe exacerbations of asthma. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms.
- Patients with two or more asthma exacerbations per week (i.e., progressively worsening symptoms that may last hours or days) tend to have moderate-to-severe persistent asthma.

Source: Practical Guide for the Diagnosis and Management of Asthma. NIH Publication No. 97-4053. 10/97.

pulmonary function, and increases the risk of recurrent attacks. The choice of medications is based on both the severity and persistence of symptoms. The main categories of asthma drugs for long-term maintenance include (1) inhaled or systemic corticosteroids (e.g., Vanceril, Flovent, prednisone), (2) cromolyn sodium (Intal) and nedocromil (Tilade), (3) long-acting beta$_2$-agonists (e.g., Serevent), (4) methylxanthines such as theophylline, and leukotriene modifiers (e.g., Singulair). In addition to short-acting inhaled beta$_2$-agonists, anticholinergics such as ipratropium bromide, or short courses of oral corticosteroids may offer relief [40]. The National Heart, Lung, and Blood Institute Web site (www.nhlbi.nih.gov) provides access to the most current guidelines on asthma management. In general, newly diagnosed asthma should be evaluated in consultation with or by referral to a physician experienced in respiratory care.

During pregnancy, asthma symptoms may worsen as the lung space is compressed by the growing fetus. Women with moderate to severe asthma and recent exacerbations should be referred to a physician for evaluation. Liu and colleagues reported an increase in adverse pregnancy outcomes related to maternal asthma, including preterm labor and birth, preterm premature rupture of membranes (PPROM), and hypertensive disorders of pregnancy [42]. However, they could not identify severity of disease or level of asthma control in their retrospective cohort. Thus it is not clear that well-managed asthma with minimal exacerbations would have the same effect on pregnancy outcome. If a woman's condition is stable and she is not experiencing any limitations in physical activity, there is no reason why she should not receive prenatal care and give birth with a midwife.

Gastrointestinal Disorders and Abdominal Pain

Stomach aches and pains, diarrhea and constipation, and bloating are all common complaints presenting in primary care. As part of the history for any woman of childbearing age, last menstrual period and potential pregnancy risk are routinely assessed. Ensuring that women of childbearing age are not pregnant is essential in working up any abdominal complaints. This section will focus on general gastrointestinal health concerns common to all women, although obstetric concerns such as ectopic pregnancy or gynecologic complaints and gynecologic concerns such as ovarian cysts and endometritis will be addressed in other chapters.

Gastroenteritis and Acute Diarrhea

Some women may complain of diarrhea if they have any change in bowel habits that produces soft, frequent, or less formed stools. When assessing history, true diarrhea has increased water content and may have increased mucus content. Acute diarrhea is predominantly infectious; chronic diarrhea, lasting for more than two consecutive weeks, can result from diverse conditions, including infections, medication, chronic illness, malabsorption syndromes, stress, and irritable bowel syndrome. Most midwives will need to refer women with chronic watery diarrhea to a physician for further evaluation after completing a careful history and physical examination.

Viral gastroenteritis is a generally self-limiting disease, in which oral exposure to a pathogenic virus leads to explosive onset of nausea, vomiting, and/or diarrhea, fever, and malaise within two to three days of exposure. The abdomen is tender; no guarding is present. Bowel sounds are increased. Workup of acute diarrhea includes a stool sample to check for white blood cells or frank bleeding. Laboratory evaluation of electrolytes should be reserved for more severe or persistent cases when dehydration is suspected, as should stool for culture or ova and parasites.

Most viral cases in healthy adults will clear spontaneously within one to four days. Rest and oral fluids are the basic components of care. Intravenous rehydration with electrolytes can be used for severe dehydration and for individuals at increased risk, such as the elderly and the immunocompromised. Medications such as kaolin/pectin (Kaopectate), diphenoxylate (Lomotil), or loperamide (Imodium) can be offered to decrease the frequency of stools. If symptoms are not resolving or the patient is becoming dehydrated, closer evaluation is warranted. Stool samples for culture or for ova and parasites (depending on the suspected pathogen) as well as a toxin assay for *Clostridium difficile* (with recent antimicrobial use) would be indicated [43].

Other causes of diarrhea-linked infections include *E. coli* species, *Salmonella*, and a host of other bacteria, most of which are foodborne. The American Medical Association and the Centers for Disease Control and Prevention have published a reference for foodborne illnesses that identifies the

major contributing organisms, diagnostic criteria, and management [44]. *E. coli* is the most common cause of traveler's diarrhea. These bacteria may cause symptoms either as a result of toxin release or by directly attacking the bowel wall. With mild bacterial gastrointestinal infections, fever is less likely to be present than with viral diseases. As with the viral causes of diarrhea, symptomatic measures will usually suffice when the cause is bacterial. The use of antibiotics in the treatment of diarrhea should be reserved for culture-proven or severe disease that is clearly bacterial in nature.

Constipation

Straining to produce hard stools, infrequent bowel movements (fewer than once in three days), and painful defecation are characteristic of constipation. Initial questioning of women with these complaints should include an assessment of their "usual" bowel function. Among healthy women, inadequate dietary fiber, possibly decreased fluid intake, and iron therapy for anemia (whether real or simply suspected by the woman) are common causes. Other medications, such as tricyclic antidepressants (e.g., Elavil), anticholinergics (e.g., Atrovent), and calcium channel blockers (e.g., Cardizem and Verapamil), may slow peristalsis and increase stool transit time, leading to constipation. Misuse of laxatives, leading to decreased natural stimulation of the bowel, is also common, more so among the elderly. More serious causes range from neurological dysfunction to abuse of opiates. Stress, anxiety, and depression may lead to changes in bowel habits, as would abnormalities of the bowel and functional problems such as irritable bowel syndrome. A careful history and physical assessment of women with any chronic bowel changes is necessary to rule out serious underlying disease that would require a medical referral [45].

Management of chronic constipation in healthy women includes counseling about diet and exercise, and an increase in fluid intake. Avoidance of straining, and recognizing the physical cues that indicate the need to defecate, are included in teaching. Women should also be counseled to stop the overuse of laxatives, cathartics, and enemas. If any medication is necessary during early treatment, a bulk-forming over-the-counter drug such as Metamucil should be used; however, adding fiber to the diet is a better strategy since it promotes a pattern of healthy eating to maintain normal function. If symptom relief is not obtained with the above measures, a trial of laxatives such as docusate sodium (Colace) is in order before referring the woman to a physician.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) consists of lower gastrointestinal tract complaints of increased bloating, diarrhea, and/or constipation in the absence of any structural or biochemical cause. It is chronic in nature, and one of the most common presenting complaints in primary care practice. The current definition (Rome II) includes onset associated with changes in the frequency or composition of the stool and pain relief with defecation, persisting over 12 weeks within the last year. To meet the diagnostic criteria, the symptoms need not be continuous. Intermittent symptoms totaling 12 weeks are considered significant. Increased or decreased stool frequency, abnormal stool formation (either hard or watery), bloating, difficulty in the passage of stool (straining, urgency, or failure to completely empty the bowel), and mucus in the stool are further confirmation of the diagnosis [46]. The onset of IBS usually occurs during the young adult years; because organic causes of bowel changes are more common with increasing age, a new diagnosis should be made with care in adults over 40. Assessment includes evaluation for bowel obstruction, including malignancies, and for gastrointestinal bleeding. Irritable bowel syndrome should not be confused with inflammatory bowel diseases such as Crohn's disease and ulcerative colitis, which are chronic, recurrent inflammations of the bowel. The relationship of symptom relief to having a bowel movement is strongly suggestive of IBS.

Care plans may include short-term use of therapy for diarrhea or constipation, but their chronic use should be avoided. Some women will complain of food allergies or conditions such as lactose intolerance. Most food allergies present as acute upset, not as chronic bowel changes. If a patient has severely restricted her dietary intake, adding foods back into the diet may improve general health and nutrition as well as symptoms.

There is a strong psychosocial component to seeking care for IBS, although the symptoms are common among adults who do not seek care. Thus, an important step in managing care for individuals with this complaint is building a trusting relationship. Education about IBS, reassurance about the course and management possibilities, and dietary modification are important in helping women man-

age their symptoms effectively [47]. Because of the strong likelihood of underlying psychological distress among patients with IBS, a careful assessment for anxiety disorders and depression is warranted. Considerations in managing this aspect of the disease include the use of antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs) such as Prozac or Zoloft, psychotherapy, and supportive behavioral therapy [48].

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD), a condition affecting up to one in five adults, produces symptoms of heartburn that worsen with meals, bending over, and lying down. Other less easily recognizable symptoms include an asthmalike wheeze, cough, laryngitis, and chest pain. Persistent severe disease may produce complications such as injury to the epithelium of the esophagus (Barrett's esophagus) and stricture formation [49].

Therapy for GERD includes weight reduction, maintaining a diet high in protein and low in fat, and the avoidance of triggers such as caffeine, tobacco, and spicy or acidic foods. Remaining upright after meals will help prevent symptoms. If reflux is occurring primarily at night, elevating the head while in bed will also help avoid discomfort. If these measures do not relieve symptoms, the use of antacids will bring short-term relief, while H2 receptor antagonists such as cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid) will relieve symptoms for longer periods. Proton pump inhibitors can be used for persistent problems. They include prescription drugs such as omeprazole (Prilosec), esomeprazole (Nexium), and lansoprazole (Prevacid). (See Table 7-12 for common regimens.)

Midwives whose patients fail a trial of H2 receptor antagonists should obtain consultation from a physician, to assess the need for endoscopy or possible fundoplication of the stomach [49]. Comparison of surgical outcomes with medical management has been shown to improve quality of life in severe cases, or when the patient is not satisfied with the results of medication therapy [50]. Treatment to eliminate *Helicobacter pylori* has also been demonstrated to have a beneficial effect on the course of GERD [51]. GERD is a common cause of chronic cough, due to reflux into the esophagus or larynx triggering a cough reflex, or to aspiration of refluxed stomach contents into the respiratory tract. Cough may be the only symptom of GERD, in which case treatment for GERD will relieve a cough not otherwise responsive to therapy [52].

Ulcers

Peptic ulcers are open lesions of the stomach or duodenum, penetrating through the mucosa into muscle. Common causes are excessive use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen or aspirin, and *H. pylori* infection, a condition responsible for 80 to 90 percent of all gastric and duodenal ulceration. It is more common among the elderly, persons of lower socioeconomic status, and Black and Hispanic ethnic groups; however, most persons who are colonized with *H. pylori* do not suffer from ulcers [53].

Endoscopy with collection of biopsy samples for histology is the most accurate technique for diagnosis as well as assessment of lesions for cancer risk. Culture for *H. pylori* is an additional useful tool in areas where antibiotic resistance is becoming a serious problem, in order to utilize the most ef-

TABLE 7-12 Medications for the Management of Gastroesophageal Reflux Disease (GERD)

Medication	Dose	Duration of Therapy	FDA Pregnancy Category
H2 Receptor Antagonists			
Cimetidine (Tagamet)	400 mg po QID or 800 mg po BID	12 weeks	B
Famotidine (Pepcid)	20 mg po BID	6 weeks	B
Nizatidine (Axid)	150 mg po BID	12 weeks	B
Ranitidine (Zantac)	150 mg po BID	12 weeks	B
Proton Pump Inhibitors			
Esomeprazole (Nexium)	20 mg po QD 20 mg po QD	4 weeks maintenance	B
Iansoprazole (Prevacid)	15 mg po QD	8 weeks	B
Omeprazole (Prilosec)	20 mg po QD	4-8 weeks	C

fective therapy first. Noninvasive testing methods such as serology and urea breath tests are most appropriate in symptomatic, healthy adults at low risk for stomach cancer. However, urea breath tests are more expensive and less widely available, and thus are more commonly used only to confirm the eradication of infection [54, 55].

Counseling about avoiding aspirin and NSAIDs, stress reduction, and smoking cessation are all useful interventions in conjunction with medication for the management of ulcers. Alone, they will not resolve the disease. Midwives should consult with or refer to a physician if considering the management of peptic ulcers. First-line drug therapy for peptic ulcer disease begins with removal of the *H. pylori* from the stomach and duodenum with aggressive antibiotic therapy, usually with more than one antibiotic, for two weeks. One example of this sort of therapy would be omeprazole (Prilosec) 20 mg po bid, plus clarithromycin (Biaxin) 500 mg po bid, plus metronidazole (Flagyl) 500 mg po bid for 14 days. Unless the ulceration has been caused solely by use of NSAIDs, no other therapy will provide lasting results. Drugs to reduce the acid content of the stomach—including antacids, H2 receptor antagonists, and proton pump inhibitors—are useful in promoting the healing of tissue [56]. Following the eradication of *H. pylori*, recurrence rates are low; maintenance doses of a proton pump inhibitor or sucralfate (Carafate) may be used when refractory or severe ulcers are resolved [57]. Gastric ulcers which remain unresolved need to be evaluated to exclude cancerous lesions of the stomach [58].

Assessing Abdominal Pain

This section limits itself to consideration of two common nonreproductive causes of acute abdominal pain: cholecystitis and appendicitis. Either of these may also present initially with more subtle symptoms. The differential diagnosis includes a host of other conditions, among them pyelonephritis, drug withdrawal, ulcers, pancreatitis, ectopic pregnancy, ovarian cysts, and heart attacks. The diversity of this list reinforces the idea that midwives confronted with acute abdominal pain should not hesitate to seek consultation when the diagnosis is unclear. Reproductive health issues related to abdominal pain are discussed in Chapter 14.

When a woman presents with acute abdominal pain, assessment begins with a comprehensive history. Onset of symptoms and their progress are determined, as well as identifying whether the pain is localized, and, if so, to which quadrant. Characteristics that distinguish the acute abdomen are abdominal rigidity or distention, guarding, rebound pain, tachycardia, and decreased or absent bowel sounds. Fever may be present but is not essential to the diagnosis. Vomiting as well as urinary, bowel, or vaginal symptoms may be present. An acute abdomen is often a surgical emergency, and immediate referral to a physician is an appropriate plan.

Cholecystitis

Cholecystitis is an inflammation of the gallbladder, an organ that collects, concentrates, and dispenses into the digestive tract the bile produced by the liver. Occasionally, the gallbladder will form gallstones, developing when excess cholesterol triggers a crystallization process. Cholecystitis is more common among women and the obese, and its incidence increases with age. When cholecystitis develops, symptoms range from diffuse discomfort to sharp epigastric pain following meals. The pain may last for several hours and is often associated with nausea and vomiting. Acute attacks present with severe, persistent right-upper quadrant pain, often radiating to the right shoulder blade or the central back opposite the epigastrium. Murphy's sign is positive if the woman has an inspiratory arrest with deep palpation of the right upper quadrant. Occasionally there is a palpable mass at the gallbladder. Leukocytosis, elevated liver function tests, and elevated bilirubin are common laboratory findings.

Once a diagnosis of cholecystitis is considered, the midwife should arrange for a medical referral. The usual treatment for symptomatic gallstones is surgical removal of the gallbladder. Laparoscopic techniques are commonly used. Nonsurgical treatments for small stones include medication therapy with bile acids, or dissolution by lithotripsy, or a combination. However, there is a substantial risk of recurrence following nonsurgical approaches.

A recent study looked at outcomes of cholecystectomy during pregnancy [58]. Preterm contractions, leading in one case to preterm delivery, were more common in the group that had laparotomy rather than a laparoscopic procedure performed. One maternal death occurred, in a woman who had experienced an ileus following her laparoscopic procedure, and then returned several days later with an intra-abdominal hemorrhage with no iden-

tifiable bleeding site. One fetus aborted spontaneously five weeks after an open procedure. In spite of these significant complications, the authors concluded that cholecystectomy was preferable to the risks of conservative management, which included pancreatitis and preterm labor.

Appendicitis

The classic descriptive symptoms for appendicitis are anorexia and generalized abdominal pain, resolving into acute right-lower quadrant abdominal pain, vomiting, fever, and the appearance of leukocytosis on complete blood count. Deep tenderness over McBurney's point in the lower right abdomen is an early sign of acute appendicitis. Rebound pain with release of pressure from the left lower abdomen is known as Rovsing's sign.

During pregnancy, appendicitis is the single most common abdominal emergency not directly related to the pregnancy itself. In addition, the common discomforts, such as round ligament pain, and physiologic and hematologic changes of pregnancy such as elevation in WBC, may mask symptoms of appendicitis. Pain commonly remains in the right-lower quadrant, although the original concept of appendicitis pain in pregnancy was that it would migrate into the right-upper quadrant as pregnancy advanced. False positive diagnoses in pregnancy are generally higher than in nonpregnant women, and false positive rates as high as 30 percent may be necessary to avoid missing this emergency diagnosis [59]. While maternal morbidity does not seem to be increased when appendicitis occurs during pregnancy, the risks of spontaneous abortion and preterm labor and/or preterm birth are increased [59, 60].

Genitourinary Problems

The close proximity of the urinary tract to the reproductive organs means that women frequently call their gynecologic provider for management of urinary tract symptoms. In pregnancy, lower urinary tract infections become more common, and asymptomatic bacteriuria is associated with an increased risk of preterm labor. Office evaluation and management of uncomplicated cystitis is an essential skill for midwives, as are prompt recognition and triage of the more serious pyelonephritis.

Acute Cystitis

Uncomplicated acute cystitis can be identified as the presence of as few as 100 colonies per milliliter of urine in symptomatic women, or more traditionally, as 100,000 colonies per milliliter whether or not symptoms of urinary tract infection (UTI) are present. The predominant organism is *E. coli*, with *S. saprophyticus*, *Enterobacter*, and *Enterococci* species making up most other pathogens. Symptoms include pain on urination and increased voiding frequency. In healthy young women, those who are sexually active will have a higher risk, primarily associated with delayed voiding after genital sex and the use of spermicides and diaphragms (which may promote the growth of bacteria in the periurethral area) [61]. In office practice, identification of positive leukocyte esterase on a urinalysis is adequately sensitive to initiate therapy. Most of the pathogens associated with UTIs remain sensitive to any of several standard drug regimens (see Table 7-13).

The Group Health Cooperative of Seattle developed clinical guidelines for triage of patients based on symptoms of UTI, which demonstrated decreased use of cultures, increased utilization of recommended drug regimens for treatment of cystitis, and no increase in adverse outcomes due to missed diagnoses or delayed treatment [62]. Their guidelines are shown in Figure 7-3.

Three-day antibiotic regimens are generally adequate for uncomplicated bladder infections. Single-day treatments are effective as a clinical cure, but they are associated with a higher rate of recurrent infection. The former "gold standard" of seven-day therapy is highly effective but not necessary in most women. Those who would benefit

TABLE 7-13 Anti-Infectives Commonly Used in the Treatment of Uncomplicated Urinary Tract Infections

Trimethoprim/sulfamethoxazole (Bactrim)	160 mg/800 mg po BID × 3 days*
Nitrofurantoin (Macrodantin)	100 mg po BID × 3 days*
Amoxicillin (Amoxil)	500 mg po TID × 3 days
Cephalexin (Keflex)	500 mg po QID × 3 days

During pregnancy, treat with 7-day therapy at the same dose.

* Avoid use in term pregnancy.

from longer regimens include pregnant women, immunosuppressed patients, diabetics, and patients whose symptoms had persisted for several days before beginning therapy.

Pyelonephritis

Acute pyelonephritis, an inflammation of the kidneys, might also have been included in the section on abdominal pain, as its characteristic presentation is severe flank pain and fever with associated nausea. The diagnosis should be confirmed by a urinalysis positive for white cells or pyuria and by culture. Physician consultation or referral is required when pyelonephritis is diagnosed. Outpatient treatment of healthy nonpregnant women can be appropriate if the infection is diagnosed early. However, many women will require hospitalization for intravenous antibiotics in the initial stage of treatment. A 10- to 14-day course of IV/oral therapy is required. Cephalosporins (e.g., Rocephin), quinolones (e.g., Cipro), and trimethoprim/sulfamethoxazole (Bactrim) are all effective [61]. During pregnancy, ampicillin plus gentamycin, cefazolin (Ancef), and ceftriaxone (Rocephin) have each been demonstrated to be effective. When pyelonephritis is treated effectively in pregnancy, it is not associated with an increase in adverse pregnancy outcomes [63].

Diabetes

Because of the increased rates of obesity in the United States, diabetes has become an increasingly common disease. Approximately ten times as many adults have Type II diabetes as Type I; 8 percent of American adults have Type II diabetes according to the most recent National Health and Nutrition Examination Survey (NHANES) data [64]. Diabetes is more common among the obese and women of color, and its prevalence increases with age. The disorder is associated with increased risks of hypertension, hyperlipidemia, and coronary heart disease, and it may also produce damage that will result directly in vascular disease, renal failure, and retinopathy.

The current classification strategy for diabetes focuses not on whether insulin is necessary, but on the cause of insulin deficiency. Type I diabetes is almost always mediated by the immune system causing pancreatic B cell destruction; Type II diabetes, which is far more common, is the result of resistance to insulin and the inability of the pancreas to increase insulin production to compensate. The term *impaired glucose tolerance* is used for adults with fasting glucose values that are elevated above normal but do not meet the criteria for overt diabetes. Other rare forms of diabetes have also been identified [65].

The diagnosis of diabetes is based on laboratory values. The presentation of women in clinical practice depends on both the type and severity of onset. Young women with Type I diabetes generally present with clear complaints of polyuria, including the need to urinate during the night, increased thirst, hunger with associated weight loss, and weakness or fatigue. Those with Type II diabetes may also complain of thirst, frequent voiding, and weakness, but they are more likely to present with recurrent vaginal yeast infections, itching, skin infections, blurred vision, or even peripheral neuropathy. In many cases, particularly with obese women, diagnosis will only occur with laboratory screening. Women with a history of large infants and unexplained fetal losses should be considered at risk. Table 7-14 presents the laboratory criteria for diagnosing diabetes. Two consecutive fasting values greater than 125 mg/dL can also be used as diagnostic.

Hemoglobin A_{1C} measurements can be used to assess both background level of blood sugar in newly diagnosed diabetics and maintenance of glycemic control. The test results are expressed as percentage of total hemoglobin. Normal, nondiabetic samples run 4.0 to 7.0 percent. Because red blood cells have a turnover period of 120 days, the A_{1C} levels will decline toward normal values as the patient develops better control.

When a woman is diagnosed with new onset diabetes, she needs a referral from the midwife to an endocrinologist and may also benefit from a nutrition referral. Based on the severity and duration of her disease prior to diagnosis, adult women with delayed recognition of Type II diabetes may already have hyperlipidemia, hypertension, and vascular damage. Smoking cessation, weight loss, and diet and exercise modification are essential components of maintaining health in diabetic women—as indeed they are for all women. It is in these areas that the midwife can play an important role. Women with diabetes continue to need regular gynecologic care and family planning, have an increased need for preconception counseling, and will remain prone to vaginal symptoms if glucose control is not optimal. Contraceptive methods can be chosen freely with regard to the woman's stated preferences as to method. However, when using hormonal contraceptives, attention to choosing a drug with minimal effect on the lipid profile is important. Because of the increased risk of vascular disease and hypertension experienced by diabetic women, the selection of a combined oral contraceptive with less than 35 μg of estrogen is recommended [66]. The risks of pregnancy versus those of the contraceptive method must be carefully weighed. Women choosing a barrier method should consider their individual risk for recurrent vaginal infections.

Medication for Type I diabetes is always insulin, which serves as a replacement for a nonfunctioning pancreas. Insulin is administered in split doses to maintain normal or near normal glucose levels throughout the day. Many adults with Type II diabetes are able to manage with diet,

TABLE 7-14 Criteria for the Diagnosis of Diabetes Mellitus

1. Symptoms of diabetes plus casual plasma glucose concentration ≥200 mg/dl (11.1 mmol/l). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

2. FPG ≥ 126 mg/dl (7.0 mmol/l). Fasting is defined as no caloric intake for at least 8 h.

or

3. 2-h PG ≥ 200 mg/dl (11.1 mmol/l) during an OGTT. The test should be performed as described by WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use.

exercise, and weight loss. Others move through a progression of diet and exercise, to single or multiple oral agents, to insulin. Common oral medications include the sulfonureas—for example, glyburide (Micronase) or glipizide (Glucotrol), repaglinide (Prandin), metformin (Glucophage), and rosiglitazone (Avandia).

Women with impaired glucose tolerance need consistent counseling regarding the importance of exercise, weight loss, and dietary changes. A recent comparison of metformin therapy versus lifestyle changes to reduce the onset of Type II diabetes among persons with impaired glucose tolerance found that an intervention to promote weight loss and exercise was more effective than medication in delaying the onset of diabetes [67].

Thyroid Disease

Diseases of the thyroid gland are more common among women than men; in addition, hormonal changes, including pregnancy, may require alterations in therapy. Thyroid-releasing hormone from the hypothalamus stimulates pituitary release of thyroid-stimulating hormone (TSH). In turn, TSH stimulates the production and release of triiodothyronine (T3) and thyroxine (T4) from the thyroid gland. Although T3 is the more active of the thyroid hormones, little is produced in the thyroid itself. Most T3 is produced from circulating T4 as it loses iodine.

In screening for or diagnosing thyroid diseases, the first tests performed are generally TSH and free T4. Because most circulating thyroid hormones are bound to thyroid binding globulins (TBG) and other serum proteins, a total T4 is not as useful. Other laboratory tests may be valuable in confirming a clinical diagnosis. Table 7-15 shows the changes in screening laboratory values associated with common thyroid disorders.

Hyperthyroidism

The single most common cause of hyperthyroid states (also referred to as thyrotoxicosis) is Graves' disease, an autoimmune disease. It is far more common among women than men and is the cause of greater than 90 percent of cases of thyrotoxicosis in young adults. The thyroid is typically enlarged and tender. Many women will complain of irritation of the conjunctiva, diplopia, or blurred vision, or present with proptosis (the projection of the eye forward in its orbit) and periorbital edema. (Table 7-16 lists the common signs and symptoms of thyroid disease.)

Other causes of hyperthyroidism include toxic multinodular goiter, toxic adenomas, early stages of Hashimoto's thyroiditis or postpartum thyroiditis. It has also been associated with very high levels of circulating hCG, such as those found in hydatidiform mole. Subclinical hyperthyroidism occurs when the TSH is low or undetectable and free T4 and T3 are normal. This is most commonly found with suppressive thyroid therapy, although mild Graves' disease is a possible cause. The midwife should refer for physician consultation any woman in whom hyperthyroidism is diagnosed or suspected.

Various therapies exist for treatment of hyperthyroid states. The thiourea drugs such as methimazole (Tapazole) and propylthiouracil, radioactive iodine, and surgical removal of the thyroid are all used successfully. Beta-blockers may be given for symptomatic relief. None of these treatments is without risks, including the subsequent development of hypothyroidism. Thus the midwife whose patient complains of symptoms of hypothyroidism after treatment for Graves' disease or other hyperthyroid states should screen for the presence of hypothyroidism.

During pregnancy, the dose of the thiourea drugs is limited to prevent fetal hypothyroidism and goiter, and propylthiouracil is considered safer; radioactive iodine is contraindicated during pregnancy. The goal is to maintain the free T4 in a high normal range, to minimize fetal risk.

TABLE 7-15 Thyroid Hormone Values

Condition	Thyroid-Stimulating Hormone (TSH)	Free T4	Serum T3
Graves' disease	Absent	Elevated	Elevated
Subclinical hyperthyroid	<0.1 mU/L	Normal	Normal
Hypothyroid	High with primary, low with secondary	Low	Low/normal
Subclinical hypothyroid	Mildly elevated (<10.0 mU/L)	Low/normal

Weight gain (occasionally weight loss)	
Slowed speech and body movements	
Bradycardia	
Goiter	

Hypothyroidism

By far the most common cause of hypothyroidism in the United States is the autoimmune disorder known as Hashimoto's thyroiditis. Common causes of hypothyroidism are listed in Table 7-17. Hypothyroidism is more common among women than men, and the incidence increases with age. A positive family history also increases one's risk. Testing women 50 or older and those with abnormal lipid profiles is a reasonable consideration, given that disease prevalence in older adults may reach 10 percent.

TABLE 7-17	Causes of Hypothyroidism
Primary	
Autoimmune thyroiditis (Hashimoto's thyroiditis)	
Radiation of head or neck	
Radioiodine therapy for Graves' disease	
Thyroidectomy	
Iodine deficiency	
Medications (e.g., lithium, amiodarone, thioureas, interferon-alpha, interleukin-2)	
Scleroderma	
Amyloidosis	
Enzyme defects	
Secondary	
Pituitary diseases	
Hypothalamic disease	

Hypothyroid conditions can result either primarily, from failure of the gland to produce adequate hormone, or secondarily, from pituitary or hypothalamic disease. In primary hypothyroid states, the TSH will be elevated. If the original problem is along the hypothalamic-pituitary axis, the TSH will be low. Additional laboratory testing when hypothyroidism is suspected includes antimicrosomal antibodies (to confirm Hashimoto's thyroiditis), CBC and B12, and a lipid profile (often abnormal in thyroid disease).

Fortunately, therapy for uncomplicated primary hypothyroidism is generally a straightforward matter of supplementing reduced gland function. In healthy young adults, a starting dose of 50 to 100 μg/day of L-thyroxine can be titrated upward every two to three weeks until symptoms resolve and laboratory values are normal. Among older women, the increase should be slower. Usual therapeutic doses are 100 to 150 μg.

During pregnancy, total T3 and T4 rise as a result of increased TBG secretion, but free T4 should change only minimally. Monitoring thyroid status will allow for any necessary increases in levothyroxine therapy [68].

Postpartum thyroiditis is a transient condition affecting up to 5 percent of women [69]. The presentation is initially that of hyperthyroidism, followed by a period of clinical hypothyroidism, usually three to six months following birth. Most women recover spontaneously. It can recur with subsequent pregnancies and suggests an increased future risk of thyroid disease. Women who present with symptoms suggestive of postpartum depres-

sion should also have this condition considered as part of their evaluation.

Gynecologically, women with menorrhagia who do not have an obvious cause for their bleeding, such as submucosal fibroids, should have a TSH and free T4 done as part of their workup. Even subclinical hypothyroidism, with TSH in the range of 5–10 mU/L, can produce excessive menstrual bleeding [70]. It has also been suggested that women using estrogen replacement therapy may need adjustments in their levothyroxine dose [71].

Carpal Tunnel Syndrome

The carpal tunnel carries the median nerve through the wrist, where compression from edema, inflammation of the tissue, or anatomical distortion can produce the classic symptoms of carpal tunnel syndrome (CTS)—tingling, numbness, or altered sensation across the palmar surface of part of the thumb, the first two fingers, and part of the ring finger in the affected hand. Figure 7-4 illustrates the area affected by CTS. Over time, CTS almost always becomes bilateral. Pain and numbness often worsen at night.

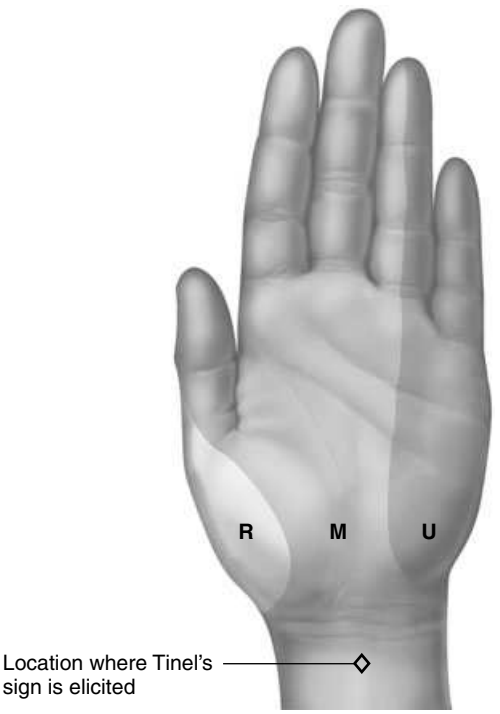

FIGURE 7-4 Distribution of sensation by the radial (R), median (M), and ulnar (U) nerves.

Two simple tests can help to confirm that the woman's complaint is consistent with carpal tunnel. First, tapping over the wrist crease in the midline should produce tingling in the affected area; this is referred to as Tinel's sign. Second, holding the wrist flexed for 30 to 45 seconds and releasing should produce symptoms; this is referred to as the Phalen test. When women engaged in a repetitive motion of the wrists at work or school complain of numbness or loss of sensation in this pattern, the risk is increasingly recognized, in part because of the increased insistence on ergonomics to reduce workplace injuries. However, pregnancy, contraceptive hormones, obesity, hypothyroid states, and diabetes, as well as arthritis and collagen vascular diseases can also produce the edema and constriction that underlies CTS [72, 73]. Other forms of nerve damage can also resemble these problems. If additional symptoms, not attributable to the median nerve, are present, prompt referral is warranted.

Initial treatment is conservative, and begins with splinting at night to place the wrist in a neutral position. For time-limited conditions like pregnancy, this may be all that is necessary. Aerobic exercise has been shown to improve the symptoms of CTS [74]. If symptoms worsen or persist, the woman should be referred to an orthopedic surgeon or neurologist for further evaluation. Treatment may then include surgical release of the nerve or injections of steroids. If left untreated, the condition will only worsen over time and eventually lead to permanent decrease in sensation.

Headache

The common categories of headache in women of reproductive age are migraines and tension-type headaches, with up to 90 percent of women reporting at least one headache per month. Other less common causes include infections, cluster headaches, arteriovenous malformations, cerebrovascular events, meningitis, tumors, glaucoma, sinusitis, medication overuse, and even dental problems. For this reason, atypical, unusually severe or unresponsive headaches should be promptly referred to a neurologist for evaluation. In addition, anyone who complains of "the worst imaginable headache" or "the worst headache I've ever had" should have an urgent evaluation by a physician to consider the possibility of hemorrhage into the brain. Finally, headaches which are of new onset

after the age of 40 carry an increased risk of being associated with a tumor and should be referred promptly. Midwives who choose to manage common headaches should have a readily available consulting physician who is knowledgeable about headache therapy. The increasing use of antidepressants in the treatment of headache may limit the ability of midwives to manage these conditions in states where the ability to prescribe psychoactive drugs is limited.

Taking a careful history as well as collecting a full description of headache symptoms, their frequency and onset, precipitating factors, menstrual history, family tendency, and secondary symptoms—for example, rash, fever, stiffness of the neck, visual changes, and head trauma—are essential to diagnosis. Physical examination assesses for neurological changes, pain from sinus or jaw problems, localization of current symptoms, and symptoms of headache secondary to other conditions. Characteristic features of the common headache types are shown in Table 7-18.

Migraine

Migraine headaches usually develop in late adolescence or early adulthood, and their frequency rises into middle age, after which they become less common. Classic descriptions include severe, unilateral, throbbing pain, often with associated nausea, vomiting, photophobia, or phonophobia. Migraineurs—people who have been diagnosed with migraine—are more common among women, with a population estimate of approximately 18 percent [75]. However, among those whose self-described symptoms meet the International Headache Society criteria for migraine, only half are diagnosed by their physicians [76]. Because of the severity of migraine, underdiagnosis and undertreatment lead to significant loss of productivity and decreased quality of life. It is important to recognize that the basic cause of migraine is an increased sensitivity to neurological stimuli, not the vascular changes that follow.

A prodrome of widely varying symptoms lasting for hours or several days before the onset of headache may be described by half or more of all

TABLE 7-18 Clinical Characteristics of the Primary Headache Syndromes

Feature	Migraine without Aura	Migraine with Aura	Tension-Type Headache (Episodic)	Cluster Headache (Episodic)
Prevalence	Common	Uncommon	Common	Rare
Gender	Females>males	Females>males	Females>males	Males>females
Family history	Frequent	Frequent	Frequent	Rare
Age at onset (yr)	10–30	10–30	20–40	20–40
Prodrome	Common	Common	None	None
Aura (visual)	None	Present	None	None
Site of pain	Hemicranial, bilateral	Hemicranial, bilateral	Bilateral, occipital, frontal	Unilateral, frontotemporal periorbital
Character of pain	Pulsatile	Pulsatile	Aching, tight, squeezing	Boring
Severity of pain	Moderate to severe	Moderate to severe	Mild to moderate	Severe
Onset to peak pain	Minutes to hours	Minutes to hours	Hours	Minutes (rapid)
Duration of pain	Usually 4–24 hrs	Usually 4-24 hrs	Hours to days	30–90 min
Frequency of attack	Variable, several per month	Variable, several per month	Variable, several per month	Daily during cluster period
Periodicity of attacks	No (exception, menstrual migraine)	No (exception, menstrual migraine)	No	Yes, "like clockwork"
Accompaniments	Nausea, vomiting, photophobia, phonophobia, osmophobia	Nausea, vomiting, photophobia, phonophobia, osmophobia	Nausea on occasion	Ipsilateral nasal congestion, rhinorrhea, conjunctival injection, ptosis, lacrimation
Behavior during headache	Still, quiet	Still, quiet	No change	Pace
Nocturnal attacks of pain	Can occur	Can occur	Very rare	Extremely frequent
Triggering factors	Multiple	Multiple	Stress, elevation	Alcohol, sleep, emotional upset

migraineurs. Photophobia, phonophobia, mood changes, irritability, drowsiness, increased thirst, and hunger are the most commonly mentioned symptoms. Aura is experienced in the hour before headache onset by 10 to 20 percent of migraineurs. Visual changes such as scotomata, subjective visual images, and loss of visual field after appearance of bright, zigzag visual images are the most common aura. Paresthesias, disturbance of motor function, and disturbances of thought or speech are less common [77].

A number of lifestyle changes may improve the frequency of migraine. These include the avoidance of substances that the individual can identify as headache triggers (such as cheese, alcohol, or chocolate), stress reduction, and stable patterns of eating and rest.

Pharmacologic therapy depends on the severity and frequency of attacks. In mild cases of migraine, NSAIDs taken in maximal doses can be used as abortive therapy, especially if they can be taken during the warning prodrome. Acetaminophen 1000 mg can also be tried. There is evidence that the combination of aspirin, acetaminophen, and caffeine may have an increased benefit [78]. Among prescription drugs, ergotamine preparations such as Cafergot, the triptans—for example, sumatriptan (Imitrex) and naratriptan (Amerge)—and tricyclic antidepressants such as nortriptyline or amitriptyline are common first-line therapies. Women of childbearing age should be on an effective contraceptive method when using these medications, and those planning a pregnancy may require a change in therapeutic management.

During pregnancy, the incidence and severity of migraine are reported to decrease by as much as 70 percent, with rebound occurring during the postpartum period. Treatment is limited in most cases to acetaminophen and supportive measures. For obvious reasons, ergotamines should be avoided during pregnancy. The use of triptans is still controversial, although recent data do not indicate an increase in adverse pregnancy outcomes with sumatriptan [79, 80].

Menstrual migraine is the term used for headaches appearing only in association with menses and ovulation, which occurs in about 14 percent of women. Maintaining a stable estrogen environment can decrease the severity and frequency of these headaches [81]. One way to do this is with the use of monophasic combined oral contraceptives, particularly if they are prescribed to be taken in a long cycle, skipping the inert pills until three cycles are complete (i.e., the 21 hormonally active pills from each of three packages are taken sequentially before the pills are stopped for one week).

Tension Headache

Tension headaches are divided into two categories: chronic and episodic. Occurring in women more often than in men, the typical onset is in young adulthood. When tension headaches are episodic, women rarely present seeking treatment; chronic tension headaches that persist for hours and recur frequently are a more serious problem. Holroyd and colleagues reported that among persons with chronic tension headaches most were able to continue working and managing daily activities, but they had decreased ability to function, their sleep was disturbed, and emotional well-being was decreased [82]. Compared with matched controls, those with a diagnosis of chronic tension headache were significantly more likely to have anxiety or mood disorders.

Respect for the woman's complaints, assessment of the risk and need for treatment for anxiety or depression, and promotion of lifestyle changes that include relaxation and stress reduction are all part of providing care. Symptomatic therapy with NSAIDs or acetaminophen can be used, although the relief obtained may be greater with milder disease. One study recently compared the combination of ibuprofen 400 mg plus caffeine 200 mg with either drug separately and to placebo, and demonstrated a significantly increased benefit from the combination as reported by participants [83]. In another study, comparison of behavioral therapy for stress management with tricyclic antidepressant therapy showed a modest benefit for either intervention [84]. A combination of the two modalities reduced overall headache activity in about two-thirds of the participants by 50 percent [84].

Depression

Depressive disorders may affect more than 20 percent of women seen in primary care, depending on the definitions used. Approximately twice as many women as men suffer from depressive disorders, with an annual incidence of 13 percent, and a lifetime risk of one in five for major depression alone [85]. There is good evidence that depression is underdiagnosed in primary care, either because clini-

cians do not know how to identify it or because they choose not to recognize it when presented with symptoms. Major depression is a recurrent illness for half of the women who experience these symptoms.

The DSM-IV criteria for major depression include five or more of the following symptoms, present for a two-week period and representing a change from prior function. Either of the first two criteria must be present:

1. Depressed mood nearly every day for most of the day either by self-report or observation
2. Diminished or absent pleasure in all or most activities, most of the day, most days
3. Significant weight loss or gain (>5 percent), or decreased or increased appetite nearly every day
4. Insomnia or hypersomnia
5. Psychomotor agitation or retardation (must be observed by others)
6. Fatigue or loss of energy
7. Feelings of worthlessness, or inappropriate or excessive guilt, possibly delusional
8. Decreased ability to concentrate or think clearly, indecisiveness
9. Recurrent thoughts of death, suicidal ideation, or a suicide plan or attempt

The symptoms must cause significant impairment of life activities or distress, and cannot be accounted for by loss of a loved one or other major life loss [86].

Dysthymia is a more low-grade, chronically depressed state, in which mood is depressed most days, for most of the day, for two or more years. It is associated with at least two of the following characteristics:

1. Changes in appetite
2. Insomnia or hypersomnia
3. Fatigue, decreased energy
4. Low self-esteem
5. Poor concentration, difficulty with decision-making
6. Hopeless feelings [86]

Women who present with complaints that suggest depression should also be evaluated for medical conditions such as hypothyroidism or severe anemia that might produce similar symptoms. Pain or chronic disability from conditions such as arthritis, stroke, or heart disease may also produce depressive symptoms. It is important not to neglect either aspect of the woman's needs. Her depression is as real and as significant in her life as the physical conditions with which she is living.

Both psychotherapy and medications are important in the management of depression. Behavioral changes need to be incremental, as women with depression are already feeling overwhelmed. Goals need to be set in increments that allow for the positive reinforcement of visible achievements. Apart from crisis intervention, counseling is a long-term process, one for which few midwives are qualified or have the time to provide in the office setting. Maintaining a referral network that includes psychiatric services is essential.

Common medication classes for depression include the selective serotonin reuptake inhibitors (SSRIs), tricyclic compounds, and monoamine oxidase inhibitors (MAOIs), as shown in Table 7-19.

TABLE 7-19 Examples of Medications Used in the Treatment of Depression and Related Disorders

Class	Initial Dose	Maximum Dose	FDA Pregnancy Category
Selective Serotonin Reuptake Inhibitors (SSRIs)			
Citalopram (Celexa)	20 mg po QD	60 mg po QD	C
Fluoxetine (Prozac)	20 mg po QAM	90 mg po QAM	C
Paroxetine (Paxil)	20 mg po QD	50 mg po QD	C
Sertraline (Zoloft)	50 mg po QD	200 mg po QD	C
Antidepressants			
Venlafaxine (Effexor)	37.5–75 mg po bid	375 mg/day	C
Buproprion (Wellbutrin)	100 mg po bid	450 mg/day	B
Tricyclic Antidepressants			
Amitriptyline (Elavil)	50–100 mg po QHS	150 mg/day	C
Imipramine (Tofranil)	75 mg/day	200 mg/day	N

SSRIs are generally favored as first-line drugs because they have fewer anticholinergic effects as well as problems related to weight gain and the cardiovascular system. MAOI drugs are less commonly used because of the many food interactions that require dietary restriction. All of these classes of drugs do have negative side effects, and the midwife who considers prescribing any of these should be familiar with them.

Medication, while easy to prescribe for depression requires monitoring for titration to an effective dose and subsequent stability. Patients newly started on an antidepressant need information about interactions and side effects. They then need to be seen on a one- to two-week basis for six weeks, and reevaluated at 12 weeks. If the first choice of medication is partially effective, a dose change is advised. If the first choice is ineffective, a change in therapy, after a washout period to clear one drug from the body if another class is prescribed, is recommended. Those not in complete remission by 12 weeks need referral to a mental health specialist.

Because the antidepressant medications, particularly SSRIs and the atypical antidepressants, are being used for management of other problems, including premenstrual syndrome and menopausal symptoms, the midwife may find herself using these medications more frequently.

Conclusion

Deciding the scope of midwifery practice issues used to be a simple matter: Midwives took care of healthy pregnant women and helped them give birth. The recognition then came that women's family planning needs could be well served by midwives. Managing office-based gynecologic problems like infections, answering the questions that came with life changes, and addressing menopause all began to be recognized as part of the core of midwifery practice.

Of course, midwives never did care only for healthy women, if for no other reason than that many of the women we have traditionally served were at risk by age, socioeconomic status, and lack of access to other health care resources. Today midwifery is practiced in a health care system in which the only provider many women see is their "women's health" provider. And midwives still care for pregnant women.

What does this mean for the student of midwifery? First, it means an obligation to correctly identify common complaints—minor and major. This includes the obligation to describe accurately those symptoms or signs for which you cannot make a diagnosis. Second, it requires an ability to assess and triage these complaints. Which can you personally manage? Which require referral? Which will you care for, or direct the care of, because the woman is pregnant and her other sources of care are not familiar with the interactions of mother and fetus? These are matters for individual decision-making, with the stipulation that as a midwife you must have a resource for consultation and referral that is accessible. Midwives who practice primary care need to be sure that consultants include resources who are knowledgeable about primary health care concerns. In fact, all midwives need to know to whom they will refer cases beyond their scope of practice. This can include nurse-practitioners or physician assistants as well as physicians. Not all obstetrician-gynecologists are comfortable in the primary care role; not all women have an identified primary care provider.

The astute reader may have noticed the frequency with which reference has been made in this chapter to counseling about lifestyle changes in order to prevent or treat diseases. One of the assets midwives bring to primary care for women is our understanding of the importance of health maintenance and disease prevention. This is the same strength we bring to pregnancy care and birth, the understanding that in order to maintain normalcy attention must be paid to the everyday aspects of health: from nutrition and exercise to substance use or abuse. Furthermore, to maintain normalcy, the midwife must be able to recognize when it is not present. Every midwife has an obligation to provide this aspect of primary care with all women.

CHAPTER

8

Chronic Infectious Diseases

Infectious diseases, ranging from the common cold to mastitis, are discussed in this book in several chapters. This chapter provides an overview of three separate issues, each of which is a chronic disease that carries its own risks to women and their families: (1) human immunodeficiency virus and acquired immune deficiency syndrome (HIV/AIDS), (2) the family of hepatitis infections, and (3) tuberculosis. Most midwives will not be the primary clinicians for women with any of these chronic diseases but will provide women's health care in consultation with a physician or other clinician.

HIV/AIDS

In the United States, HIV is a disease that has disproportionately attacked women who are poor, urban, and of color. These are all markers for social conditions that leave individuals at greater risk within our society. But those infected with the virus have been further stigmatized by the early perception that HIV was a disease of homosexual men and drug abusers. As the heterosexual transmission of HIV increases the proportion of those infected who are women, the U.S. data have begun to resemble more closely the statistics from the rest of the world. In considering counseling, screening, and treatment programs for women, the devastation that unchecked heterosexual and perinatal transmission bring to countries and cultures always needs to be considered. This is not a disease that can be ignored because "it can't happen here." It can.

Natural History

The human immunodeficiency virus is an RNA retrovirus that preferentially attacks T-helper lymphocytes (CD4 cells) as well as other cell types. The natural history of HIV begins as an initial viral syndrome within the first month after exposure, including fever, muscle aches, sore throat, lymphadenopathy, and other nonspecific symptoms. During this time, the virus is rapidly reproducing, causing a drop in the CD4 count and a high viral load [1, 2]. Except in cases where the risk of transmission is appreciated, these early symptoms are generally interpreted as a simple viral infection and treated symptomatically. As the body mounts an immune response, the viral load subsides and the CD4 cell number increases. In uninfected adults, a normal CD4 count ranges from 500 to 1500.

For a period of time that may exceed ten years, the disease remains hidden. Although the virus continues to replicate and destroy CD4 cells, these are rapidly replaced until the immune system is too worn down to maintain its protective effect. In the later stages of the disease, falling CD4 levels reach a point at which the body can no longer defend itself from common ailments or from diseases that do not commonly attack humans (opportunistic infections). Figure 8-1 depicts the natural history of HIV infection in the human body.

Median time from infection to an AIDS defining condition is between eight and ten years. Among the factors that can affect the rate of disease progression are age, race, gender, IV drug abuse, and both genetic and viral characteristics. Women appear to have levels of virus in the bloodstream that are relatively lower than those in men at all stages of disease progression [3]. The diagnosis of

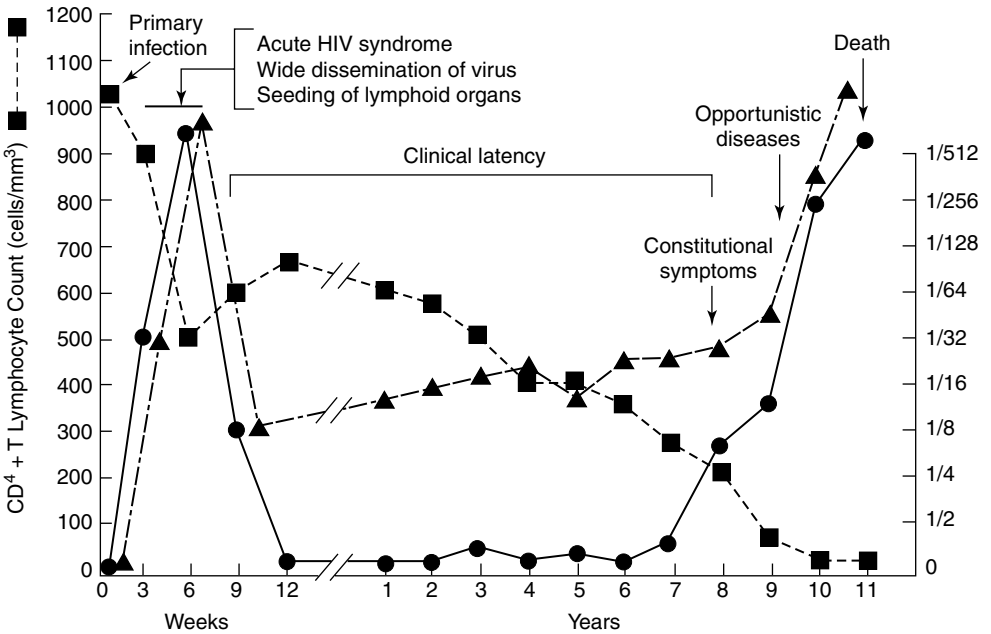

FIGURE 8-1 Natural history of HIV disease.

Source: From Fauci, et al. Immunopathogenic Mechanisms of HIV Infection. *Ann Intern Med*. 1996;124:654–663.

AIDS is based on specific clinical findings, as shown in Table 8-1.

Transmission

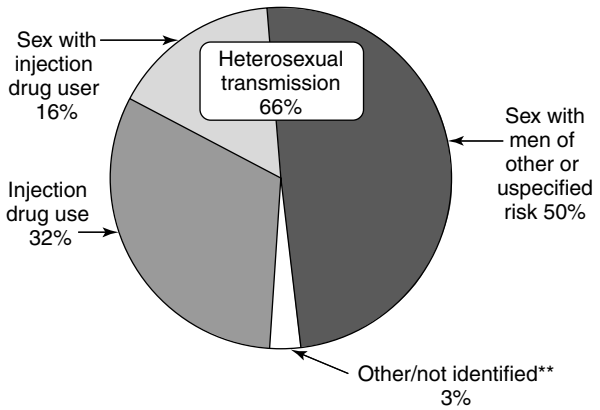
Transmission of HIV occurs sexually, through exposure to blood or other body fluids, and perinatally. For women, sexual transmission has become the prevalent mode, even in the United States, where intravenous substance abuse with sharing of needles was once believed to be the primary route. Data from the Centers for Disease Control and Prevention (Figure 8-2) illustrate the relative risks of exposure types for women. On diagnosis, many women report no known risk, which is to say that they are not involved in drug use, nor are they involved in sex work, nor do they recall any cutaneous exposure. When the final determination of risk is made, about two-thirds of all women in the United States with HIV/AIDS have been exposed sexually [4]. Younger age is associated with increased sexual risk, as are multiple partners, partners with known risk factors, history of sexually transmitted diseases, and failure to use a protective barrier during intercourse.

Rates of transmission between heterosexual partners are affected by level of infectivity in the affected partner, use of a protective latex barrier such as a condom, and concurrent infections with other sexually transmitted diseases.

TABLE 8-1 Criteria for AIDS Diagnosis

CD4 Count <200 cells/mm^3
Invasive cervical cancer
Candidiasis of bronchi, trachea, lungs, esophagus
Extrapulmonary cryptococcosis
Disseminated or extrapulmonary coccidiomycosis
Cryptosporidiosis >1 month
Cytomegalovirus other than liver, spleen, or lymphatic
HIV encephalopathy
HSV lesion persisting >1 month, or bronchitis, pneumonitis, esophagitis
Disseminated or extrapulmonary histoplasmosis
Isosporiasis >1 month
Kaposi's sarcoma
Burkitt's lymphoma
Immunoblastic lymphoma
Primary lymphoma of the brain
M. avium complex
M. tuberculosis
Other mycobacterial infections outside the lungs
Pneumocystis carinii pneumonia
Recurrent pneumonia, any cause
Multifocal leukoencephalopathy
Recurrent salmonella septicemia
Toxoplasmosis of the brain
Wasting syndrome

Source: Centers for Disease Control and Prevention. 1993 Revised Classification System for HIV Infection and Expanded Surveillance Case Definition for AIDS Among Adolescents and Adults. MMWR 41(no RR-17). December 18, 1992. Accessed online at cdc.gov/mmwr/preview/mmwrhtml/00018871.htm.



*Data adjusted for reporting delays and estimated proportion and distribution of cases initially reported without risk.
Data reported through June 2002.
** Includes patients whose medical record review is pending, who died, were lost to followup, or declined interview; and patients with other or undetermined modes of exposure. Includes sex with a bisexual male, a person with hemophilia, transfusion recipient with HIV infection, or an HIV infected person with an unspecified risk.

FIGURE 8-2 Risk factors for transmission of HIV in women.

Source: From Centers for Disease Control and Prevention. Accessed online on February 14, 2003, at www.cdc.gov.

Transmission from the male to female partner is significantly more common than the reverse. Estimates of transmission with a single act of unprotected intercourse have ranged from 9/10,000 to as high as 5/1000 [5, 6]. Some factors that affect viral shedding at the cervix, and thus increase the risk of an HIV positive woman infecting her partner, include pregnancy, cervical ectopy, hormonal contraceptives, vaginal infections, STDs, and disease progression as shown by high viral load or decreased CD4 count.

There are a number of counseling issues that arise when infected women or men are sexually active and ask about heterosexual transmission, including counseling about the use of contraception plus an effective barrier, the possible desire of a couple for a child, whether the uninfected partner is aware of their partner's status, and the affected person's level of infectivity. Midwives have an obligation to provide unbiased information to all our patients, and need to seek out community or other resources as needed to meet the woman's information and care needs. Part of that responsibility is to educate and support women in disclosing their disease status to partners, or to provide her with other resources for doing so.

Transmission through exposure to blood and body fluids (exclusive of sexual transmission) is strongly associated with intravenous substance abuse. However, it is essential to realize that any open skin lesion is a portal for this type of transmission. Health care workers, including midwives, are at risk of exposure whenever universal precautions are not followed (see Chapter 45). Most clinicians do not take chances with the person they know to be infected with HIV. But many women with HIV are unaware that they are at risk, much less infected. Universal precautions means not taking chances based on a mistaken belief that one can "tell" who is at risk.

The CDC maintains guidelines for post-exposure prophylaxis [7] that are regularly updated. These can be found at www.cdc.gov/hiv/pubs/guidelines.htm. Anyone who experiences a needlestick or splash injury should check with their employee health unit or personal physician regarding management. Not all exposures carry the same degree of risk, and the best time to deal with an exposure is immediately.

Perinatal transmission is discussed in the section on pregnancy and HIV.

Counseling and Testing for HIV

The CDC recommends testing for HIV in a number of specific circumstances. Currently described populations at increased risk include women attending STD clinics and any adolescent program with a high rate of STDs, substance abuse programs, homeless shelters, outreach/needle exchange programs, and tuberculosis clinics. Testing is also recommended in other instances regardless of identified risk [8]. Table 8-2 lists those for whom HIV testing is currently recommended. Stigma associated with HIV diagnosis, and the implication of risky behavior in asking for the test long delayed acceptance of HIV screening as an important component of preventive health care. Whether the woman is requesting HIV testing, for example, after an unplanned, unprotected sexual encounter, or whether you are recommending testing, as with pregnancy, counseling and informed consent are essential components of care.

Counseling prior to the performance of HIV testing includes a focused discussion of risk reduction for the individual including collecting the data for a risk assessment (see Table 8-3), acknowledging current attempts the woman is making to reduce her risk, and being specific in discussing her current risks and understanding of HIV. This session is also a time when further risk reduction plans can be made and skills reinforced—for example, negotiating condom use. Counseling prior to HIV testing, like all other health care counseling, should be individualized [8].

TABLE 8-2 Recommendations for When to Test for HIV

1. All clients in settings where the population is at increased behavioral or clinical risk of HIV
   a. adolescent and school-based clinics with high STD rates
   b. clinics serving men who have sex with men
   c. correctional facilities including juvenile detention
   d. drug and alcohol programs
   e. freestanding HIV testing sites
   f. homeless shelters
   g. outreach (e.g., needle exchange) programs
   h. STD clinics
   i. TB clinics
2. Individual in settings with <1% HIV prevalence
   a. clinical signs or symptoms of HIV infection
   b. have diagnoses suggesting increased HIV risk
   c. self-report HIV risks
   d. specifically request the test
3. All clients in settings where the prevalence of HIV is >1%
4. Regardless of any of the above
   a. all pregnant women
   b. all persons with possible occupational exposure
   c. all clients known to be exposed to an HIV positive person sexually or through needle sharing

TABLE 8-3 Risk Assessment Questions for HIV in Women

How many sexual partners have you had in your lifetime? This year?
How old were you the first time you were sexually active?
Are your partners men, or women, or both?
What have you used to protect yourself from pregnancy? From sexually transmitted infections?
Have you ever had an abnormal Pap smear or an STD or hepatitis?
Have you ever used an IV drug, or used other drugs like crack?
Have you abused alcohol?
Have you ever shared a needle?
Have any of your partners ever used drugs, shared needles, been in jail, had an STD, had hepatitis, worked as a prostitute, or traded sex for drugs/money?
Are you concerned that you have been put at risk for catching HIV?

Sources: From Anderson, J. R. *A Guide to the Clinical Care of Women with HIV* 2001. Centers for Disease Control and Prevention *Sexually Transmitted Diseases Treatment Guidelines* 2002. May 10; 51(RR-6):1–80. Accessed at www.cdc.gov/hiv/pubs/mmwr/mmwr2002.htm.

Posttest counseling for women whose results are negative offers a chance to reinforce positive messages about prevention of infection and makes sure that she understands the limitations of the test. For women whose results are positive, hearing the test results may block all further effective communication for a time. Empathic listening and emotional support are an important part of this visit. In this case, the next contact needs to be set before she leaves the site, for ongoing support, education, and clinical care.

Pregnancy raises some specific concerns. The Institute of Medicine report *Reducing the Odds*, which was released in 1999, emphasized the need for routinizing HIV testing during pregnancy. Most evidence suggests that 6000 to 7000 HIV seropositive women give birth every year in the United States. The concerns expressed by many of the participants and the expert panel illustrated the tension between public health and risk reduction on the one hand, and the individual's right to privacy and informed consent on the other [9]. An increasingly common approach is to offer HIV testing as a part of routine prenatal care and have women who wish not to be tested refuse consent. The CDC recommendation regarding HIV testing during pregnancy is universal counseling and voluntary testing. All pregnant women should ideally be tested for HIV as early in pregnancy as possible. However, no woman should be required to be tested or have the test done without her consent. Women with identified risk factors (e.g., STD exposure, IV drug use, multiple sexual partners) or who initially declined testing should be offered repeat testing during the third trimester, after an open discussion of any concerns.

When a woman has not been tested during pregnancy, offering her a rapid HIV test during her labor may present another opportunity for intervening to prevent perinatal transmission of HIV. At least two currently marketed tests are available that can provide results within 1 to 2 hours. The same standards apply to counseling and informed consent during labor as at any other time.

The current standard for HIV testing is to run an enzyme-linked immunosorbent assay (ELISA) and repeat it if positive, before performing the Western blot to confirm HIV-positive status. The initial ELISA can cross-react to give a false-positive result if it is used without the confirmatory test. For the Western blot to be read as positive, antibodies to two or more protein "bands" found in HIV must be present. The presence of a single band is inconclusive and may be the result of recent HIV expo-

sure or a chronic finding. Among the causes of these persistent inconclusive results are autoimmune or collagen vascular diseases, alloantibodies from pregnancy or transfusion, and infection with rare HIV subtypes or HIV-2. True false positives, to both ELISA and Western blot, are less than 0.001 percent in low prevalence areas [10].

The use of rapid tests in settings where quick results are essential or women may not return for results can expedite initial care. However, it should always be kept in mind that these tests are not conclusive until the confirmatory Western blot has been run. Since the interim results are immediately available, unlike standard tests in which results are rarely reported until both tests have been completed, the midwife has a responsibility to advise the woman tested during her labor that she is at high risk for HIV, but NOT that she has a confirmed diagnosis. Prophylaxis for the prevention of perinatal transmission of HIV can then be offered for the period of time required to obtain results of the confirmatory test. Usually this will include both intrapartum therapy for the mother and a few days of zidovudine syrup given to the newborn.

One final aspect of HIV counseling has to do with reproductive counseling for the woman known to be HIV positive, or to have an HIV-positive partner. Preconceptional counseling for these women includes the risk of transmission with sexual intercourse, the factors such as viral load that affect that risk, risks of mother to child transmission and how to decrease that risk, the risks and benefits of antiretroviral medication, and the issue of having children while living with a chronic and life-threatening disease. Family planning should also be raised as part of this discussion.

Monitoring HIV Progression

Other than the tests mentioned previously for use in diagnosis of HIV, there are many others used to evaluate health and disease progression. Several of these are particularly important for the midwife to be familiar with, in order to interpret the woman's health status. These include measurement of the CD4 subset of lymphocytes, plasma viral load, changes in the CBC and chemistry panels, and tests of disease resistance. Measuring CD4 counts is one way to measure disease progression, since over time the constant turnover of these cells depletes the body's ability to regenerate new ones. The amount of virus present in the blood is another way in which disease progress is evaluated, since higher viral loads indicate more strain placed on the immune system and therefore higher likelihood of disease progression.

CD4 Lymphocyte Count The CD4 cells are one group of the T-lymphocytes. Over the course of HIV disease, CD4 counts are used to measure the degree of immune suppression, or how effectively the body is protecting itself from the virus. Values in healthy nonpregnant adults are generally above 500 cells/mm^3. The results of this test are usually reported both as an absolute value and as a percentage of lymphocytes. The lower level of normal is about 32 percent. Factors other than HIV infection can cause drops in this value, including pregnancy, drug abuse, steroid use, and other illnesses; diurnal variation is also a factor. For this reason, the CD4 count is not a test used in diagnosing HIV. When the CD4 count falls below an absolute level of 200 cells/mm^3, a diagnosis of AIDS is made, based on decreased immune competence. As with all the tests discussed in this section, remember that each laboratory may report their own set of normal values; the midwife needs to be aware of the standard values used in the laboratory, as well as of the possibility of variation between labs.

Viral Load Testing Several genetically based tests to measure the amount of virus present in the blood are available. All of them have a lower limit, below which virus is present but not in measurable amounts, and an upper limit, although greater quantities of virus may well be present. The one most frequently reported is the HIV PCR-RNA. Initially, a standard test, which measures RNA between 400 and 750,000 viral particles per milliliter, should be used to assess the level of infectivity. Once a woman is on HIV therapy, an ultrasensitive test, which measures as low as 20 copies/milliliter, can be used to monitor the effectiveness of therapy. The same version of the test should be used consistently, since each reports slightly different values. From the standpoint of clinical care, it is essential to understand that these tests measure the level of virus only in the bloodstream. Other tissue reservoirs may persistently maintain a latent source of virus. In addition, the amount of virus in cervical secretions may vary from that in the blood [11].

Tests of Viral Resistance Over time, the HIV virus mutates in the body and can become resistant to various medications, or even classes of medication. Both phenotype and genotype assays can be performed to determine whether a rising viral load is

due to resistance or to some other factor, such as not taking medication that has been prescribed. These tests should only be ordered by the person who is responsible for the long-term management of the woman's care, since the effectiveness of future medication regimens depends on careful selection among available choices. If the midwife is participating in the care of HIV-positive women, whether during pregnancy or for family planning and well-woman care, it is essential that the woman also have access to a primary care provider experienced in HIV management on whom the midwife can call for therapeutic concerns.

Changes in General Laboratory Values Women with HIV may also experience changes in standard laboratory values. The CBC may show a macrocytic anemia in women using zidovudine during pregnancy, or with any regimen in which zidovudine included. A decrease in WBCs or thrombocytopenia may also be seen with HIV. The protease inhibitors can produce hyperglycemia. Many of the antiretrovirals cause changes in liver and kidney function as may other health issues such as alcohol use or hepatitis. Adverse reactions to some medications may produce severe lactic acidosis. Abnormalities found on blood tests should be reported to the woman's primary provider.

Medication Therapy for HIV

There are currently four classes of medication available commercially in the United States for treatment of HIV: (1) nucleoside and nucleotide reverse transcriptase inhibitors, (2) nonnucleoside reverse transcriptase inhibitors, (3) protease inhibitors, and (4) fusion inhibitors. Each is named for the timing of its intervention in viral replication. By combining medications from one or more of these classes, viral replication can be suppressed almost completely. Table 8-4 gives examples of the medications found in the major classes.

CDC Guidelines

The Centers for Disease Control and Prevention publishes and regularly updates guidelines for the management of HIV disease. These guidelines discuss such issues as when to begin therapy, appropriate drug combinations for initial and continuing therapy, adherence to therapy, and evaluation of drug resistance. Midwives involved in the care of women living with HIV should familiarize themselves with this material, which is regularly updated at the CDC Web site (www.cdc.gov) [12].

HIV in Pregnancy

During pregnancy, many of the "rules" for treating HIV disease change. In untreated populations the standard absolute risk of mother-to-child transmission (MTCT) without breastfeeding is given as 25 percent. About 5 to 10 percent is antepartum, and up to 20 percent intrapartum. Breastfeeding adds an additional 5 to 15 percent absolute risk of transmission [13].

Where the usual management as of this writing is to delay the onset of antiretroviral therapy in adults until the CD4 count has declined to 350 cells/mm^3 or less, therapy for the prevention of MTCT is aimed at maintaining a nondetectable viral load regardless of the CD4 count. The rationale is that viral levels are directly associated with infectivity. Although most perinatal infection (66 to 75 percent) occurs around the time of birth, the remaining portion has already occurred antenatally [14]. Many factors affect the risk of transmission during pregnancy and birth. An elevated viral load, clinical disease progression, coinfection with STDs, hepatitis C and other diseases, substance abuse, smoking, multiple sexual partners and unprotected intercourse, preterm birth, chorioamnionitis, and invasive fetal monitoring or testing, are among the factors that increase risk of MTCT [15–19].Viral load also varies among body compartments, so that blood levels of HIV may not directly correlate with cervical secretions, although they appear to behave similarly [11].

Medications for HIV During Pregnancy The original treatment for prevention of HIV transmission during pregnancy, zidovudine monotherapy, was initiated as the Pediatric AIDS Clinical Trial Group (ACTG) 076 Trial in the early 1990s. The clinical effect of this three-part (antepartum, intrapartum, and neonatal) treatment was to reduce MTCT by two-thirds, from 25.6 to 8.3 percent [20, 21]. This remains the minimum standard of care for pregnant women with HIV, regardless of viral load. More effective regimens, called highly active antiretroviral therapy (HAART) regimens, have further reduced the risk to 1 to 2 percent [22, 23]. The midwife providing care for HIV-positive women during pregnancy coordinates medication therapy with an infectious disease specialist or primary care physician experienced in HIV management in order to maintain the most effective long-term options for treatment. Women already taking HAART should continue without stopping medication in the first trimester; newly diagnosed women, and those not

TABLE 8-4 Classes of HIV Medication

Generic Drug Name, Abbreviation (Brand)	*FDA Category*	*Dose*
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs)		
Zidovudine, AZT (Retrovir)	C	300 mg po bid
Lamivudine, 3TC (Epivir)	C	150 mg po bid
Didanosine, ddI (Videx)	B	<60 kg 250 mg po qd or 125 mg po bid (tabs) OR 250 mg po qd or 167 mg po bid (powder) >60 kg 400 mg po qd or 200 mg po bid (tabs) OR 500 mg po qd or 250 mg po bid (powder) OR Videx EC 400 mg po qd
Zalcitabine, ddC (Hivid)	C	0.75 mg po tid
Stavudine, d4T (Zerit)	C	<60 kg 30 mg po bid >60 kg 40 mg po bid
Abacavir, APV (Ziagen)	C	300 mg po bid
AZT + 3TC (Combivir)	C	300 mg AZT + 150 mg 3TC po bid
AZT + 3TC + ABC (Trizivir)	C	300 mg AZT + 150 mg 3TC + 300 mg ABC po bid
Tenofovir DF (Viread)	B	300 mg po qd
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
Generic Drug Name, Abbreviation (Brand)	*FDA Category*	*Dose*
Nevirapine, NVP (Viramune)	C	200 mg po bid
Delavirdine, DLV (Rescriptor)	C	400 mg po tid
Efavirenz, EFV (Sustiva)	C*	600 mg po qhs
Protease Inhibitors (PIs)		
Generic Drug Name, Abbreviation (Brand)	*FDA Category*	*Dose*
Saquinavir, SQV,hgc (Invirase)	B	400 mg po bid with RTV
Saquinavir, SQV,sgc (Fortovase)	B	1200 mg po tid
Ritonavir, RTV (Norvir)	B	600 mg po bid
Indinavir, IDV (Crixivan)	C	800 mg po q 8 hours
Nelfinavir, NFV (Viracept)	B	750 mg po tid OR 1250 mg po bid
Amprenavir, APV (Agenerase)	C	1200 mg po bid (caps) OR 1400 mg po (oral solution)
Lopinavir/Ritonavir, LPV/RTV (Kaletra)	C	400 mg LPV + 100 mg RTV po bid

* Not used in pregnancy due to primate studies showing teratogenicity.

Note: Many of these drugs have specific dosing requirements, medication interactions, and/or significant side effects beyond the scope of this reference. Interested readers are referred to www.hivatis.org for current antiretroviral information.

currently on medication, should wait until organogenesis is complete before beginning therapy. Considerations in prescribing medications during pregnancy include the woman's own medication needs and ability to adhere to complex regimens, prior therapy, and potential for the development of resistance. Balancing short-term prevention of MTCT with the lifetime therapy of the mother is beyond the scope of basic midwifery practice.

Although all HIV medications currently marketed are classified as either FDA Class B or C (see Table 10-6), the data on fetal and neonatal effects largely come from pragmatic prescription of medication for the mother's own need and reduction of viral load. Zidovudine remains the only medication used for a long enough period to state that outcomes for uninfected children indicate no long-term problems [24].

Studies of women taking antiretrovirals during pregnancy, compared with HIV-positive women not on medication, have shown no increase in fetal loss, preterm birth, or low birth weight [25]. However, significant adverse events have occurred that can affect the outcome of individual pregnancies, such as mitochondrial insufficiency and lactic acidosis. Simply knowing the FDA category is not enough to ensure safe use. Efavirenz (Sustiva) is known to produce teratogenic effects in primates and is therefore not used during pregnancy despite its category C rating. The antiretroviral pregnancy registry maintains an ongoing database of infant outcomes.

During labor, women who have received antiretroviral therapy during pregnancy should receive intravenous zidovudine. Depending on the specific circumstances they may also be given a single oral dose of nevirapine. Women who have not received any antiretrovirals during pregnancy, whether because they have not obtained prenatal care or because they are newly diagnosed at the time of labor, should receive both zidovudine and nevirapine [26].

Route of Birth and Risk of Transmission Several studies have now demonstrated a reduction in risk of transmission when birth occurs by cesarean section, at term, prior to the onset of labor, and with intact amniotic membranes. This reduction can exceed 50 percent, and is independent of other factors such as viral load or antiretroviral therapy. When women were on the original zidovudine-only regimen and had prophylactic cesarean delivery, the rates of transmission were found to be as low as 2 percent, comparable to the rates achieved with HAART, nondetectable viral load, and vaginal birth [27–29]. It is unclear how much additional reduction can be achieved with cesarean birth in women who do have undetectable viral loads on HAART, given that some cases of antepartum transmission may occur as early as the first trimester. Thus, vaginal birth is a reasonable choice for these women. It is also known that the longer membranes are ruptured, the greater the risk of transmission at the time of birth [30]. For these reasons, women with viral loads greater than 1000 should always be offered cesarean birth, and any woman who, following counseling regarding risks and benefits of vaginal versus cesarean birth for both mother and infant, requests cesarean delivery, should be accommodated.

Support Systems for Infected Women

Women living with HIV are frequently isolated from their natural support systems during pregnancy by their unwillingness to discuss their HIV diagnosis and fear of community response. Coupled with the social and economic disruption often present in the lives of these women, this isolation can lead to depression, lack of self-care, and other nonmedical problems. Substance abuse may also play a role. For all these reasons, the midwife who cares for HIV-positive pregnant women needs to maintain a network of resources including treatment programs, housing assistance, counseling, social work, nutrition, and even possible doula services. Among the barriers to care perceived by women, themes that are commonly mentioned include the lack of adequate health insurance, physical inaccessibility of clinical sites, lack of child care, inefficient scheduling that produces long waits, and provider behaviors that discourage women from seeking care. Women see both gender and race as factors in their treatment.

A study by Meredith in 1997 asked HIV-positive women what they wanted from their care [31]. Their answers included the following:

Personalized care and respect
Having someone to talk to about problems
Honest answers
Medical follow-up
Reduced barriers to care
Education about their condition

Physical and emotional abuse are also factors in the lives of women living with HIV. Recent studies have noted that disclosure can be associated with abandonment by family or friends, verbal abuse, or physical assault. Women with prior histories of abuse or substance use, who were homeless, or who lived with their male partners were most at risk [32–34].

Gynecologic Care of Women with HIV

Women with HIV need regular gynecologic care and active management of any abnormalities found during care. On diagnosis, all women should have 6 month interval visits for one year. While women remain immune competent, with CD4 counts greater than 500, annual visits will then suffice, as long as the Pap smear remains normal. Counseling for STD prevention and family planning at this time is similar to that provided any other patient. Emphasis does need to be placed on condom use for prevention of heterosexual transmission, disclosure of the HIV diagnosis to sexual partners, and the importance of correct use of contraceptive measures.

Contraceptive Choice Counseling about contraception becomes increasingly important in HIV infected women, as an explanation of the need to include barrier protection against infecting a partner, reinfection with another HIV strain, and coinfection with STDs, must be included. However, the barriers are the least effective standard contraceptive measures and are often omitted when couples become comfortable with one another. Reinforcing the importance of condom use is essential to effective counseling in the younger population, who may feel that safer sex is no longer an issue. Condom use has been demonstrated to be the single most effective measure against transmission between sexual partners, and over time, HIV discordant heterosexual couples have been shown to increase their use of condoms [5, 6, 35].

Most methods of contraception can be safely used, but the use of IUDs is generally restricted. The increased severity of genital diseases in association with HIV and the increased inflammatory reaction within the uterus are specific concerns. Combined hormonal contraceptives utilize the same hepatic pathway for metabolism as some of the antiretroviral drugs; their effectiveness may be decreased by drug interactions. The woman's infectious disease provider should be kept advised as to any changes in contraception.

Pap Smears, the Human Papillomavirus, and HIV Annual Pap smear testing in women with no known cervical abnormalities is adequate unless she has developed symptomatic disease or has a CD4 count of less than 200. After that time, Pap smears should be performed every 6 months. Women living with HIV should consider having HPV testing done with Pap smears as long as they have never had a prior HPV diagnosis.

There is increasing evidence that HIV increases the risk of persistent HPV infection at the cervix, including rapidly progressive Pap smear abnormalities, increased recurrence rates for treated lesions, and increased rates of cervical neoplasia [36, 37]. The rates of complication increase with progression of HIV disease [38]. Duerr [39] found rates of HPV infection and of squamos intraepithelial lesions (SIL) Pap results three times higher among HIV-infected women. Beginning in 1993, the CDC identified invasive cervical cancer as an AIDS-defining illness.

Aggressive management of atypical squamos cells of undetermined significance (ASCUS) and SIL results on Pap smears including colposcopy and biopsy at the first abnormal finding is appropriate. During this procedure, the colposcopist should take care to examine the entire lower genital area and anus for possible lesions, since an elevated risk of anal cancer among HIV-positive persons engaging in anal intercourse has been identified [40]. Proven cervical abnormality warrants Pap testing every 3 to 4 months for one year, followed by exams every 6 months.

STDs in HIV-Positive Women All STDs can be cofactors for HIV transmission, particularly those that produce vaginal or cervical lesions. Sexually transmitted diseases all share a common risk—exposure to more than one sexual partner, either individually or through one's own partner. Thus STD counseling and screening should include a discussion of the risk of HIV and an offer of HIV testing. For women who are HIV infected, treating STDs decreases their risk of transmitting HIV by reducing associated inflammation and viral shedding.

The treatment of any sexually transmitted disease and pelvic inflammatory disease requires attention to duration of therapy and the possibility of inadequate treatment effect. Test of cure or follow-up visits should not be omitted in this population.

A Guide to the Clinical Care of Women with HIV, a reference published by the Health Resources and Services Administration, can be obtained online at www.hab.hrsa.gov/. This publication is an excellent source for more detailed information regarding all aspects of management of HIV in women.

HIV and Older Women

About 10 percent of AIDS cases are found in adults over 50, many of whom know little about HIV risks and transmission. In addition, this is not a population group that regularly considers condom use for prevention of infection, nor do women in this age group need protection against unplanned pregnancy. One study found that older women are only half as likely as men to be tested for HIV [41]. However, the physiologic thinning of vaginal mucosa and decreased lubrication following menopause actually increase risk of HIV transmission. Another study of older adults found that active sexual lives and multiple partners were not uncommon; less than 40 percent of those sexually active were using condoms. A majority of men, and 80 percent of women, did not see themselves at risk in this study [42]. Counseling messages about safer sex cannot be limited to the young.

Global Aspects of HIV in Women

Writing about the HIV pandemic from within the perspective of the resource-rich industrialized world provides a view that does not reflect the experience of the vast majority of women infected with HIV [43]. In Africa, the Middle East, and the Caribbean, half or more of all infected individuals are women [44]. Table 8-5 illustrates the relative burden of HIV in the developing world, which lacks both financial and infrastructure resources required to convert HIV from a death sentence to a serious but chronic disease. Although attempts are being made to obtain medications at reduced costs and distribute them equitably, this is far from a completed plan. Specific concerns include sexual transmission when women do not have the ability to protect themselves sexually, high rates of mother-to-child transmission (MTCT), and newly increasing concern about transmission to health care providers during birth when protective resources are not available.

Several trials of shorter courses of medication during pregnancy to prevent MTCT have been conducted. As can be seen in Table 8-6, even limited therapy can produce effective decreases in HIV transmission. These studies, performed in Africa and Thailand, were primarily intended to determine whether short courses or different drug regimens could be of use in settings where resources are limited or health care is provided over widespread areas [45–50]. Among the many complications of implementing HIV reduction programs are the inability to monitor and manage drug reactions, the need of mothers to breastfeed in order to prevent infant death from malnutrition or diarrhea, and in some communities, the need to breastfeed in order to disguise the mother's infected status.

TABLE 8-5 Global HIV/AIDS Statistics through 2002, Ranked by Percentage of HIV-Positive Women

	Adult Prevalence	Adults and Children with HIV/AIDS	Percentage of Adults Who Are Women
Sub-Saharan Africa	8.8%	29,400,000	58
North Africa and Middle East	0.3%	550,000	55
Caribbean	2.4%	440,000	50
South and Southeast Asia	0.6%	6,000,000	36
Latin America	0.6%	1,500,000	30
Eastern Europe and Central Asia	0.6%	1,200,000	27
Western Europe	0.3%	570,000	25
East Asia and Pacific	0.1%	1,200,000	24
North America	0.6%	980,000	20
Australia and New Zealand	0.1%	15,000	7
TOTAL	1.2%	50,000,000	50

Tuberculosis

Exposure to the *Mycobacterium tuberculosis* bacillus produces a latent tuberculosis infection in about 21 to 23 percent of those exposed. The CDC estimates that 10 to 15 million people in the United States have been exposed and have latent TB infection. The only evidence of infection in this group will be a positive tuberculin test. About 10 percent of otherwise healthy women with latent infection will progress to active disease at some point. For people with a damaged immune system—for example, persons with diabetes—the risk is as much as three times higher. For HIV positive women, the risk of active TB may be as much as 100 times higher than the overall rate [51]. Other factors also influence the risk of progressive disease. Table 8-7 lists the major risk factors for TB infection.

Because the bacterium is spread by droplet formation or aerosolization, casual contacts are at little to no risk. Close family members and those in close daily contact with the infected individual are most likely to have been exposed. The droplets spread through the respiratory system before being neutralized by macrophage response. In some cases, the bacterium will also reach the lymph glands and spread through the body to other susceptible tissues.

Most people who are exposed to tuberculosis and develop a reaction to the tuberculin test have no symptoms and do not offer any risk of infection to others; the term used for this condition is latent tuberculosis [52].

Even when an initial lesion in the lung develops, most immune competent people will mount an adequate response and their bodies will encapsulate and calcify the inflammatory lesion, preventing further symptoms. On x-ray, the lesion will be visible. Initial active clinical disease and reactivations of previously undiagnosed or inadequately treated disease may present with atypical pneumonia and patchy lung infiltrates, a generalized malaise and fatigue, night sweats, weight loss, fever, and/or a productive cough with or without hemoptysis. Pleuritic pain may develop. On examination, crepitus and rales may be heard [53].

TABLE 8-7 Risk Factors for Tuberculosis Infection and Progression

Overcrowded environment
Immigration from areas where TB is endemic
Nosocomial exposure (e.g., nursing homes)
Evidence of prior TB infection
HIV
Diabetes
Steroid therapy
Immunosuppressive therapy
Head and neck cancers
Renal disease
Malabsorption syndromes
Gastrectomy, intestinal bypass
Malnutrition, low body weight
Alcoholism
Substance abuse

Testing for Tuberculosis Infection

Screening tests will detect hypersensitivity to the tuberculin protein. The screening test most commonly used is the Mantoux test, commonly known as a PPD (purified protein derivative) test. The purpose of screening for tuberculosis is to detect those individuals who have inactive disease, and those who have recently been exposed and converted. If a woman was screened previously and had a negative screening test, administer the PPD. If this PPD is positive, the woman is a converter representing new disease that may or may not be currently active. The tuberculin test does not need to be repeated in anyone with a documented prior positive result.

Many individuals from countries outside the United States (e.g., England, Carribean Islands) receive Bacillus Calmette-Guerin (BCG) vaccine in childhood to prevent tuberculosis infection. These individuals should still be screened with PPD; they will have a positive PPD for up to two years secondary to the BCG vaccine. After that, one should not assume that positive PPD is secondary to vaccination [54, 55]. Since many people who received BCG vaccine as children may not know this is what they were given, look for the scar caused by the vaccine before giving PPD.

The midwife should take a history prior to administration of PPD to determine the presence of conditions that might alter the reaction to the tuberculin (i.e., give a false positive or a false negative) and what classification of tuberculin reaction to use in reading the test. This history should include the following:

1. Previous history of tuberculosis
2. Previous screening test and results
3. Vaccination with BCG
4. Close contact with a person with infectious tuberculosis
5. Chest x-ray suggestive of previous tuberculosis with inadequate or no treatment

6. Current signs and symptoms of tuberculosis (see Table 8-8)
7. Whether the woman is HIV positive
8. Whether the woman is an intravenous drug abuser
9. Whether the woman is foreign-born, from an area of the world where tuberculosis is common (e.g., Latin America, Africa, Asia)
10. Whether the woman is in a high-risk racial or ethnic group (e.g., Native American, African American, Hispanic, Asian, or Pacific Islander)
11. Whether the woman is a member of a medically underserved, low-income population
12. Severe or febrile illness, measles, or other viral infections
13. Live-virus vaccination
14. Hodgkin's disease
15. Sarcoidosis
16. Whether the woman is currently on corticosteroids or immunosuppressive drugs
17. Whether the woman is a member of a locally identified high-prevalence group (e.g., homeless person, migrant worker)
18. Whether the woman is a resident of a shelter or long-term facility (e.g., nursing home, correctional facility)
19. Occupational exposure to tuberculosis (e.g., health care worker, on staff of long-term care facility, on staff of homeless shelter or drug treatment center)

TABLE 8-8 Signs and Symptoms of Active Tuberculosis

Fever: Initially minimal to moderate temperature elevation occurs daily in the late afternoon or evening, usually accompanied by a feeling of euphoria and well-being; as disease progresses, temperature elevations reach 103°F (39.5°C) or higher.

Night sweats: The daily rise in body temperature reverses at night with accompanying diaphoresis.

Weight loss: Minor weight loss with anorexia occurs early in the disease; increased weight loss, fatigue, and irritability occurs as the disease progresses.

Chronic cough: A cough that is worse in the morning.

Chronic, productive cough: A cough that produces large amounts of purulent, greenish-yellow sputum sometimes accompanied by hemoptysis.

Pleurisy with effusion: This is particularly significant in young childbearing women, as pleurisy in this age group is uncommon.

Spontaneous atelectasis: Especially in a young person, this may be a sign of active tuberculosis.

Crepitant rales: This is heard best on auscultation after the woman coughs.

The Mantoux test consists of 0.1 mL of purified protein derivative (PPD) tuberculin containing 5 tuberculin units, administered intradermally in the forearm. The reaction to the PPD should be read 48 to 72 hours after injection. If a patient's reaction is not read until after 72 hours and it is negative, the test should be repeated. A positive reaction may be measurable up to 1 week after testing. Reaction is the diameter of a palpable swelling (induration), measured in millimeters. Erythema is not included in the measurement. Tuberculin reactions are classified as positive according to risk factors, as follows [52] :

1. Induration ≥5 mm:
   a. persons known to have HIV infection
   b. persons in close contact with a person who has infectious tuberculosis
   c. persons whose chest x-ray is suggestive of previous tuberculosis with inadequate or no treatment
   d. patients who are immune suppressed
2. Induration ≥10 mm:
   a. recent immigrants from an area of the world where tuberculosis is common (e.g., Latin America, Africa, Asia)
   b. persons who have high-risk health conditions
   c. children exposed to high-risk persons
   d. residents and employees of a homeless shelter, jail, long-term care facility, or any congregate living setting
   e. intravenous drug abusers
   f. mycobacteriology laboratory employees
3. Induration ≥15 mm:
   a. persons with no known risk factors for tuberculosis

Both false-positive and false-negative readings may occur, as shown in Table 8-9.

TABLE 8-9 Factors That May Cause False-Positive and False-Negative Responses to the Tuberculin Skin Test

False Positive	Nontuberculous mycobacteria BCG vaccination
False Negative	Anergy Recent TB infection Very young age (<6 months old) Live-virus vaccination Overwhelming TB disease

Source: Centers for Disease Control and Prevention. *Core Curriculum on Tuberculosis: What the clinician should know*, 4th ed. 2000. Accessed online at www.cdc.gov/nchstp/tb/pubs/corecurr/default.htm

Anergy is the condition in which the tuberculin reaction decreases or disappears, even when exposure to tuberculosis has occurred. Causes include HIV/AIDS, overwhelming TB disease, viral or febrile illnesses, sarcoidosis, live-virus vaccinations and immune suppression [52, 56, 57]. Although anergy panel testing is no longer recommended, awareness of this possibility should lead the clinician to follow patients at risk of TB disease and possible anergy with chest x-ray or sputum culture, and referral to a provider experienced with tuberculosis.

Chest X-Ray The appearance of active pulmonary TB is seen on radiography most often in the upper lobes or the superior aspect of the lower lobes, while old healed TB scars appear as nodules or fibrotic changes. Although chest films will show abnormalities suggestive of TB, they are not by themselves diagnostic.

Sputum Culture Sputum cultures should be performed when there is clinical suspicion of active tuberculosis. The long delay in obtaining results (as much as 2 weeks) should not be a reason to delay assessment, even though diagnosis is not final without the confirmation of cultures. A smear from the sample can be evaluated for the presence of mycobacteria by acid-fast or fluorescent stain. Even when the stain is negative, the sputum sample should be sent for culture [52].

Treatment of Latent Tuberculosis

Those who have positive skin testing and in whom active tuberculosis has been ruled out by chest x-ray should be offered Isoniazid (INH) prophylaxis. The standard adult regimen is 300 mg per day in a single dose. Directly observed therapy regimens with twice a week dosing have been used for persons who had difficulty in complying with several months of daily therapy [52, 58]. Nine months is considered the optimum length of therapy. Pregnant and breastfeeding women may safely take this regimen, with the addition of a pyridoxine (vitamin B_6) supplement [59]. Prior to beginning INH therapy, women should be screened for historic risk factors for HIV or hepatitis, contraindications to the medication, and current medications. Teaching includes the benefits and risks of long-term therapy, the importance of adherence, and side effects. Baseline liver function studies should be obtained in persons with hepatic disease, HIV, and women who are pregnant or postpartum. At least monthly, the patient should be assessed for adherence to medication regimen, signs and symptoms of active disease, and for symptoms of hepatitis [52].

Other regimens for prophylaxis of latent TB include rifampin and pyrazinamide for those resistant to INH, and those with multidrug resistant TB exposure should receive ethambutol plus either pyrazinamide or a fluoroquinolone. Any of these regimens should be managed by the patient's primary care provider or an infectious disease specialist, not by the midwife.

Management

Both latent and active tuberculosis are managed by providers other than the midwife, and any patient suspected of TB infection on screening should be promptly referred. In some settings, it may be appropriate for the midwife to order the chest x-ray as the woman is being referred, to expedite therapy.

Hepatitis*

Viral hepatitis is actually a group of pathogenic viruses, identified by the letters A through G. While hepatitis A is usually spread by the fecal-oral route, others are spread by contact with blood and body fluids and can be contracted sexually. Both acute and chronic viral hepatitis often affects women and, if pregnant, their infants. Among the issues to be considered by midwives are when to test for hepatitis, what the risk factors and symptoms are, and management strategies. Hepatitis is a condition for which referral to and collaboration with medical consultants is essential.

Hepatitis A and B are the most common forms of hepatitis in the United States. There are fewer new cases per year of hepatitis C, but it becomes chronic about 75 to 85 percent of the time, in contrast to hepatitis B, which develops as a chronic state in 2 to 6 percent of adult cases [60]. These three common types of viral hepatitis will be discussed in more depth in this section.

Hepatitis D occurs as a coinfection with hepatitis B or as a secondary infection, and is most common in Mediterranean countries. It is uncommon in the general population of North America although it may occur in intravenous drug users and persons with frequent exposure to blood products (e.g., hemophiliacs) as well as their sexual contacts.

* Revised with Mary Curran, CNM, MPH

Perinatal transmission is unlikely, because neonatal prophylaxis for hepatitis B is effective against hepatitis D as well [61].

Hepatitis E is common in Asia, South America, and Latin America and has been diagnosed in the United States only in individuals traveling from developing countries. Like hepatitis A, it is transmitted by fecal-oral contamination. It is significant in women for causing a fatality rate in pregnancy as high as 21 percent in the third trimester. There are no long-term effects of hepatitis E, nor does it have a carrier state [62, 63]. Hepatitis F is a "novel" agent that is associated with liver disease in hepatitis A, B, and C negative patients. There are no diagnostic tests or therapies other than support and symptomatic treatment [63]. Hepatitis G has both acute and chronic states, but appears to have a mild presentation with little or no lasting damage. There is no therapeutic agent available for its treatment. It can be transmitted perinatally [64].

Hepatitis can also result from generalized infection by other viruses, including cytomegalovirus, Epstein-Barr virus, herpes simplex virus, and measles virus. Nonviral causes of liver infection include bacterial sepsis and syphilis. Hepatitis can also be chemically induced by chronic alcohol ingestion or by medications such as aspirin (acetylsalicylic acid), Tylenol (acetaminophen), Dilantin (phenytoin), INH (isoniazid), and rifampin [65].

Hepatitis A

Hepatitis A (formerly called infectious hepatitis) is the most common form of hepatitis worldwide and generally occurs more frequently in impoverished populations, where good hygienic practices are difficult to maintain. Fecal-oral contamination is the usual route of transmission. Contaminated water and food (especially shellfish) are common sources of hepatitis A (HAV) viral infection. The burden of the infection includes a case rate of about 4.9 per 100,000 people in the United States, or 10,600 infections in 2001 [66]. An estimated 15 to 30 percent of reported cases of HAV are attributed to household or sexual contact with an infected person, and an additional 10 to 15 percent of reported cases are among children and employees of child care centers and members of their households [67]. Rare transmission of HAV in blood products has been documented during the viremic or prodromal phase of the infection [68]. The incubation period is short, with an average of 28 days (range of 15 to 50 days) [69] with virus shed through the feces approximately 2 weeks prior to clinical symptoms, and it is the period of time when the risk of transmission is greatest.

Clinical Illness Signs and symptoms of hepatitis A resemble those of the "flu" and include abrupt onset of anorexia, malaise, fatigue, weakness, nausea, and low-grade fever. Uncommonly, urticaria, arthritis, arthralgia, and myalgia may occur. Jaundice may be present, along with upper right quadrant or epigastric pain, an enlarged and tender liver, pruritus, splenomegaly, muscle pain, and weight loss. Hepatitis A has a short acute phase of 10 to 15 days, with symptoms resolving within 2 months, although 10 to 15 percent of symptomatic persons have prolonged or relapsing disease lasting up to 6 months [70]. The disease does not result in the chronic or carrier state. If contracted during pregnancy, there is no known risk to the newborn.

Diagnosis In order to diagnose acute hepatitis A virus, serologic testing with the findings of immunoglobulin M (IgM) antibody is required to confirm infection. IgM anti-HAV usually becomes detectable 5 to 10 days before the onset of symptoms and can persist for up to 6 months after infection [71]. Immunoglobulin G (IgG) anti-HAV appears early in the course of the disease and will indicate lifelong protection against the disease [72].

Treatment Ninety-nine percent of those individuals infected with hepatitis A will recover without treatment. Each year in the United States there are about 100 cases of fulminant hepatitis A that lead to death from acute liver failure [73]. Between 11 and 22 percent of persons with hepatitis A are hospitalized and those adults who become ill lose an average of 27 days of work [74, 75].

Pregnancy and Lactation Hepatitis A infection is no more severe in pregnant women than in nonpregnant individuals [76]. Maternal HAV infection during pregnancy is not associated with fetal loss or developmental abnormalities [62]. Vertical transmission from mother to infant has not been shown [77]. Maternal hepatitis A virus infection in the last trimester or during breastfeeding is not a contraindication to breastfeeding [78]. Breastfeeding is not a contraindication for vaccination; inactivated virus will not affect the safety of breast milk.

Prevention Since 1995, two licensed inactivated HAV vaccines have been available in the United States. In 1996 the CDC Advisory Committee on

Immunization Practices (ACIP) recommended HAV vaccination for specific groups at high risk for exposure such as international travelers and individuals working in countries where HAV is endemic [78]. The ACIP now recommends that in addition to those at high risk for exposure, there should be a routine vaccination of children in states, counties, and communities in the United States with rates that are twice the 1987–1997 national average or greater (i.e., greater than or equal to 20 cases per 100,000 population) and consideration of routine vaccination for children in states, counties, and communities with infection rates that are greater than or equal to the national average for 1987–1997 of 10 cases per 100,000 [79]. HAV vaccine is an inactivated virus that is safe for use in pregnant women.

People at risk for hepatitis A include the following:

- Household/sexual contacts of infected persons
- International travelers
- Persons living in American Indian reservations, Alaska Native villages, and other regions with endemic hepatitis A
- During outbreaks: day care center employees or attendees, homosexually active men, injecting drug users

Close family and household members, personal contacts, and contacts who meet the criteria of individuals at high risk for hepatitis A should receive immune serum globulin (ISG) for prophylaxis after a potential or known exposure. Hepatitis screening is not necessary prior to receiving ISG.

Hepatitis B

Hepatitis B (formerly called serum hepatitis) is transmitted through blood, blood by-products, contaminated needles, saliva, vaginal secretions, and semen. Infection with hepatitis B (HBV) may result in a chronic or carrier state, with an increased risk for chronic active hepatitis, chronic liver disease, cirrhosis of the liver, and hepatocellular carcinoma. The CDC reports that in 1999 about 80,000 new infections of hepatitis B occurred, which was a decrease from 450,000/year in the 1980s. Chronic hepatitis B presently affects 1 to 1.25 million persons in the United States [80]. Recent studies of posttransfusion hepatitis show that less than 5 percent of cases are caused by hepatitis B [81].

Clinical Illness Hepatitis B has an incubation period of 1 to 4 months. Nonhepatic symptoms (rash, fever, arthralgia, myalgia, arthritis) generally precede jaundice in hepatitis B. Signs and symptoms of hepatitis B infection may include nausea, vomiting, right upper quadrant abdominal pain, enlarged and tender liver, fever, chills, general weakness and exhaustion, and headache. Approximately 70 percent of patients with acute hepatitis B will have a subclinical infection, whereas 30 percent will develop icteric disease [82]. The clinical symptoms and jaundice generally disappear in 1 to 3 months. Approximately 90 percent of those acutely infected perinatally will progress to chronic infection [62].

Diagnosis Hepatitis B surface antigen (HbsAG) and hepatitis Be antigen (HbeAG) usually appear in the infected person's blood from 1 to 10 weeks after an acute exposure to HBV, before the onset of clinical symptoms or elevation of the liver enzyme serum alanine aminotransferase (ALT). Persistence of HbsAg for more than 6 months implies progression to chronic HBV infection. HbeAG is a marker for viral replication and infectivity. During pregnancy, it is associated with higher rates of vertical transmission. Hepatitis B core antibody (IgM class) appears during the midphase of the clinical course, with hepatitis B core antibody (IgG class) becoming predominant late in normal recovery. IgM core antibody may remain detectable for 2 years following acute infection; IgG will persist, and will also be present in chronic infection. Reports of seroconversion from acute to chronic hepatitis B vary from 5 to 10 percent. Hepatitis B surface antigen will usually disappear by 4 to 6 months and be followed by the presence of hepatitis B surface antibody (anti-HBs), which will confer lifelong immunity. Hepatitis B core antibody and hepatitis B surface antibody may persist in noncarriers for many years. Figures 8-3 and 8-4 illustrate the relationship over time among these values [82].

Treatment Acute hepatitis B is not responsive to any treatment and must run its natural course. A person with acute or chronic hepatitis B should be evaluated for liver disease.

Pregnancy and Lactation In the United States, 15,000 pregnant women who are hepatitis B surface antigen (HbsAg)-positive deliver annually [83]. HBV infection is no more severe in pregnant women than in nonpregnant individuals [84]. Chronic HBV carriers usually have normal pregnancies, unless there is also severe chronic hepatitis or secondary cirrhosis and associated complications

[85]. Maternal-newborn transfer of hepatitis B can occur at the time of delivery through contact with the infected maternal blood, or during close maternal-infant contact in the postpartum period. The transfer can occur regardless of route of delivery. Women who are HBsAg-positive and hepatitis Be antigen-positive have a 90 percent chance of transmitting their disease to their infants. Of the infected infants, 90 percent will become carriers; 25 percent will eventually die of liver failure from cirrhosis or primary hepatocellular carcinoma. The infants of potentially infectious mothers are treated with HBV human hyperimmune globulin (HBIG) within 12 hours of birth and are also inoculated with the first of three injections of HBV vaccine prior to discharge from the hospital [86]. Immunoprophylaxis at birth followed by a hepatitis B vaccine series reduces vertical transmission of hepatitis B to less than 3 percent [82].

Breastfeeding is not contraindicated. With the treatment regimen of HBIG and the first inoculation with HBV vaccine there is no increased incidence of HBV infections in infants of breastfeeding mothers who are chronically infected [78]. Vaccination of the mother is not contraindicated during pregnancy or when breastfeeding.

Prevention The American College of Obstetricians and Gynecologists and the Centers for Disease Control and Prevention recommend routine hepatitis B virus screening for HbsAg for all pregnant women in order to identify those women who are chronic carriers of hepatitis B. Those women who test negative for HBsAb should be considered for vaccination if they have not been previously vaccinated [87]. Pregnancy is not a contraindication for either hepatitis B vaccine or HBIG. If a susceptible woman has never been vaccinated for either hepatitis A or hepatitis B, there is now available a combination vaccine (TWINRIX), which is administered in a 3-dose schedule that will provide immunity to both viruses [88].

The Advisory Committee on Immunization Practices (ACIP) and the American Academy of Family Physicians (AAFP) presently recommend the following 3-dose schedule of vaccinations for hepatitis B in childhood:

Hepatitis B initial dose: at birth prior to discharge from hospital w/minimum interval to next dose 4 weeks

Hepatitis B second dose: 1 to 4 months; minimum interval to next dose 8 weeks

Hepatitis B third dose: 6 to 18 months; should not be administered before age 6 months [89]

Those at risk for hepatitis B include the following:

1. Individuals with multiple sex partners or diagnosis of a sexually transmitted disease
2. Intravenous drug users
3. Infants/children of immigrants from areas where hepatitis B is endemic, such as Asia, Africa, Pacific Islands, Haiti
4. Sex partner(s) and household contacts of hepatitis B carriers
5. Homosexual males
6. Women who have intimate contact with bisexual males
7. Public safety personnel and health care personnel in obstetrics, surgery, emergency room, laboratory, and housekeeping
8. Infants born to mothers with hepatitis B (active, chronic, or carrier)
9. Hemodialysis patients

Health care providers who work with populations at high risk for hepatitis B have the option of obtaining hepatitis B vaccine. Hepatitis B vaccine is an inactivated vaccine and the only true contraindication to receiving this vaccine is a prior anaphylactic reaction to it. Their options are to obtain hepatitis B vaccine or to do nothing; each has its own set of risks that should be carefully weighed.

Hepatitis C

Hepatitis C (HCV), formerly known as non-A non-B hepatitis, is the major cause of posttransfusion hepatitis and was identified as the hepatitis C virus in 1989 [90]. Hepatitis C is found in highest concentrations in the blood and is primarily transmitted through the bloodborne route; however, for many individuals the method of acquisition of the virus is unknown [91]. Sexual transmission is not unknown but is rare at approximately 5 percent [92]. Hepatitis C is the leading cause of chronic liver disease in the United States, with an estimated 40,000 new cases per year in 1998, but with an estimated 2.7 million persons chronically infected. Eighty-five percent of those infected with hepatitis C become chronic carriers, which accounts for the high number of infected individuals who may have serious and often asymptomatic chronic liver disease [93].

Clinical Illness The average incubation period for hepatitis is generally 6 to 7 weeks, with a range of 2 weeks to 26 weeks. Hepatitis C is different from hepatitis A and B in that the acute phase of the infection is often asymptomatic and without jaundice: Only 30 to 40 percent of patients will present with the typical clinical signs of hepatitis and only 20 to 30 percent will appear with jaundice [94]. Reports of progression to chronic infection range from 70 to 85 percent, with long-term sequelae including cirrhosis and hepatocellular carcinoma [95]. Liver failure from chronic hepatitis is presently the leading indication for liver transplantation in the United States.

Diagnosis Diagnosis of HCV infection is made by serum enzyme immunoassay (EIA) detection of antibody to the hepatitis C virus. Targeted screening for the hepatitis C virus is based on risk factors as recommended by the CDC:

1. Injecting drug users
2. Recipients of clotting factors made before 1987
3. Hemodialysis patients
4. Recipients of blood and/or organ transplants prior to June 1992
5. People with undiagnosed liver problems

6. Infants born to infected mothers (testing after 12 to 18 months old)
7. Healthcare/public safety workers (only after known exposure)

If antibody to HCV is positive, recombinant immunoblot assay (also known as "Western blot," or RIBA) is used to confirm the result. If this confirms the antibody to HCV, then because of the high (70 to 85 percent) incidence of chronic disease, serum alanine aminotransferase (ALT) and quantification of HCV-RNA (viral load) should be performed. The midwife would then refer this patient to her primary care physician, hepatologist, or gastroenterologist. The midwife would counsel the patient to expect an evaluation of her liver function with serum testing and possibly biopsy.

Treatment Treatment for clinical hepatitis C is the same palliative care as for hepatitis A and B. Treatment for chronic hepatitis includes combination therapy with injections of alpha interferon and the oral antiviral drug ribavirin. This treatment is not appropriate for pregnancy and it should be noted that ribavirin is a teratogenic drug (category X) and is contraindicated during pregnancy [96]. It should also be avoided in a patient's partner when trying to conceive a pregnancy. Patients can be counseled to expect a 24- to 48-week course of therapy, with this medication regimen.

Pregnancy and Lactation The U.S. Public Health Service has estimated that the likelihood of perinatal transmission of the hepatitis C virus, in the absence of coinfection with HIV, is on the order of 5 to 6 percent. The incidence of transmission does increase when associated with a maternal viral load of 10,000,000 copies/ml^3 of circulating virus [92]. Data collected to date show no increase in HCV infection among breastfed babies; therefore, breastfeeding is not contraindicated in a mother with chronic hepatitis C infection [97].

Prevention There is no vaccine to prevent hepatitis C. Prevention centers around education and avoidance of lifestyle choices that would put one at risk for exposure to hepatitis C.

Diagnosis of Hepatitis

Hepatitis may be detected through history, physical examination, and laboratory data, as follows:

1. History
   a. blood transfusion or blood products/organs prior to June 1992
   b. previous hepatitis or jaundice
   c. exposure to someone who has hepatitis or is jaundiced
   d. multiple sex partners
   e. male homosexuals
   f. sex with a bisexual male
   g. intravenous drug use, even one episode, even in the remote past
   h. immigration or travel from a country with endemic hepatitis
   i. occupation—health care worker or public safety worker, day care worker
   j. clinical signs of hepatitis
      (1) anorexia
      (2) nausea
      (3) vomiting
      (4) upper right quadrant abdominal pain
      (5) epigastric pain
      (6) malaise
      (7) weakness
      (8) fatigue
      (9) arthralgia
      (10) arthritis
      (11) urticaria
      (12) myalgia
   k. hemophilia
   l. history of dialysis
2. Physical examination
   a. tender, enlarged liver
   b. enlarged spleen
   c. jaundice (of sclera or entire body)
3. Laboratory tests
   a. positive hepatitis screening test or identification of specific hepatitis antigens and antibodies
   b. elevated liver function tests AST (SGOT), ALT (SGPT), LDH, and bilirubin

Evidence or suspicion of hepatitis should be reported to the woman's primary care provider, or to the midwife's consulting physician if there is not an established primary care relationship. Any hepatitis is significant in a pregnant woman if it leads to anorexia, nausea, and vomiting, as these may interfere with her nutritional status. Women with debilitating acute disease and chronic or carrier status should be collaboratively managed with a physician. Hepatitis is a reportable disease. Midwives need to know their state reporting regulations and be in compliance with them.

CHAPTER

9

Women and Exercise

ANN COWLIN, M.A., C.S.M., C.C.E.

The focus here will be on supporting and monitoring women's participation in physical activity as a method of promoting their health and well-being. The chapter begins with a brief discussion of the value of exercise to women's health, which provides the rationale for the midwife's acquiring competency in this area. The impact of exercise on women at various life stages is discussed throughout, as are other key topics: management procedures for determining needs and motivations, screening for risks, assessing fitness levels, recommending exercise regimens, making referrals to appropriate fitness professionals, and evaluating outcomes.

The Value of Exercise to Women's Health

Exercise can be defined in a general way as the recreational physical activities and activities of daily living that enhance physical fitness, which has been identified as an effective strategy for the reduction of disease and death [1]. Public health experts recognize that adequate and appropriate physical activity is a factor in the prevention of premature death, heart disease, non–insulin-dependent (Type II) diabetes, obesity, some cancers, osteoporosis, osteoarthritis, falls, anxiety, and depression for both women and men [2]. However, as the Surgeon General has reported, women are less likely than men to participate in exercise [2]. Issues of safety, time pressures in women's lives, and the inability of measurement techniques to account for the effect of activities of daily living on women's overall activity level have been identified as factors contributing to this situation [3].

As more is learned about a female-centered approach, it is becoming apparent that recreational physical activity can be a gateway to health promotion for women. One study involving rural midlife women identified participation in physical activity as the predictor of other health-inducing behaviors, such as a nutritious diet or not smoking [4]. Adequate appropriate activity is also associated with reduced health risks, such as fractures or deformities due to low bone mineral density (BMD). High levels of current physical activity are predictive of high levels of BMD in midlife and older women, while low levels of childhood physical activity are associated with low levels of BMD in these women [5]. Physical fitness has a positive influence on well-being. Vigorous activity commenced prior to six weeks postpartum appears to have a favorable impact on a woman's physical and psychological adaptations to motherhood [6]. Because a high level of support from a woman's health care provider is a significant factor in successful lifestyle change [7], the midwife has an important influence on increasing participation by women in health-enhancing physical activities at critical stages in their lives.

Five key times provide opportunities for girls and women to develop effective exercise strategies: (1) adolescence, (2) pregnancy, (3) the postpartum period, (4) menopause, and (5) senescence. These are the key phases during which women undergo dramatic physical and psychological changes—transition points at which a woman can redefine herself. Meaningful activities that enhance prowess and self-image at each critical stage profoundly affect a woman's physical and mental health.

By understanding the impact of exercise on health during these life stages, as well as devising strategies for guiding women toward satisfying activities, the midwife gains important tools for facilitating a woman's progress along a path of healthful living. Participation in physical activity drives other

behaviors that support an active life, such as the desire for nutrient-dense calories or improvements in sleep and mood, as well as reducing the risk of disorders such as Type II diabetes. The health care provider with a formidable grasp of appropriate activity for a patient, the means to support that activity, and the ability to prompt a woman to uncover an internal impetus for activity exerts a powerful positive influence on the women she serves.

Any background knowledge needed for understanding exercise begins with a basic fact of modern life: the postindustrial world has become increasingly sedentary. Despite gains in sanitation and technologies that improve health, processed food and labor-saving devices have contributed to lowered levels of physical activity and an increased incidence of poor nutrition, stress, obesity, heart disease, and cancer. As mechanization and technology have increased productivity, the human body's physiologic adaptations to exertion and restoration—i.e., strength, endurance, range of motion, motor control, and a sense of well-being—became separated from daily living.

Kenneth Cooper's 1968 monograph, Aerobics [8], and Herbert Benson's 1974 article in the journal *Psychiatry* [9] marked a major shift in understanding the discipline of pursuing exercise and relaxation in order to gain beneficial adaptations as separate measurable entities rather than as inherent aspects of living. These two researchers recognized the physical adjustments that occur in work and reflection, studied them, and created descriptive vocabulary comprehensible to Western minds. Since the early 1970s, research in physical fitness and stress reduction has yielded a growing list of health benefits, including benefits for women. While one of the first aspects of women's health to receive major attention was prenatal exercise, interactions of exercise and women's health from the onset of menses through senescence have been documented [10–13].

Understanding the benefits of woman-centered physical fitness and having methods of translating that information into something desirable and accessible to one's clients are reasonable objectives in the midwife's pursuit of knowledge and practice in this area. The remainder of this chapter discusses the information that will help the midwife reach these objectives.

A New Exercise Model for Adolescent Girls

Adolescent girls need information and reassurance about their changing bodies, sexuality, identity, and health status. Midwives are in a unique position to be helpful in this regard. During adolescence, significant nonparent adults play an important role in the process of transforming the emotional attachment to parents into a sense of self with feelings for significant others [14–19]. One study found adults other than parents comprised 22.3 percent of all persons adolescents listed as significant [20], and another study found nonparent adults comprised 27.2 percent of adolescent girls' social networks [21]. While allowing a degree of autonomy from parents, these relationships provide emotional support and advice from an adult [16]. Girls, more often than boys, participate in intergenerational relationships, where alternative female models other than the mother are available for identification or attachment [22]. These types of relationships also cross racial and ethnic lines [23–27]. It is important to note that such relationships are most effective when they occur naturally, as might happen in the case of the midwife, rather than as arranged mentoring [28].

The Impact and Benefits of Exercise

Identity issues, stress management, reproductive issues, eating disorders and obesity, and disease prevention form the major areas in which physical activity can have profound effects upon adolescent females' healthy development. With highly athletic girls, midwives must be alert for signs of female athlete triad, which involves disordered eating, amenorrhea, and bone loss [29, 30], as well as injuries. For girls less inclined to the competitive environment so often associated with sports, helping them increase their level of physical activity or remain adequately active to prevent loss of self-efficacy and the disorders of a sedentary lifestyle may require keeping track of local teen aerobics classes, dance studios, community service programs, or other creative physical activity outlets.

Identity Issues Girls come into sexual maturity in a milieu in which the dominant modern world view is that traits of independence and self-assertion have the greatest value [31]. But girls often value the self more in relation to others. Just at the time when independence and belief in self are most valued, girls look to others for meaning. It appears that the self-esteem of white girls plummets drastically after about age 9 [32]. Participating in vigorous physical activity in adolesence has a positive effect on their self-esteem [33–35]. African-American girls appear less susceptible to falling self-esteem, but they and girls of many ethnic backgrounds benefit psychologically from developing self-efficacy, in part through physical activities [36–39].

How does this transfer to the playing field? Many girls place higher values on the cooperation aspects of games than boys do. Examining play-time activities of fifth graders in the 1970s one researcher found that aggressive legal debates over the rules appeared to be enjoyed by the boys as much as the game itself [40]. Girls, on the other hand, viewed the rules as open to innovation and less significant than keeping harmony among the smaller group. Curiously little has changed in girls' social values when it comes to athletic games since this study. Despite more serious athletics for girls and an easing of access to higher levels of sport for physically gifted, aggressive girls, many female players continue to place value in social support, to stretch the rules to keep the peace, and to be rewarded for nurturing behaviors. For these girls, who often stop exercising during adolescence, the aim is to help them develop an activity model in which fitness is a by-product and dominance is not the goal. A new focus of physical activities can be established: having fun, being with others, helping others, learning new skills, and facilitating aesthetic inclinations [41]. For example, some girls will benefit from volunteering at a veterinary clinic or a nursing home, where physical tasks involve activities that help others, while other girls might enjoy teaching younger children the latest dance steps. Increasingly, fitness professionals are developing programs for adolescent girls that address these matters. The midwife can keep abreast of such community programs and encourage participation by girls at risk of inactivity.

Stress Management Both vigorous physical activity and stress management exercises can provide outlets for the daily hassles and major life changes that adolescents experience. Stress generates tension in the body, which is alleviated during vigorous activity [42–47]. Stress-management exercises can be tailored to this population. Relaxation techniques can be undertaken while sitting in chairs, which is often more socially comfortable for adolescents than lying on the floor. Creative exercises such as theatrical role-playing also allow opportunities to discharge difficult feelings. Girls can be encouraged to participate in expressive or fun tasks, like contributing their own rules to a traditional game, or making a funny version of a favorite workout video. Offering simple choices such as playing basketball or jump rope provides a sense that they have some control of their lives.

Eating Disorders and Obesity A key factor in the relationship between nutrient intake and energy expenditure is balance. In a healthy situation these two things are in balance. Eating disorders combined with high levels of exercise or inactivity can lead to disease. In the current culture, balance is hard to maintain; it is an environment that combines abundant "toxic" food with ideal, unrealistic body images [48, 49]. Data on eating disorders are constantly being reported: 2 percent of the female population is affected by eating disorders; a third of the population is obese [50]; virtually all girls are affected to some degree by disordered eating as part of their maturation process [51].

The connection between chronic, high-volume exercise in girls and women, unhealthy eating behaviors, and suppression of reproductive functions has been noted for some time [52–63]. The incidence of anorexia nervosa in dancers is considered to be between 3.5 and 7.6 percent [64]. Other athletes who may be at risk are runners, swimmers, gymnasts, ice skaters, and cyclists. Athletes whose sport or art requires a lean aesthetic or high doses of endurance activity are at greater risk than those in other activities. While hypoestrogenic states are usually associated with menstrual irregularities in competitive athletes, swimmers are more likely to experience mild hyperandrogenism [65].

Because body fat is positively associated with both insulin and cardiovascular reactivity to exercise, prevention of childhood obesity may be important as a preventive measure for both Type II diabetes and cardiovascular disease [66]. Fasting insulin concentration has been shown to be associated with cardiovascular reactivity to exercise in young children, supporting the hypothesis that the relationship between hyperinsulinemia and hypertension is mediated by sympathetic nervous tone and that the process begins in childhood [66]. Although aerobic exercise favorably affects risk factors in adults, evidence is less clear with children and adolescents. One study demonstrated no significant relationship between cardiovascular fitness and lipid profiles in these age populations [67]. Others did find high levels of body fat related to unfavorable risk factors [68, 69].

Exercise and Disease Prevention Bone health is an area where we have a fairly clear understanding of the connections between physical activity in puberty and adolescence, good nutrition, and strong bones. Peak bone mass probably occurs in the early twenties, with the teen years critical for the attainment of high peak bone mass [70–73]. Athletic amenorrhea [74–76] and nutritional deficits [77, 78] can lead to detrimental bone changes. It appears that weight-bearing exercise and the maintenance of a normal weight in the teen years are the key factors for development of peak bone mass [79].

Premature puberty may signal reproductive endocrine disturbances over time [80]. The resulting exposure to increased estrogen production may be associated with a high degree of breast epithelial proliferation and possible hyperplasia [81]. Intense physical activity in girls has been associated with a lowered risk of reaching menarche at an early age [82]. Women with an ongoing exercise history may have a lowered risk of breast cancer [83], and exercise history often begins in youth. The role of physical activity as a possible primary prevention lies partly in its ability to reduce the risk of early menarche and reduce exposure to ovarian hormones through reduction of the number of ovulatory cycles [84]. Results from large studies that include exercise in adolescence and breast cancer are mixed. Two major studies demonstrate conflicting outcomes. One study looked at 6888 women with breast cancer between the ages of 17 and 74 and 9539 controls ages 18 to 74. Women reporting any strenuous physical activity between the ages of 14 and 22 showed a modest reduction in breast cancer, while those who exercised vigorously at least once a day had a 50 percent reduction in breast cancer [85]. Another study examined the correlation between physical activity and risk of breast cancer in middle-aged women and found only a weak correlation, including no association between any duration or intensity of exercise between the ages of 12 and 21 and risk of breast cancer [86].

Evidence strongly supports the theory that sedentary lifestyles are a major factor in the development of Type II diabetes [87]. Obesity in girls is linked to overweight in women [88] and is, by this association, suspect as a possible marker for Type II diabetes in girls whose parents demonstrate a central adiposity or weight-gain pattern. While information is still forthcoming on the relationship of physical activity in girls in puberty and its effect on Type II diabetes, it has been reported that women 34 to 59 years old who performed vigorous exercise at least once a week had a 16 percent lower risk [89].

Researchers have shown that the mechanism by which obese children receive cardiovascular benefits through regular physical training over a four-month period may be the favorable reduction of the ratio of sympathetic to parasympathetic activity in cardiac autonomic function [90]. It seems clear that exercise will improve fitness in obese adolescent girls [91–93] as well as reduce obesity [94, 95].

Adolescent girls with Type I diabetes represent a special risk, particularly if they show signs of disordered eating. Research has indicated that these girls often skip or underdose themselves with insulin [96]. It is important to help young women with Type I diabetes remain on their insulin regimen and follow the dietary and activity guidelines prescribed to them.

Management of Exercise

Supporting and monitoring physical activity in young women under a midwife's care involves gathering background information, screening for injuries and risks, making referrals to appropriate activity programs, and ongoing assessment of the activity regimen. These steps are easily integrated into the care-giving process:

1. Establish a database
   a. interest and motivation
   b. exercise history and classification
   c. nutritional status
2. Screen
   a. injuries
   b. risk factors
3. Refer to appropriate exercise or activity programs
4. Periodically assess and evaluate the exercise program

Establishing a Database

Interest and Motivation. Initially, it is useful to have knowledge about a girl's interests and background in sports or exercise, in addition to her health and nutritional status. Although her interests may be evolving, understanding her talent and skills helps to tap her existing beliefs about what she can do [97, 98]. Asking about motivations—finding out whether a girl is interested in skill acquisition, helping others, aesthetic or expressive concerns—gives the midwife clues about providing support and enthusiasm if a girl joins a particular program.

In some cases, demographic information may also be helpful [99–103]. Demographics and motivations can often intersect: for example, in Hawaiian culture girls learn values that include many subtle types of helping and community building, which are important motivators for this population [104]. Being effective with this group means respecting these subtleties and proposing projects that fulfill specific aspects of helping others.

Exercise History and Classification. Determining the type and amount of physical activity in which a given patient is currently involved will provide information about half of the equation on balancing energy output and intake. Direct questions can be used. For example, the midwife might ask which sports or activities a girl participates in and how often. She can also use established physical activity questionnaires to quantify the amount of activity [105–113]. Or more indirect methods can be used, such as following through on more general questions about interests. On the basis of the information obtained, the activity levels of girls might be categorized as one of the following:

1. *Inactive or sedentary:* no exercise and little or no physical activity such as walking or low-intensity activities of daily living.
2. *Low activity level:* low-intensity activities such as painting or drawing, singing, working at a service or retail store; low-intensity daily activities such as making the bed, loading the dishwasher; one or two 30-minute low-intensity exercise sessions per week, such as yoga or stretching; walking to and from school—five minutes each way.
3. *Moderate activity level:* moderate-intensity sports such as cheerleading or drill team; moderate-intensity activities of daily living such as vacuuming or yardwork; three or more 30-minute moderate activities per week, such as vigorous play with young siblings, step aerobics, jogging, or cheerleading; brisk walking to and from school—ten minutes each way.
4. *Athlete or dancer:* regular, near daily moderate- to high-intensity physical activity; playing on a school or community sports team, dancing with a dance company, or participating in four or more hours of aerobics per week.

Nutritional Status. Asking a girl to keep a food diary for several days provides information about the second half of the equation for balancing energy intake and output. The situation is in hand if there is an energy balance: the girl falls into the second, third, or fourth exercise classification; she is in a normal weight range and not unhappy about her size; and no problems arise in her primary health care history. If she is under- or overweight, or if she is unhappy (realistically or otherwise) with her size, or the primary care exam determines a problem like insulin resistance or amenorrhea, intervention is indicated. If there are signs of an eating disorder, referral to an appropriate professional specializing in these matters is appropriate. If a girl needs to increase or reduce her activity level, referral to a special teen program or a fitness professional may be helpful. In the case of a low activity level or inactivity and high food intake, increasing energy output by increasing the intensity, duration, and/or frequency of activity is recommended, whether or not food intake needs to be reduced.

Screening

Injuries. When an active girl presents with injury or chronic discomfort, and the health history rules out an underlying cause, she needs to be seen by a pediatric orthopedist. To play varsity sports, most schools require students be screened by a primary care provider for injury and health risks. In this case, it is helpful to be aware of the types of injuries that prevail in girls' sports. There are forms that are used for injury screening and inventory [114–117]. Major injuries and upper–body injuries are most likely in football and baseball—sports girls rarely play—with the greatest number of injuries occurring in football [118, 119]. While absolute numbers of sports-related injuries in high school students are higher in males, research suggests that basketball and soccer may have the greatest injury rates for adolescent girls, and higher rates for girls than for boys [118–121]. Knee injuries and anterior cruciate ligament (ACL) surgeries appear to be higher for girls than for boys in these sports or for girls in other sports [118, 122]. Other lower-limb and spinal injuries are distributed among both boys' and girls' sports at much lower rates.

Risk Factors. The health history will help in determining if a girl is at risk for various diseases and disorders. In addition, her energy equation should be evaluated. Girls at risk of obesity may also be at risk for the associated cascade of metabolic disorders, including diabetes, heart disease, and some cancers. Underweight girls are at risk for infertility and bone loss.

Referral to Appropriate Exercise or Activity Programs

The transformation of information about physical activity in a given population into practical, effective, real-world programs is the province of exercise professionals. There are also personal trainers qualified to work one-on-one with adolescent girls. Once a girl's database has been established, if she is not readily able to participate in school or community-based programs, such a specialist may be useful in developing a physical activity strategy. If this step is beyond her emotional or financial capacity, it may fall to the midwife to assist a girl in developing an effective plan.

A productive strategy might start with a simple homework assignment to help educate a girl about what it means to live a healthy life, including participation in physical activity. When females learn how to generate health, they pass this information on to their families and communities. In the United States, it is clear that commercial enterprises are aware of this phenomenon, because they point health-related advertising toward women. When developing nations spend more money educating girls than boys, this produces a higher rate of return in the following ways: Birthrates drop, infant mortality drops, maternal mortality drops, overall health increases, the incidence of AIDS drops, more women enter the workforce, wages increase 10 to 20 percent for each additional year of school, educated mothers are more likely to have educated children, and all of these factors contribute to a stronger economy [123]. Using an educational tool such as the Health Activity Survey in Figure 9-1 allows a girl to see

Healthy Activity Survey

Name: Date:

Ask your classmates, friends, and family about their health behavior. Get someone's signature for each item below.

Someone who . . .

1. Drinks 8 glasses or more of water, juice, and/or milk each day:

2. Walks at least 20 to 30 minutes almost every day:

3. Brushes her/his teeth at least twice a day:

4. Eats 5 fruits and vegetables a day:

5. Has never smoked cigarettes or quit smoking more than 2 years ago:

6. Gets 8 hours of sleep almost every night:

7. Exercises vigorously at least 3 days per week:

8. Practices relaxation, meditation, or stress management:

9. Does not do drugs or alcohol, and does not practice unsafe sex:

10. Has regular health checkups:

FIGURE 9-1 Healthy activity survey.

what constitutes healthy behaviors and who among her acquaintances is making healthy choices.

Some girls have greatly benefited from the cultural and political context that has allowed them to run the marathon and pole-vault in the Olympics, or become professional basketball and soccer players. However, for most girls the focus of physical activity needs to shift from developmental tasks primarily associated with adolescent males—learning dominance—to the developmental tasks of adolescent females—emphasizing expression, functional acts, and biomechanics based on balance rather than overcoming resistance. With the assistance of a midwife, a girl can create her own fitness program, chart her own progress, and determine her own standard of success.

Periodically Assessing and Evaluating the Exercise Program As a regular part of the physical examination and health history updating, the midwife can talk with her young clients about their exercise levels and satisfaction with the activities in which they are engaged. If interest wanes, it may be helpful to start again by asking about evolving interests and motivations. Getting back to the original regimen may not be the answer. Going in a new direction may be in order. It cannot be assumed that a woman will want or need to do the same activities as she passes from one phase to another—although she may come back to the activities of her youth later in her life.

Appropriate Exercise during Pregnancy

It has been estimated that at least 1.5 million pregnant women participate in physical activity each year [124, 125], with a fair number of these involved in moderate- to high-intensity sustained cardiovascular exercise [126, 127]. A range of activities are reported—from walking and yoga to swimming, running, and aerobic dancing [124]. During a well-designed moderate- to high-intensity exercise program, the ability of the body to deliver and use oxygen and to move with endurance, strength, elasticity, balance, coordination, and efficiency improves. As a result of these training effects, the body is not stressed as much when working at a lower intensity. This is a considerable benefit in sustaining low- to moderate-intensity long-distance endurance activities such as pregnancy, labor, birth, and nursing, and in delivering oxygen and nutrients to the fetus.

The Impact and Benefits of Exercise in Pregnancy

The countless dramatic physiological adaptations that occur during pregnancy are perceived by the body as work. In response to the demands of the developing fetus, the body increases blood volume, raises the maternal heart rate, increases stroke volume, strengthens the heart muscle, and increases vasculature. These adaptations—protective mechanisms to ensure that the fetus is supplied with necessary nutrients—are also observed over time in the body's response to sustained exercise, athletics, and dance, which are also perceived by the body as work.

Research supports the view that maternal adaptations of pregnancy—including adjustments in cardiovasculature and hemodynamics, fetal responses, metabolism, acid-base balance, thermoregulation, respiration, and biomechanics—can be enhanced by regular moderate exercise without fetal detriment, providing there is no uteroplacental insufficiency or life-threatening disorder [128–131]. Physically active women also have significantly greater blood volumes and vasculature than sedentary women, as well as improved heart function, cardiac output, and aerobic training effects. These factors, along with favorable changes in blood pressure, hemoglobin concentration, and placental function, augment oxygen and nutrient delivery in a healthy pregnant woman who continues exercising throughout her pregnancy. It appears that initiation of a moderate exercise regimen in early pregnancy also produces favorable adjustments.

Cardiovasculature and Hemodynamics Studies have demonstrated that aerobic exercise during the first and second trimesters enhances placental volume and function in women who continue vigorous exercise into and through pregnancy [132, 133], and that those who commence moderate-intensity exercise three to five times a week at eight weeks' gestation benefit from enhanced feto-placental volume and function [134]. Previously sedentary women benefit from aerobic conditioning, showing increases in maximal aerobic power and submaximal duration, and preservation of anaerobic working capacity in late gestation [135], all of which are valuable assets during the prolonged, low-intensity endurance test of the first stage of labor followed by the strength test of the second stage.

Strength training, while not extensively studied, also appears to be well-tolerated by pregnant women and their fetuses, providing they avoid the Valsalva maneuver, extreme muscle fatigue, or long stretches

of time in positions that may lead to orthostatic hypotensive syndromes, such as the supine position after the fourth month, and standing for long periods or doing leg presses in the inclined (semirecumbent) position in the last trimester [128, 136].

Hypotensive Syndromes. Detrimental hypotensive syndromes can result from the relaxation of vasculature with pregnancy. Placement of the uterus in relationship to the vena cava, the size and weight of the uterus, and the proportions of the woman are factors in this condition. In the third trimester, cardiac output while standing is reduced by approximately 18 percent from a side-lying position; thus standing without moving for long periods of time is particularly dangerous. Similarly but less dramatically, in the static supine position cardiac output is reduced by approximately 9 percent in the second and third trimesters. This effect has stirred a controversy about the advisability of strength exercises in the supine position [128, 137, 138]. It is important to note that no detriment has been reported despite theoretical considerations. During supine exercise, the woman is moving and generally remains on her back for only a few minutes at any one time. Pregnant women have sharp protective instincts concerning movements with which they are not comfortable or of which they are fearful. In practice, approximately one woman in 30 will decline to perform exercises in this position [139].

While exercising in an upright, weight-bearing alignment, the pregnant woman may find blood pooling in her fingers or lower legs after 15 to 20 minutes of sustained aerobic work. It is very important to use a cooldown that includes repeated contractions of proximal muscles—that is, deep muscles close to the core of the body, such as those controlling movement and position in the iliofemoral joint, spine, abdomen, thorax, and shoulder girdle—in order to drive the blood back toward the heart and gut. To avoid the possibility of hypotensive syndromes resulting from relaxation of vasculature, the following modifications are recommended for exercise during pregnancy:

1. Limit supine exercise to two or three minutes and perform them prior to aerobic exercise or cardiovascular conditioning activities. Avoid supine position in late pregnancy. There are many creative alternatives to exercises ordinarily done in the supine position and they should be employed after the first trimester.
2. Limit aerobic exercise duration on the feet at any one time to 20 to 30 minutes for less fit women and 30 to 45 minutes for more fit women.
3. Avoid sudden changes of position or level (e.g., sitting up quickly after lying down).
4. Include a thorough cooldown to prevent pooling of blood in the extremities.
5. Rest daily in the side-lying position to maximize blood flow during the second and third trimesters.

Hypertensive Disorders. The occurrence of hypertensive disorders in pregnancy was traditionally considered a contraindication for exercise. However, regular moderate exercise continued into and through pregnancy, or commenced early enough in pregnancy, provides some protection. The ability of exercise to improve antioxidant processes, lipid metabolism, and sympathetic nervous system regulation of vascular responses provides the basis for this protection [140, 141]. Because maternal hypercholesterolemia has a downstream effect on offspring atherogenesis and vascular dysfunction [141], exercise is helpful both to mother and fetus and avoids undesirable side effects that may be incurred with pharmaceutical interventions.

A prospective study published in 2000 examining the effect of exercise on blood pressure in pregnant women with risk factors for hypertension in pregnancy found that following 10 weeks (18–28 weeks' gestation) of exercise at a rate of perceived exertion (RPE) of 13 on a scale of 6 to 20, or *somewhat hard*, there was a strong trend in the exercise group for lowered diastolic blood pressure among pregnant women at risk for hypertensive disorders [142]. The exercise sessions lasted for 30 minutes three times per week. The RPE was moderate and resulted in a mean metabolic equivalent (MET) level for the exercise of 4.7, with a standard deviation of 0.8. One MET equals 3.5 ml O_2/kg/min. The more METs a woman can tolerate, the greater her functional capacity (FC), or ability to metabolize oxygen and recover rapidly. The FC rate improves with regular, sustained exercise as it enhances cardiovascular and hemodynamic parameters.

The complex of biological and psychosocial factors that can contribute to hypertensive disorders makes exercise an interesting topic for study in this regard. Are the physical changes induced by exercise the only factors that could influence the development of these disorders? Could group fitness activities that provide social support and stress management techniques also be factors in reducing the incidence or severity of hypertensive disorders?

Uteroplacental Blood Flow. In the 1970s and early 1980s the question of diversion of maternal blood flow away from the uterus to the skeletal muscles gave rise to an extremely conservative view of exercise in pregnancy. Animal research, conducted primarily on sheep, raised the question of how much could the blood flow be diverted in humans before any detriment occurred, when in animals it was considered to be about 50 percent [143, 144]. It is thought that in moderate recreational exercise, the diversion is approximately 50 percent and in competition can be 70 to 80 percent. There is no documentation of detrimental fetal outcomes in women who participate in regular moderate- to high-intensity exercise on the basis of uterine perfusion. The primary reason for this lack of detrimental fetal outcome is probably the feto-protective combination of increased blood plasma due to both the aerobic training effect and pregnancy [129, 145, 146]. This over-expansion reduces the fall in visceral blood flow and helps maintain fetal substrate delivery during exercise. The increased hematocrit associated with exercise, as well as enhancements of placental function in fit women, also help account for the ability of the cardiovascular system to deliver needed nutrients [129, 147].

Since the mid-1980s, research has continued to evaluate the effects of exercise on uterine blood flow in human subjects. Using Doppler echocardiogram technology, investigators have looked at both the systolic to diastolic (S/D) ratio and the pulsatility index (PI) of the uterine arteries during bicycle and aerobic dance exercise with mixed results [148–153]. There continues to be no documentation of detrimental fetal outcomes in healthy women who participate in regular moderate- to high-intensity exercise. One study reports fetal cerebral vasodilation induced by submaximal exercise [154], which the authors speculate could be due to moderate fetal hemoglobin desaturation. However, they report no significant alteration in uterine profusion. Another study tested the hypothesis that pregnancy increases portal vein blood flow, and regular exercise during pregnancy limits the shunting of blood flow away from the uterus in response to gravity (i.e., standing) or exercise-induced hemodynamic stress. The researchers concluded that portal vein flow increases significantly during pregnancy and that exercise training in mid- and late pregnancy reduced the shunting of blood flow away from the uterus during exercise and improved recovery at five minutes post exercise [155].

Deconditioning. Individuals placed on bedrest rapidly become deconditioned, by as much as 25 percent in three weeks [156]. It is important to keep this in mind with women who must rest in bed or reduce their level of activity during the first trimester, near the end of their pregnancy, or postpartum. Following bedrest, reconditioning is slow but steady, whether the individual is returning to exercise or simply to the activities of daily living. Regaining a previous state of fitness takes longer than the deconditioning process [156] in the nonpregnant population. Cardiovascular enhancements of pregnancy may alter this formula in the pregnant population, but no specific data are available and a conservative approach is wise.

Recently, the efficacy of prolonged hospital bedrest has been called into question for conditions such as premature rupture of membranes (PROM), premature labor, and intrauterine growth restriction (IUGR) [157]. While the major detriment is maternal muscle atrophy, lower birth weight among infants of mothers on prolonged bedrest than those of mothers who are returned to daily activities has been observed for these conditions [157]. Women placed on bedrest for at least 20 hours per day for three weeks or more described a high level of physical, emotional, familial, and economic hardship resulting from the experience [158]. A clue regarding the negative effects of bedrest may be found in two studies conducted on rats. These indicate that when cardiovascular conditioning has occurred pre-pregnancy, cessation of exercise during early pregnancy negatively affects offspring viability [159, 160].

Fetal Responses Many mechanisms that protect the fetus are at work during pregnancy. Although it might seem counterintuitive, it appears that some mechanisms of vigorous exercise also protect the fetus. Maternal cardiovasculature, thermoregulation, metabolism, and respiratory responses seem to enhance the environment in which the fetus grows. The fetus itself appears to adapt to exercise through its own mechanisms.

Fetal Cardiovasculature and Hemodynamics. The fetal heart rate normally accelerates but maintains variability during and after maternal exercise [126, 161–167]. Gestational age and exercise type, intensity, and duration influence the extent of change in fetal heart rate during and following exercise. Accelerations of a few beats to 20 beats per minute for periods up to 30 to 90 minutes following the exercise session are not uncommon. In healthy pregnancies, reports of

greater increases in fetal heart rate (and maternal temperature) after higher intensity or longer duration have been noted without adverse fetal heart changes [168]. One study reports "signs of transient fetal impairment" including adverse fetal heart and movement changes after very heavy exercise [169]. However, this study demonstrates a difference in interpretation of exercise levels from the findings of other studies. Transient fetal bradycardia may occur occasionally in maximal exertion, but no ill effects are reported as a result [170]. Two studies documented fetal bradycardia, but both involved untrained women in rapidly progressing cycle ergometry near maximal capacity, suggesting the potential for fetal hypoxia in the unconditioned population during acute strenuous exertion [126, 171]. Another study found slight fetal cerebral vasodilation in submaximal maternal exercise, which could be due to fetal hemoglobin desaturation, although there was no significant alteration in uterine perfusion [154]. Another study—involving mothers with high trait anxiety scores—found significantly higher PI values in the umbilical artery, significantly lower PI values in the fetal middle cerebral artery, and significantly lower cerebro-umbilical PI ratios, suggesting a shift in blood distribution in favor of the fetal brain in these mothers [172].

Placental Function and Birth Weight. The frequency, intensity, and duration of physical activity in which a woman engages and at what level during the final months of gestation may have a profound effect on birth weight, with continuing high-intensity exercisers producing infants with low body-fat levels that account for the reduced birth weight (as opposed to small-for-gestational-age structure and weight). Women who reduce or cease exercise during the final months may produce higher weight infants because placental function has been well established and the fetus has little competition for nutrients during the restriction in exercise level.

Fetal Movement. Studies on fetal body or breathing movements have found changes to be small, inconsistent, and transient [162, 166, 167]. In practice, during group exercise classes mothers seem to be most aware of fetal movement during relaxation, at which time they frequently report high levels of activity, or during strength and flexibility activities. There are no reports in the literature of detrimental fetal outcomes in this regard. There is one report that fetuses of mothers with relatively high trait anxiety spent significantly more time in quiet sleep and had less gross body movement when in active sleep during the last few weeks of gestation than fetuses of mothers with low trait anxiety [173]. The level of recreational physical activity in these mothers was not tracked. Since there is a relationship between physical activity and trait anxiety (see the discussion below on stress and childbearing), it could be of interest to know if fetal movement is also affected by exercise in women with high trait anxiety.

Thermoregulation An early theoretical consideration of researchers was the possibility of detrimental teratogenic effects due to elevated core body temperatures associated with moderate- to high-intensity aerobic exercise. The risk of neural tube defects during the first trimester owing to this effect was considered grave. The first set of conservative exercise guidelines issued by the American College of Obstetricians and Gynecologists reflects concern over this matter [174]. Exposure to elevated temperatures—such as a hot tub—in early pregnancy has been shown to have detrimental effects [175, 176]. However, no evidence of this phenomenon in association with exercise has been forthcoming [177]. Research in this area [178, 179] has yielded the following considerations:

1. Core temperature falls in the early stages of exercise during pregnancy, in part due to high blood volume to carry off heat.
2. Pregnant women begin to perspire more rapidly than nonpregnant women.
3. Greater skin area and increased vasculature allow added evaporation surface to promote cooling.
4. Pregnancy-induced increased ventilation promotes cooling.
5. Habitual exercisers' regulation of internal temperature is enhanced.

A paramount concern during maternal exercise is hydration. The availability of water to contribute to the cooling process and to ensure adequate blood expansion is a fundamental principle that must be emphasized. Prior to participating in an exercise session, pregnant women should drink four to eight ounces of water, and they should drink two to four ounces every 20 to 30 minutes thereafter. The importance of consuming at least two quarts of water or other hydrating fluids per day cannot be overemphasized. Up to twice this amount may be needed at high elevations. Very active women should be en-

couraged to drink water until their urine is clear. During hot, humid weather, exercise should take place only in a cooled or air-conditioned room.

Metabolism Two major physiological priorities in pregnancy are the nourishment and protection of the fetus. It thus makes sense that human development includes a complex glycemic response that encourages storage of nutrients as fat and diversion of energy supplies from the mother to the fetus. The maternal endocrine system is in a state of chronic metabolic stress. An increased need to deliver fuel combined with hormonal actions that rapidly deplete available fuel creates a situation of large fluctuations between postprandial and fasting blood glucose levels [180].

Gestational Diabetes. The incidence of pregnant women with gestational diabetes mellitus depends upon the criteria used to screen for this disorder; reports range from 1.4 to 12.3 percent [181]. Physiologically, there is good reason to view exercise as an effective method for prevention and management of gestational diabetes. During pregnancy, there is an increased presence of hormones that have a diabetogenic effect, including estrogen, progesterone, cortisol, prolactin, and human chorionic somatomammotropin (HCS) [182]. Exercising muscles, on the other hand, participate in contraction-stimulated glucose transport, while other factors such as catecholamines, corticosteroids, and thyroid and growth hormones also affect this transport [182]. Following exercise, glucose tolerance temporarily increases, the length of time depending on insulin and contractile activity [183]. Benefits to a woman with gestational diabetes are most likely derived from insulin receptor regulation and improved insulin sensitivity that occurs post-exercise [184–186], as well as a decrease in glucose-stimulated levels of serum insulin [187], which happens in the nonpregnant population. The effects of exercise are associated with improved functions of carbohydrate and lipid metabolism. Consequently, exercise is being used as an adjunct treatment for both diabetes and obesity. This protection extends to pregnancy as well [188,189], and both the Second and Third International Workshop-Conference on Gestational Diabetes Mellitus endorsed the concept of pregnant diabetic women pursuing an active lifestyle under medical supervision [190, 191]. The management of gestational diabetes through nutrition and exercise is well accepted [192, 193].

Weight Gain and Obesity. Healthy, fit women who continued regular sustained recreational exercise throughout pregnancy at any level above a baseline for cardiovascular conditioning gained less weight and deposited less subcutaneous fat than women who stopped exercising, but this effect was limited to the latter portion of pregnancy [194]. Women who were fit prior to pregnancy and ceased exercise, or dropped their amount of exercise below conditioning levels during pregnancy, had increased weight gain and subcutaneous fat deposition. This effect may reflect excessive calorie intake on their part rather than any nutritional inadequacies in the exercising group [194–197].

As our ability to uncover metabolic markers and genetic predispositions increases, we are better able to specify which clients are at risk for excess weight gain and the extent to which exercise can mitigate this outcome. Researchers looking at two metabolic markers (tumor necrosis factor alpha and leptin) that reflect changes in fat mass and insulin resistance concluded that regular weight-bearing exercise during pregnancy suppresses the pregnancy-associated increases in both of these markers that indicate increases in body fat and insulin resistance [198]. It has been noted that first-time mothers of the G protein beta3 subunit 825 TT genotype are at high risk of obesity and post-pregnancy weight retention if they do not exercise regularly, because this is an energy-thrifty genotype [199].

Stress and Childbearing. In practice, prenatal exercise instructors encounter the question of the extent to which exercise has a salubrious effect on stress or anxiety during pregnancy. There is a relationship between the mediation of stress by corticotropin-releasing hormone (CRH) and opioid peptides, and the effect of stress on disturbed reproductive function—disrupted menstruation, parturition, and lactation—via increases in corticotropin and beta-endorphin, and their ability to inhibit gonadotropins and oxytocin [200, 201]. During labor, corticotropin and beta-endorphin are found at levels exhibited by athletes during maximal exercise; in addition, the placenta produces increasing amounts of CRH toward the end of pregnancy, signaling that the placenta may be involved in adaptive stress mechanisms to help mother and fetus withstand the stress of labor [200].

How exercise influences this equation is unknown, although it would seem theoretically possible that exercise helps mediate the stress of labor. In

a small sample, researchers found the responses of stress hormones and placental steroids in late pregnancy exercisers to be similar to those of nonpregnant exercisers [202]. Although the researchers found some incidence of uterine contractions brought on by increased levels of norepinephrine, the increase in epinephrine mitigates this effect and regular contractions did not start in any subjects [202]. Another study found that women who participated in recreational activities had a decreased risk of spontaneous preterm birth [203].

Another exercise factor that might mitigate stress is a group exercise setting. Clearly, social support is a valuable tool in the effort to avoid low maternal weight gain, premature birth, and low birth weight that may result from, or be exacerbated by, anxiety, stress, or life tensions [204–212]. Women who participate in well-run group prenatal exercise programs report that the group support is at least as important to their well-being as the actual exercise component [213].

One uncontrolled study compared exercise modalities and found different results depending upon the conditions under which the exercise took place. As a result of their findings, the researchers suggest that for exercise to reduce stress it must be enjoyable, aerobic, devoid of competition, predictable, and repetitive [214]. The release of stress hormones during exercise is related to both intensity and psychotropic effects. During the ergotropic (fight or flight) response, increased levels of norepinephrine contribute to uterine irritability. This response is often present in competitive exercise situations. In practice, we have found that, during periods of rapid uterine growth (often in weeks 24 to 34), it is helpful to avoid work or exercise environments in which the ergotropic response is activated.

Relaxation. By contrast, the trophotropic—or relaxation—response is marked by an organizing alpha brain wave, leading to a sense of calm alertness and a reduction in stress response [9]. Athletes who develop the capacity to remain relaxed during strenuous work by using an associative mental focus are at less risk for injury [215]. This has profound implications for the design of prenatal exercise activities. Midwives can help women avoid inappropriate activities by inquiring into the prevailing attitude toward exercise in women's classes or workout sessions: Is the setting flexible and conducive to teamwork and support, or is it competitive and tension-filled?

Immune System Responses. Women are more susceptible than men to all of the diseases of the immune system. The impact of gonadal hormones on immunologic function appears to be mediated through special receptors [216]. Findings show that estrogen stimulates transcriptional regulation of the CRH gene, which is the likely source of sex differences in immune/inflammatory reactions and the prevalence of autoimmune disorders in women [217]. CRH coordinates the stress response and immune/inflammatory reaction [218]. In pregnancy, the intensity of immune responses is blunted [219–221]. During the secretory phase of the menstrual cycle, progesterone fosters the production of immunological suppressor substances by the proliferative endometrium, without affecting the secretory endometrium during the time that implantation might occur [222]. Natural killer (NK) cell activity is depressed just prior to ovulation [223]. These and other mechanisms are responsible for a complex relationship between sex hormones and immune function. Theoretically, the female body would have the ability to depress immune function in order to tolerate the presence of foreign DNA belonging to the fetus. Unfortunately, the price appears to be an increased susceptibility to autoimmune disorders. The relationship between exercise and immune function in the nonpregnant population is itself a new subject about which little is known, although adequate activity appears to have positive effects. How exercise in pregnancy might affect a woman's immune system is an interesting question that will require longitudinal data.

Energy Needs and Nutrition. Both pregnancy and exercise require additional energy beyond normal levels. Standard assessment of additional nutritional needs during pregnancy is about 300 kcal, with 30 grams (120 calories) of protein per baby. How many extra calories are required beyond that for exercise will depend on the activity level of the woman.

A regular supply of simple and complex carbohydrates (fruits, vegetables, grains) with a protein complement (milk, meat, poultry, fish, nuts, and legumes in combination) is essential. A good rule of thumb for exercising women is to take in 200 to 300 kcal every two to three hours—depending upon gestational stage, size of the mother, and level of activity—and to eat a wide variety of foods. Approximately 70 to 90 grams of protein per day for a single baby, spread among the various meals, is essential, along with a minimum of two quarts of water to maintain an adequate blood supply.

Women should eat high-quality fats, such as olive or canola oil, avocados, nuts, and seeds, and avoid saturated fats and fast foods.

Careful attention to fatigue when exercising is critical. Women should stop exercising at the point of muscle fatigue, and not begin exercise when fatigued. Watered juice or sports drinks can be taken during the workout. Alternating cycles of activity, nutrition and side-lying rest/relaxation are beneficial as this allows the body systems time to complete metabolic processes and maximize circulation.

Respiration and Acid-Base Balance Ventilation and ventilatory responses to exercise are affected by pregnancy. Although some of the mechanisms are understood and their effects have been validated, there continue to be questions regarding the various responses. One key issue is whether the collection of data that compares pregnant with nonpregnant exercisers, or data comparing pregnant exercisers with themselves postpartum, produces a more accurate picture of the situation. Furthermore, there is a question of when postpartum comparisons should be made in order to reflect true values.

Another issue is the effect of conditioning on exercise test responses. The total effect of changes in ventilation due to pregnancy is generally considered to be a decrease in oxygen availability for aerobic activity and a lowering of the level of onset of blood lactate accumulation. However, in fit women, including those who become fit in the course of the pregnancy, maximal aerobic power and the capacity for sustained submaximal exercise is greater than in nonexercising pregnant women [135]. Regular exercise also contributes to the preservation of anaerobic working capacity in late gestation [135], clearly a desirable attribute for the second stage of labor. When comparing physically active pregnant women (mean gestational age 33 weeks) with nonpregnant controls, researchers found that the pregnant group had reduced PCO_2 and weak acid concentrations, which are important mechanisms to regulate hemoglobin concentration and maintain a less acidic plasma environment at rest and after exercise in late gestation, compared with nonpregnancy [224]. Additional research has found that cardiovascular conditioning reduces both ventilatory demand and respiratory perception of effort in late gestation [225].

The practical reality of pregnancy is that breathing is affected at two points. Toward the end of the first trimester many women experience an uncomfortable tendency to hyperventilate resulting from the effects of increasing levels of progesterone as the placenta takes over from the corpus luteum as the primary progesterone producer, affecting the respiratory control center in the medulla oblongata [226]. This increase is tied to lowering levels of carbon dioxide and increasing oxygen levels that benefit the fetus. The increased metabolic activity in pregnancy causes an increase in carbon dioxide levels. Hyperventilating lowers the carbon dioxide level. As pregnancy progresses, the upward growth of the uterus puts pressure on the diaphragm. There is some widening of the rib cage, and the total effect is a reduction in functional residual volume. This may cause a sense of labored breathing and a tendency to hyperventilate in response. Both of these breathing difficulties fall under the heading of *dyspnea*. Even women who are very fit may experience these sensations. To alleviate the symptoms, women should breathe slowly and deeply, taking advantage of intercostal expansion, and slow down if they are exercising.

Biomechanics The potential for damage in pregnancy and the postpartum period to a woman's neuro-musculo-skeletal structure is great. Shifts in the center of gravity (COG) forward and slightly up destabilize her posture and realign the carriage of weights and forces through her joints, predisposing nerves, muscles, bones, and connective tissues to damage. Increased levels of relaxin and elastin further aggravate this situation.

In the antepartal period, changes in posture occur gradually and can be responsible for a great many discomforts over the course of the pregnancy. Women can relieve these structural stresses by doing the following:

1. strengthening muscles that are overstretched (hamstrings, gluteals, abdominals, and upper back)
2. stretching muscles that are shortened (psoas, low back, and chest)
3. engaging in centering activities that promote efficient alignment
4. resting in the side-lying position when muscle fatigue occurs

The brain receives a continuous supply of afferent information about the shifting postural dynamic and eventually accepts the altered arrangement and balance of body segments. This process involves feedback from cutaneous, joint, and muscle receptors. By the end of pregnancy, the brain has reconfigured its image of the body in balance.

Pregnant women are particularly subject to nerve compression syndromes, such as carpal tunnel syndrome and piriformis muscle impingement of the sciatic nerve. Methods to alleviate these problems during exercise include stabilizing and elevating the affected part, avoiding weight-bearing on the affected part, and avoiding extreme range of motion. During relaxation, it is also useful to focus on releasing the muscles surrounding the joints in the region of the insertion of affected nerves into the spine—i.e., upper back, chest and shoulder for carpal tunnel syndrome, or sacroiliac and posterior iliofemoral joints for sciatica.

Strength work and stretching help alleviate discomforts due to joint stress and instability. Striking a balance between strength and elasticity among the muscles that control a given joint tends to balance and protect the joint. Physical balance is one of the components of centering. When the joints are balanced, the neuromusculature is less busy with remaining upright than when misalignment or unbalanced muscle development places demands on the superficial skeletal muscles to help maintain the body upright as well as to cause movement in space. Instead, when joints are balanced, incipient contractions of deep muscle fibers nearest the joint centers are the primary righting mechanism.

When balanced, relaxed, and able to breathe deeply, a person is centered. Movement or behavior goals are easily and efficiently achieved as there is less physiological stress within the system to claim the brain's attention [227–229].

Psychophysiological Responses The physical gains in strength, endurance, flexibility, and motor control that accrue through exercise, coupled with associated gains in self-awareness, confidence, mental discipline, and attention to healthy behavior (good hydration and nutrition, avoidance of smoking or drugs), predictably result in physiologically enhanced function. These attributes also accrue in the childbearing period. In addition, persons who participate in regular exercise, athletics, or dance demonstrate psychophysiological adaptations, including a sense of well-being [230, 231] and relief from discomfort [232–235]. Women participating in regular exercise throughout their pregnancies report lower levels of perceived exertion during pregnancy and labor, experience less discomfort, and recover more quickly than those who do not exercise or stop exercising during pregnancy [11].

The question of whether and how physical fitness affects a woman's perception of pain and might therefore alter her tolerance for pain in labor is an interesting and complex issue. It appears that the level of beta-endorphins—or endogenous painkillers—in the blood, while stimulated by the aerobic component of exercise, is primarily connected to fatigue, discomfort, and/or anaerobic activity [236] and that improved aerobic capacity does not lead to improved performance of psychological tasks [237]. Clearly, components of exercise other than aerobic fitness play fundamental roles in the capacity of the exerciser, athlete, or dancer to deal mentally with what is commonly perceived as pain. A survey published in 1978 sheds light on how the ability to deal with pain in a constructive way may work. In comparing average marathon runners with exceptional marathon runners, W. P. Morgan discovered that the average runners tend to dissociate from their bodies, while the exceptional runners tend to associate with their body sensations except in situations where the end was well within sight or there was no other successful strategy than dissociation [215]. The average marathoners created elaborate schemes (such as designing and constructing buildings) for distracting themselves from discomfort, often fearing *the wall*—the 20-mile mark in the 26-mile race where many runners experience severe distress. The exceptional runners, on the other hand, claimed the wall was a myth and only happens if you are not paying attention to your body, monitoring discomfort, staying relaxed, and making necessary adjustments in your form.

What one person might call a *pain*, a highly skilled athlete or dancer might call a *tight spot* or *tense area*, and make some adjustment in form to relieve the discomfort. This capacity to sense, compute, and modify movement is an aspect of the phenomenon of *attention* [238]. By directing attention to goals of being relaxed, fluid, balanced, and achieving the desired movement (such as releasing a baby from one's body), it is possible to acquire the kind of mentation that promotes ease of movement even under difficult circumstances [227, 239–241]. Research into women's views of fulfillment in the birth process supports the theory that sensation associated with difficult but purposive physical events may bear the title *pain* but has a different emotional content than pain associated with nonvoluntary body trauma [242].

Pregnancy and Birth Outcomes Associated with Exercise

There is no evidence that exercise contributes to congenital anomalies, spontaneous abortion,

abruptio placentae, intrauterine growth restriction (IUGR), pregnancy-induced hypertension (PIH), or fetal demise [129, 243]. Rather, there may be a slight protective factor for some of these conditions [143]. Evidence also suggests that heart rate abnormalities, cord entanglement, and the presence of meconium are significantly reduced for babies of exercising women [129, 143]. In addition, while there is no increase in gestations of fewer than 260 days, there may be fewer postdate gestations [37, 38]. The incidence of low Apgar scores is reduced among infants of exercising mothers, there is no indication of long-term neurological or physical deficit [143, 244, 245], and research indicates some psychomotor enhancement for these infants [143].

Those who engage in vigorous exercise require less intervention in labor—including a substantially decreased rate of cesarean birth—and may have shorter active phases of the first stage and shorter second stages of labor than nonexercisers [129, 245–247], according to studies in the late 1980s and 1990s. A study released in 2000 concerning aerobic exercise participation during the first two trimesters and type of delivery in first-time mothers demonstrated that sedentary women were 4.5 times as likely as exercising mothers to deliver by cesarean [248].

Pregnant Adolescents and Exercise

Only one study has directly addressed exercise in pregnant adolescents. This research examined the effects of a six-week aerobic exercise program and found that the exercise group had a significant decrease in depressive symptoms over time and and an increase in total self-esteem, while the nonexercising group reported a significant increase in physical discomforts associated with pregnancy [249]. The study's author concluded that aerobic activity should be viewed as an important aspect of prenatal self-care for healthy pregnant adolescents.

Researchers looking at outcomes among adolescent mothers and infants found that both those who sought prenatal health care in the first trimester and those who delayed prenatal care until the third trimester reported similar self-care knowledge and practices regarding diet, exercise, and other topics. However, those who sought early prenatal care had significantly more positive outcomes [250], suggesting the need for combining early prenatal care with development of self-efficacy in this population as a means of improving outcomes.

Management of Exercise in Pregnancy

Supporting and monitoring prenatal exercise can be integrated relatively simply into the caregiving process. Gathering relevant information, assessing and evaluating the information, helping a woman choose her activities, assessing her progress, and evaluating the outcome can all be done within the existing framework for management of care. The following steps can be included in the management process during the antepartal period:

1. Establish a database
   - **a.** motivation
   - **b.** exercise history and classification
   - **c.** nutritional status
2. Screen
   - **a.** contraindications to exercise
   - **b.** conditions for assessment
   - **c.** conditions that may benefit from exercise
   - **d.** warning signs
3. Make exercise recommendations
   - **a.** priorities and components of exercise
   - **b.** appropriate types of activities
   - **c.** special exercises for pregnancy
   - **d.** safety issues
4. Periodically assess and evaluate the exercise program
5. Evaluate the exercise program in relationship to outcome

Establishing a Database

Motivation. Women exercise during pregnancy for a number of reasons. An exercise habit, a desire to be with other pregnant women, and/or fear of losing control of her body are some of the major reasons a pregnant woman might choose to exercise. In order to satisfactorily determine an appropriate exercise regimen for any individual, it is important to ascertain her motivation. Exercise—like pregnancy—requires a commitment, and unless she is involved in activity that engages her attention, loss of interest is likely to occur. When a woman has a strong desire to be with other pregnant women, a prenatal group exercise class may be a good choice for her primary weekly activity. A certified prenatal group fitness instructor will be able to create a setting in which support and education occur and to provide safe and effective exercise routines. The instructor can also monitor participants' other activities to ensure they are accumulating sufficient amounts of necessary exercise components.

If a woman has acquired an exercise habit and is fearful of losing her sense of accomplishment with her regular routine, she may be encouraged to combine parts of her weekly routine with more gentle, new activities that will provide a challenge without pointing out her new limitations. Or she may benefit from joining a prenatal class where she can learn to modify her activities without embarrassment, bringing what she learns back to her regular exercise setting. A personal trainer, qualified to deal with pregnancy, might be a solution for a hightly competitive or professional athlete or dancer.

Many women turn to exercise out of fear or worry that their bodies will become foreign to them or that they will lose control of themselves in some manner. This is not an ungrounded fear and should be treated seriously. Assurances should be given that physical activity will promote familiarity with a changing body. Being in a prenatal exercise group for support is also helpful. Other women—particularly those who have already experienced a previous pregnancy—are a great source of information and reassurance.

Exercise History and Classification. It is important to gain as much information as possible about the type and quantity of exercise in which a woman has engaged in the year or two prior to her pregnancy and in the first few weeks of gestation. Conditioning is specific and will vary depending upon the recent activities of any given individual. Remember that the best adaptations are small changes in the routine. Taking an exercise history, such as the one presented in Figure 9-2, is essential. It helps the midwife determine how much of what type of activity the pregnant woman has as a base, how much guidance she may need as she progresses, and whether or not to refer her to a specialist.

If a woman claims to get little exercise but has a physically demanding job and a toddler at home with whom she plays several hours each day, she may need a recreational activity that permits her to slow down, such as a prenatal yoga class. On the other hand, a woman who was accustomed to doing regular vigorous aerobics classes, lifting weights, and swimming for the year prior to her pregnancy but has been ill and inactive for the last two months may need to find a group class where she can be safely monitored and slowly return to an appropriate level of fitness.

Women's impressions of their activity levels can be at odds with reality. Sometimes women claim to be highly active but in fact are highly stressed, getting very little activity that truly produces health and fitness. Others—especially those with small children at home—may think they do very little exercise but actually are on the go for much of the day. Finding out as much specific information as possible will be of great help in establishing an appropriate regimen for a given woman during a given pregnancy.

Once a history has been taken and reviewed, it is useful to classify a woman as to her activity level to help determine how much activity may be appropriate. If a woman is motivated by a desire to obtain the beneficial outcomes of exercise in pregnancy, such as relief of discomforts, increased stamina, help with her labor, and quick postpartum recovery, being in at least the "active" category is critical. If she is so motivated and is not very active, positive feedback about progress, encouragement, and rewards in the form of verbal praise are very important in assisting her to become sufficiently active to attain benefits. Five gross classifications of activity level are typically used when designing a prenatal regimen [139]:

1. *Inactive or sedentary:* no exercise; may perform most activities of daily living, but not more strenuous tasks, such as moving furniture or mowing the lawn.
2. *A little active:* accumulates one to three 30-minute activity sessions over the course of a week; may involve walking, gardening, bicycling, badminton, or other recreational activities.
3. *Active:* accumulating at least 30 minutes of activity or exercise almost daily, with at least three days involving 15 to 30 minutes of sustained moderate-intensity aerobic work, two days involving strength and stretch work, and some centering, relaxation, and/or imagery.
4. *Very active:* more than five regular exercise days per week, with regular moderate and/or high-intensity aerobics, strength, stretch, relaxation, centering, and/or imagery.
5. *Professional or competitive:* exercise as a job or lifestyle; strenuous exercise daily and appropriate recovery work.

The first three levels parallel adolescent girls' activity levels, but at the high end of activity participation, we can identify two categories instead of one. As physically gifted or motivated girls become college athletes and move into adulthood, some retain their high activity level as a recreational outlet (classification 4), while others become professional or competitive athletes and dancers (classification 5), who may require special consideration.

Exercise History (Prenatal)

Name:_____ Date:_____ Due Date:_____

For the year prior to your pregnancy, which of the following things did you do regularly?

Aerobic exercise

No. of sessions/week_____ Approx. length of each session_____

What was your target heart rate range?_____bpm

What was your RPE (rate of perceived exertion) range? (Circle lowest and highest intensity)

Very light Light Fairly light Somewhat hard Hard Very hard Very, very hard

List your activities (running, aerobic dancing, etc.): _____

_____

Strength activities (weight lifting, calisthenics, etc.)

No. of sessions/week ____ Hip and knee flexors/extensors and ab/abductors

____ Chest and back; shoulders and arms

____ Abdominals; spine (core strength)

____ Pelvic floor

Flexibility activities (yoga, stretching, dance, etc.)

No. of sessions/week ____

Combination activities (advanced dance, martial arts, basketball, etc.)

No. of sessions/week ____ List your activities:_____

Relaxation (progressive relaxation, autogenic training, hypnosis, etc.)

No. of sessions/week ____

Centering (mediation, dance, t'ai chi, etc.)

No. of sessions/week ____

Do you have one or more children in the 1- to 5-year-old range who are very active? (circle one) Yes No

If so, how much time do you spend with her/him/them?_____

Do you have a physically demanding job? (circle one) Yes No Is it stressful? Yes No

Are you on your feet a lot? (circle one) Yes No Describe your work activities:_____

Describe your exercise and/or physical activities since the start of this pregnancy: _____

_____

Nutritional Status. It is also critical to gather information about a woman's nutritional status, including her hydration. Clearly, women who refuse to eat an adequate amount of food or drink enough water should not exercise. Those who refuse to make healthy choices about nutrition should be persuaded to make whatever changes are possible. Nutrition, exercise, rest, and avoidance of drugs and alcohol form the bases of the optimal approach to childbearing, based on the premise that a healthy mother makes a healthy baby.

There are two major considerations in analyzing nutrition for women who choose to be active in pregnancy. One is the protein and hydration status: Is the woman taking in sufficient quantities of usable protein and water that she is able to (1) produce the additional blood volume required to sustain both fetal growth and her own muscle efficiency and (2) grow a neurologically adequate fetus? The second consideration is the carbohydrate status: Is the woman taking in sufficient quantities of carbohydrates (and especially complex carbohydrates and whole fruits and vegetables) to meet the energy requirements of her own body and her fetus? In addition, her fat intake should include high-quality fats—that is, vegetable oils, nuts, seeds, avocados, and, occasionally, fish such as salmon.

A food diary is a useful tool for both gathering information about a woman's nutritional status and helping to educate her about her dietary needs as a mother-to-be. The sample shown in Figure 9-3 includes the information needed to make a determination about the adequacy of the daily food intake. After asking for a recall of the day's food, the care provider, patient educator, or fitness specialist can go over the list, determining calories and grams of protein. A glance at the types of foods eaten will provide an idea about whether or not there is adequate intake of calcium, iron, folic acid, and other vitamins and minerals, as well as fluids and fiber. Reviewing the diary with the woman is helpful in adjusting a diet that has room for improvement.

Screening Assessment of medical conditions, physical signs, and symptoms is an essential ongoing function of monitoring the exercise regimen, and screening is a fundamental first step in the assessment process. Adequate screening protects the mother and baby, the midwife, and the perinatal fitness instructor or trainer. By eliminating conditions that are contraindications to exercise, noting conditions that may benefit from exercise, reviewing conditions that may require ongoing assessment, and paying attention to warning signs and symptoms, problems are most easily avoided and the chance of a positive outcome is maximized. A perinatal fitness specialist will require completion of a screening form before taking a woman into a group class or as a one-on-one client. The screening form serves as another educational tool for the mother-to-be and gives the care provider and fitness specialist an important means of ensuring that a woman is not engaged in inappropriate activities. An example of a medical screening form is shown in Figure 9-4. Care providers may also wish to refer to recommendations about contraindications in the 2002 committee opinion paper issued by the American College of Obstetricians and Gynecologists concerning exercise in pregnancy and the postpartun period [174].

If a woman is a competitive athlete or a professional athlete or dancer who plans to continue working at a high level throughout her pregnancy, prepregnancy fitness testing is advisable. This should be done in conjunction with a member of the health care team trained in both exercise physiology and obstetrics. The woman's activities and fetal responses should be recorded and reviewed regularly thoughout the pregnancy.

Most women who wish to exercise, however, will present themselves after the fact of conception, often at six to ten weeks' gestation. Screening all women at this point may be useful to locate not only those who may have problems but also those for whom it may be an advantage to be more active. The advisability of continuing exercise or making alterations should be reviewed whenever conditions for assessment or warning signs and symptoms occur.

Making Exercise Recommendations

Priorities. Above all else, safety must be accounted for. Women who have conditions for which exercise is contraindicated obviously must be discouraged from strenuous exertion. Some conditions will allow for gentle activities that include centering, relaxation, and imagery—for example, meditation, t'ai chi, or prenatal yoga. Others will not. Conditions that require monitoring—such as a low-lying placenta—may require patience on the part of the expectant mother, especially if she is used to a high level of activity. But safety is an acceptable issue to most women as a reason to be cautious. In the first trimester, fatigue or nausea may also slow women down. When returning to exercise, a reminder about the effects of deconditioning is advisable, along with a caution to go slowly.

Food Diary

Name:_____ Date:_____

Age:_____ Weight:_____ Gestational age in weeks:_____

How much water, juice, milk, or other noncaffeine, nonalcohol fluids do you drink each day?_____

How many times a day do you eat?_____ Approximately how many calories each time?_____

Food Diary for One Typical Day

Time of Day	Name of Food(s)	Quantity	Calories	Protein Grams

Medical Screening Form for Prenatal Exercise Participants

Name:_____ Date: _____

Signature of care provider: _____

TO THE CARE PROVIDER: Review these conditions and indicate if any now exist or existed previously. Add any notes you think may be helpful to the fitness instructor.

Contraindications for Exercise
____ Placenta previa
____ Premature rupture of membranes (PROM)
____ Incompetent cervix
____ Chronic heart disease
____ Premature labor
____ Toxemia or PIH
____ Tearing or separation of placenta (abruptio)
____ Fever (or presence of infection)
____ Acute and/or chronic life-threatening condition

Conditions That May Benefit from Exercise
____ Diabetes
____ Gestational diabetes
____ Hyperinsulinemia
____ Overweight
____ Discomforts
____ Depression
____ Weakness
____ Lack of stamina

Conditions for Assessment
____ Marginal or low-lying placenta
____ History of IUGR
____ Diabetes or hyperinsulinemia
____ Irregular heartbeat or mitral valve prolapse
____ Anemia
____ Multiple gestations
____ Thyroid disease
____ Three or more spontaneous abortions
____ Excessive over- or underweight
____ Extremely sedentary lifestyle
____ Asthma

Warning Signs or Symptoms
____ Edema of face and hands
____ Severe headaches
____ Hypertension
____ Dizziness or disorientation
____ Palpitations or chest pain
____ Difficulty walking
____ Nausea
____ Bleeding or fluid discharge
____ Regular strong contractions
____ Cramps
____ Fever

FIGURE 9-4 Medical screening form for prenatal exercise participants. *Source:* © 1985, 1995, 2002 Ann Cowlin.

For a woman starting a first-time regular exercise routine during the first or second trimester, it is wise to do so under the direction of a perinatal fitness specialist who can monitor her progress and is aware of potential problems. If the woman is enrolled in a special prenatal class where she is seen two or three times per week, the instructor is often the first to notice warning signs or symptoms that warrant immediate referral to the midwife. A well-trained instructor will ask her client who shows up one day with edema of the fingers, hands, and face to refrain from class, go to her care provider, and have her blood pressure checked.

An inactive woman should be discouraged from starting vigorous exercise after 26 weeks. Placental enhancement that takes place in exercising mothers during the first and second trimester will protect the fetus of high-intensity or high-volume exercisers in the third trimester; however, women who have been sedentary will not have that protection. Walking at a comfortable pace and special prenatal exercises such as abdominal hiss/compress, Kegels, and pelvic rocks are always suitable as long as no contraindications are present.

Modifications of ballistic or high-impact movements are important, even for highly trained individuals. Sports such as soccer or squash that require complicated equipment or a potentially hazardous environment may involve motions that are perfectly

safe by themselves but become unsafe because of the situation. A safe alternative for accomplished athletes or dancers is to execute the movements of the sport in a safe setting, without equipment or other players, or with a partner who is willing to be noncompetitive.

To determine what will be an effective program, the care provider must consider two items: (1) the individual woman, her motivations, exercise and medical histories, genetic potential, age, lifestyle, and preferences, and (2) current research findings, which emphasize the variation in individual responses to exercise in pregnancy. Clearly, if a woman is interested in being healthy, taking care of herself and her baby, being prepared for the challenges of labor, birth, and nursing, and has an active lifestyle, it will be easy to steer her toward an exercise regimen with activities she enjoys on three to five days a week. For women whose motivation is more vague or intuitive ("I know I should be exercising..."), ascertaining interests and previous experience is a key. Being a little active and enjoying it throughout the entire pregnancy will be more beneficial than pushing early on, possibly being injured or discouraged, and quitting.

Women who have the mental capacity and exercise background to work hard throughout the pregnancy may require subtle encouragement to be sure to stay attentive to kinesthetic cues and fatigue. In general, women's instincts to protect themselves and their babies are keen.

The effectiveness of any exercise regimen is tied to compliance. The gains to be had are achieved in the actual practice. When practice is fun, it is easy to comply. If exercise is viewed as a recreational activity, a game, or time to be with friends, it becomes its own reward.

Components. The following exercise components are safe and effective elements of a prenatal exercise program:

1. *Centering:* Balancing the body's bony levers and achieving the relaxation response (see below) through deep breathing and associative mental focus; often done at the beginning of activities such as t'ai chi or modern dance to promote safe biomechanics and fluid movement. Commonly used postures are shown in Figure 9-5. Upright seated postures, with weight on the ischial tuberosities and not on the coccyx—either tailor fashion or in a chair with feet flat on the floor and knees parallel to the hip joints—are commonly used. Some methods involve standing with hips, knees, and ankles slightly flexed and active. When centering, incipient righting motion will occur.
2. *Aerobic or cardiovascular conditioning:* Large, rhythmic and repetitive movements using more than 50 percent of the body's muscle mass in a sustained manner, challenging the circulatory system and elevating the pulse; use Table 9-1 to assess the range of appropriate intensities for an individual. Submaximal exercise measure-

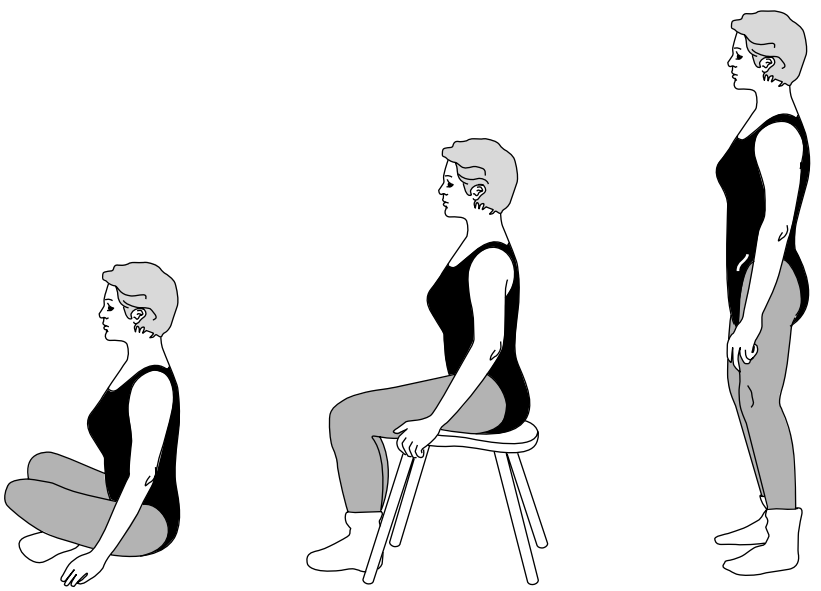

FIGURE 9-5 Centering postures.

TABLE 9-1 Range of Aerobic Intensities for Healthy Pregnant Women

Intensity	Rate of Perceived Exertion (RPE)[a]	Functional Capacity[b] (% VO_2 max)	Heart Rate[c] (beats/minute)	
	Very light			
		50	100	120
			103	123
Low			106	126
	Fairly light		109	129
			112	132
		60	115	135
			118	138
			121	141
	Somewhat hard		124	144
			127	147
		70	130	150
Moderate			133	153
			136	156
	Hard		139	159
			142	162
		80	145	165
			148	168
			151	171
	Very hard		154	174
			157	177
High		90	160	180
			163	183
			167	187
	Very very hard	95	170	190

[a] RPE is a subjective measure of how hard a person is working. There is a rough correlation between most people's subjective sense of exertion and objective measures of their oxygen consumption or heart rate.

[b] Functional capacity is a measure of how much oxygen a person is consuming during work and is given as milliliters of oxygen consumed per kilogram of body weight per minute. The unit of measurement is the MET; 1 MET = 3.5 mL O_2/kg/min. The number of METs an individual can tolerate is her or his functional capacity. Aerobic training effects occur in the range of 40 to 85% of the maximum amount of oxygen an individual can consume (VO_2 max). The maximum capacity varies with individual genetic potential and conditioning. Anaerobic threshold is approached at approximately 85 to 90% VO_2 max.

[c] Heart rates shown are for women in the age range of 20 to 40. Rates in the left column are likely values for women who are closer to 40 or who are less fit; those in the right column are likely values for women who are closer to 20 or who are extremely fit. The correspondence between exercising heart rates and the percentage of functional capacity is a complex relationship that depends on genetic potential, training, and age and is further complicated by the responses of pregnancy.

ments vary somewhat from nonpregnant values. However, in practice, perceived exertion has proved to be an effective method of estimating how hard a woman is working in pregnancy. Subjective perceptions of working "somewhat hard" to "hard" three to five times per week for a minimum of 20 minutes provides cardiovascular enhancement and improves delivery of nutrients as well as outcomes.

3. *Strength conditioning:* Contracting the skeletal muscles against resistance, using equipment or the body's own weight; protects the skeleton and connective tissue, increases lean body mass, and raises the resting metabolic rate.
4. *Flexibility exercises:* Elongating the muscles in a controlled fashion employing balanced alignment, small increases in range of motion (ROM), and static stretching; relieves discomfort and promotes proprioception (balance) and kinesthesia (awareness of position and movement).
5. *Relaxation:* Resting in a comfortable position and achieving the relaxation response; reduces stress and elicits feelings of well-being. After the first trimester, women should rest in the

side-lying position, not on the back. The following prerequisites are needed to elicit the relaxation response, as outlined by Benson [9]:

a. a quiet location
b. conscious relaxation of skeletal muscles
c. a single mental device, such as a word, phrase, or image
d. a passive attitude toward intrusive thoughts

There are five physiological measures that indicate a person has achieved the relaxation response:

a. alpha brain waves
b. low resting pulse
c. slow respiration
d. lowered blood pressure
e. lowered metabolism (decreased oxygen requirements)

During an activity session, observing the rate of respiration is the least invasive means of determining if a woman is actually able to relax.

6. *Imagery (or mental rehearsal) of desired action:* Once relaxed, mentally watching or imagining oneself doing something like properly swinging a tennis racquet or pushing out a baby without actually trying to do it; this activates subcortical neural pathways that most efficiently pattern the action. While physical practice refines movement execution, imagery refines the intention of the action. Neither the physical nor mental aspect can be completely disconnected from each other, but by focusing on one aspect, the entire process is enhanced. Most human movement is composed of unconscious, subcortical reflex actions and rhythmic motor patterns. The cognitive contribution is largely one of seeing in the mind's eye and refining intention by ideation and sensory feedback. Beyond having a precise and accurate intention, there is little one can do to govern execution. Attention to intent is a powerful command to see that it is efficiently patterned at the subcortical level. *Ideokinesis* refers to the practice of refining the image (*ideo-*) of movement (*-kinesis*) while in the relaxation response, such as watching oneself shoot a basketball or open the birth canal.

Appropriate Activities. Deciding which activities are appropriate for a particular individual is sometimes an easy process and sometimes it is not. If a woman has been participating in low-impact aerobic dancing for many years prior to her pregnancy, she may simply need to adjust her intensity level on any given day if she feels like taking it easy. If she is fine with the physical aspect of the activity but is feeling like a fish out of water, she may need to find a prenatal group class where she will get the support of her peers.

On the other hand, a professional downhill skier may need a lot of help finding something challenging yet safe. If she is comfortable with the biomechanics, perhaps a water class or beginning African dance class would provide an interest that she can work to master over the course of her pregnancy. As an anonymous beginner, she may not feel compelled to compete and yet may have plenty of small learning moments ahead of her that will be rewarding.

A sedentary woman who may be a health risk if she does not begin to work with her body may provide a great challenge to the care provider. Unless she is highly motivated, it is likely she will require much education and support, even if a simple walking program is all that she can do. Depending on her circumstances, the best approach may involve a personal trainer, a group situation, or merely a friend with whom she can walk on a regular basis. Someone trained to evaluate the physical capabilities and assess the motivational requirements of an untrained individual can be of great assistance at this point.

It is important to take into account the inherent challenges of a given activity, including movement patterns (which parts of the body do which actions in what sequence); effort-shapes (the way the energy takes form—for example, some actions are gliding while others are slashing motions); and the dangers from equipment, other players, or the environment. Obviously, more active women will have more movement skills, which means that more activities will be reasonably appropriate for them. Nonetheless, if changes need to be made in a woman's typical activity for safety reasons, it is good to look at similar activities that may be less risky. Doing more than one type of activity also has benefits. Cross-training—or varying activities from session to session—helps prevent overuse injuries and avoids boredom.

Table 9-2 lists common recreational sport, exercise, and dance activities that may be suitable for women during pregnancy. On the basis of movement patterns, effort-shapes, the requirements of the equipment, and special skills, the suitability of each activity has been assessed for women with varying activity levels, during each trimester. Every woman must ultimately make her own decision about whether or not to participate in a given activity, but it is useful to have some guidance based on the difficulty of the activity and the experience of the participant.

KEY: 1 = first trimester; 2 = second trimester; 3 = third trimester.

* Requires special skills and/or familiarity with equipment and poses dangers because of demands of those skills or equipment.

† Risky even with previous experience because the environment cannot be controlled; becomes increasingly dangerous as pregnancy progresses.

‡ Not recommended for women in any stage of pregnancy.

Reminder: The appropriateness of any activity is ultimately a matter that only the expectant mother herself can assess.

Source:

Special Exercises for Pregnancy. The following movements, performed regularly for many months prior to birth, provide relief of discomfort during pregnancy and preparation for labor:

1. *Hiss/compress—in a seated position:* Exhale by making a hissing sound and compressing the transverse abdominal muscle, then relax the abdomen and inhale through the nose. Hissing sets up a resistance that is overcome by the forced exhalation action of the transverse abdominal muscle as it compresses the abdominal contents. Repetition of this action in two or three sets of five compressions strengthens this muscle in preparation for pushing or bearing down in the second stage of labor, which combines contraction of the transverse abdominal and downward effort of the diaphragm toward the vaginal opening with the release of the pelvic floor muscles. Postpartum, this muscle helps flatten the lower abdomen and protect the lumbar spine.
2. *Spinal c-curve:* Flex the spine forward while exhaling. Try to focus on the abdominal muscles and avoid tightening the gluteals or pelvic floor. Beginning with a hiss/compress, increase the action by curving the spine, bringing the more superficial abdominal muscles (obliques and rectus abdominus) into play. This can also be done on hands and knees.
3. *Curl-downs:* In a seated position, exhale and roll onto the sacrum, exaggerating the spinal curve and placing a greater load on the abdominal muscles; after 20 weeks' gestation, splint the abdomen by placing hands on the sides of the abdomen and pressing toward the center to prevent the development of diastasis recti.
4. *Side bending and lateral pelvic rock or rotation:* Usually standing and curving slightly between the ribs and pelvis; there is a slight rotation of the ribs or pelvis around the vertical axis at the level of the lumbar spine, with accompanying iliofemoral (hip) extension and sacroiliac flexion on the forward side and the reverse on the other side; this is often also accompanied by lateral flexion in the lumbar spine. The movement can also be achieved by bringing one leg forward and lifting it several feet off the ground, or by making a lunge to one side. Trained dancers and athletes will sometimes seek to counteract the natural tendency of the pelvis to twist when lifting the leg forward or lunging to the side, but they should allow the natural motion to occur. These actions involve the oblique and lumbar muscles in the trunk, as well as muscles controlling the pelvis and hip joints, and allow for changes in the internal space and resistance within the birth canal, all of which helps the baby move down in labor.
5. *Anterior-posterior pelvic tilt:* Flex the lumbar spine and extend both iliofemoral joints by contracting the gluteals to achieve posterior tilting (top of pelvis goes back); in neutral position the pelvis is vertical; to achieve an anterior tilt, bring the buttocks back and arch the lumbar spine.
6. *Kegel exercises:* Contract and release the ischiocavernous and transverse perineal muscles, the levator and diaphragm muscles, and the pubococcygeal (sphincter) muscle, separately and in unison. These exercises strengthen and relax the muscles of the pelvic floor and birth canal.
7. *Deeply folded position:* From a crawling position on hands and knees, pull pelvis back and down over feet, knees apart, and flexing deeply in the iliofemoral and knee joints; relax the spine by dropping the head forward; breathe deeply and slowly (Figure 9-6).
8. *Squats:* Sitting on the floor, bring one knee toward the armpit and place the foot on that side on floor; lean forward until weight is on that foot and both hands; bring other foot onto floor. If both feet will not stay flat on the floor, lift one heel as high as possible and bring pelvis over that foot; alternate sides (Figure 9-7).
9. *Side-lying position:* Assume the side-lying position and practice relaxation and imagery.

Safety Issues. The following guidelines can serve as a review of the safety issues arising from the interactions of pregnancy and exercise. It is a good idea to go over them with the expectant mother and to keep a copy of this list somewhere visible (perhaps on the back of the frequently used door in the office or on a bulletin board).

1. Exercise regularly and moderately, avoid jarring movements of the abdomen, and include

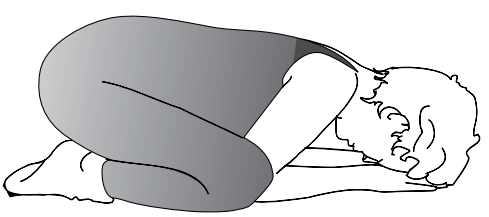

FIGURE 9-6 Deeply folded position. Begin on hands and knees. Pull pelvis back and down over feet, flexing deeply in the hip and knee joints (contraindicated for women with knee problems). Relax the spine by dropping the head forward. Relax the arms.

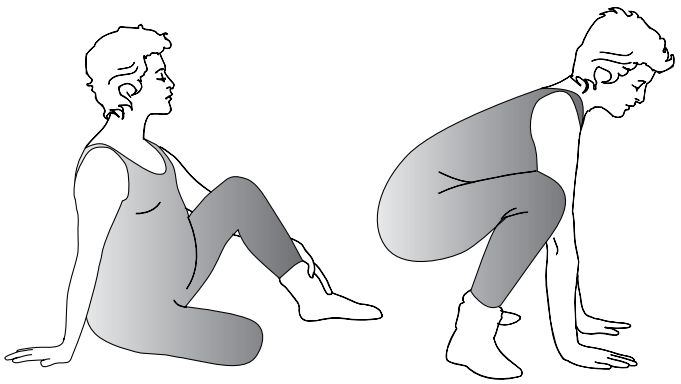

FIGURE 9-7 Squat. Begin seated on the floor. Bring one knee toward the armpit and place that foot flat on floor. Lean forward onto both hands. Bring other foot onto floor.

some relaxation in your routine. Avoid binge exercise! Although exercise will reduce blood flow to the uterus, moderate exercise is not a problem because your placenta has adjusted and provides the baby with plenty of oxygen and nutrition.

2. Make sure your midwife screens you for contraindications (conditions that exclude you from exercising), and make sure you know the warning signs that should be reported to your midwife.
3. Avoid lying on your back or standing up for long periods of time after the first trimester; your blood pressure might drop, you might get light-headed, or you may have swelling in your hands or feet. If any of these things happen, lie down on your side to rest. Tell your midwife.
4. Avoid fatigue and overtraining.
5. Eat a combination of healthy foods, in small amounts, all through the day.
6. Drink at least eight cups of water or fluids daily and avoid hot, humid situations.
7. Make sure any equipment you use is in good condition and is safe (for example, make sure it can't hit you in the abdomen). Wear clothes in layers, so you can remove something if you get too warm. Make sure your shoes are comfortable and provide good support.
8. If you are a professional or competitive athlete or dancer, you may need extra food, fluids and rest. Your baby's growth must be monitored carefully by your health care provider.

Periodically Assessing and Evaluating the Exercise Program During regular visits, inquiring into exercise activities allows the midwife to learn not only how the individual woman is progressing in her program, but also enriches the midwife's knowledge of what is available to women in her area. Having the expectant mother maintain an exercise log, including the day, time of day, activity, components of exercise included (centering, aerobics, strength, stretch, relaxation, imagery, special exercises such as Kegels, tilts, etc.), and how she felt before, during, and after the session, is a good tool for evaluation. If a woman is enjoying her activities, is feeling good, is healthy and feels she is benefiting from her program, and her baby is growing properly, this is obviously a successful situation. If she is unhappy, complaining of discomfort, or not healthy, it is important to determine if there is something in her program that is detrimental or if she herself is unable to comply with a safe program. Clearly, if conditions that require assessment, contraindications, or warning signs apppear, adjustments must be made. This may include cessation or modification of activities. It is helpful in this case to remind the woman of the primary goal: a healthy baby. Commitment, planning, flexibility, and compromise are all helpful here.

Evaluating the Exercise Program in Relation to Outcome It is useful to maintain records regarding a woman's activities during pregnancy. Comparing her original motivations for exercise with her feelings regarding the contribution of exercise to her pregnancy and birth experience will provide an important component of evaluating the success of the exercise program. Health care practices may also want to track birth outcomes to see if there is any difference between mothers who exercise and those who do not. The following are major items to track:

1. length of the active phase of the first stage of labor

2. length of second stage of labor
3. complications
4. type of birth
5. use of monitoring technology
6. procedures
7. use of analgesia, epidural, etc.
8. fetal responses and Apgar scores

Exercise Guidelines for Pregnant Adolescents

Including exercise in teen pregnancy programs can offer positive results. A variety of activities can be offered in such a program:

1. *Cardiovascular exercise:* Provide activities that incorporate a practical learning experience—What makes your heart beat faster? How do you count your pulse? How do you feel during exertion? How does exercise affect your baby? Taking a pulse before, during, and after 20 minutes of step aerobics could lead to a discussion of these questions.
2. *Special exercises:* Demonstrate or explain Kegels, abdominal exercises, squatting, relaxation, centering, and other preparatory exercises that will develop practical skills the girls will need in labor and the postpartum period. Other strength and flexibility activities can be included, providing diet and physical development are adequate. As with all fitness components, this population needs to uncover their significance through a combination of doing and learning about them—what various exercises do and why they are important.
3. *Self-care elements:* Explain topics of self-care for girls, including personal hygiene, nutrition and exercise, preventing sexually transmitted diseases (STDs), getting to prenatal visits, techniques of stress management, and academic education as a means for survival.
4. *Childbirth education:* Create interactive learning units around major topics, including pregnancy, labor and delivery, and recovery. By integrating this component into a school-based setting, barriers to this information can be greatly reduced and healthy behaviors improved [251].

Exercise for Postpartum Recovery

The postpartum period represents a challenging mix of potentials. There are positive cardiovascular changes associated with pregnancy that continue for some time following birth, providing the new mother with survival enhancements during this stressful period. However, motherhood also produces the greatest barriers to exercise participation of any of her roles in life [252]. Modern influences and social structures can lead to a lifestyle that is detrimental to physical and psychological well-being. Without informal social support, institutional supports for child care, education on healthy behaviors, safe environments, and transportation, women in a variety of settings undergo lifestyle and psychosocial changes that lead to postpartum weight gain, inactivity, isolation, and depression. One British study has demonstrated that women with postpartum weight gain are at increased risk of long-term weight gains [253], raising their long-term disease risk. For women of color, these problems are exacerbated by a greater lack of exercise settings that encourage them to participate [254]. Poor women and adolescent mothers are other groups disenfranchised by a lack of suitable, accessible programming and education. Yet, bringing an active lifestyle or recreational exercise to these populations is possible and can provide benefits in both short- and long-term well-being.

The Impact and Benefits of Exercise in the Postpartum Period

Technically, the postpartum period—or puerperium—refers only to the first six weeks following birth. Returning the body to a true nonpregnant state takes longer than six weeks. This longer duration is sometimes referred to as the extended postpartum period by fitness professionals, and may last six months or more. Generally, giving birth is a long-duration event, which means that the mother may be tired and bruised and her reproductive system will need time to recover from the birth itself. Over a longer time the body can return to a nonpregnant alignment and normal muscle balance. In addition to the physical healing that must take place, the mother needs time to adapt to her new identity and to get used to caring for the new person who has come into her world—a baby who will need care—including stimulation for growth and development—for survival. Even if she has a partner or extended family who shares the caregiving, in the first few weeks, months, or years, much of the physical labor falls to the mother.

When surveyed concerning self-care and baby-care topics of interest at seven weeks postpartum, more than three-fourths of the 1161 women questioned in one study wanted more information on at least one topic, and the largest percentage wanted

more information on exercise, diet, and nutrition [255]. While women who exercised in pregnancy are more likely to continue exercise afterward than those who did not [256], there are still significant numbers of women who join postpartum fitness programs who were not active during pregnancy, and very likely more would join such a program if it were accessible. There is less information available concerning the interaction of exercise with the postpartum period than with pregnancy; however, it is sufficient to conclude that appropriate exercise has both physical and psychosocial benefits for mothers and infants.

Cardiovasculature and Breast Milk Production One area in which we know that physiological shifts due to pregnancy do not return to nonpregnant parameters in six weeks is cardiovascular change. Stroke volume and end-diastolic volume remain elevated over preconception values at six and 12 weeks [257]. Systemic vascular resistance remains decreased at one year; the effect is additive with successive pregnancies [258]. Mothers who nurse and exercise continue to need sufficient fluids. Before working out, a nursing mother should be sure to drink an extra six or eight ounces of water. The volume of milk production will not be compromised if the mother is drinking adequately [259, 260]. Counseling by the care provider of a nursing and exercising mother should include information on increased fluid intake [261]. If the infant of an elite athlete is not gaining weight at an acceptable pace, supplementation may be necessary.

The effect of exercise intensity on milk composition has been studied. Research in the late 1980s and early 1990s demonstrated the accumulation of lactic acid (LA) and its persistence for 90 minutes in the milk of women exercising at maximal levels [262, 263] and reported problems with infant acceptance of postexercise breast milk [264]. Consequently, women who find their infants have an aversion to postexercise breast milk often express milk prior to exercise to give to their infants afterward, and express and discard postexercise breast milk. Studies in the late 1990s also focused on the composition of breast milk of exercising mothers with more detailed findings. Looking at the accumulation of LA at various exercise intensities, along with changes in milk pH, lipid, ammonium, and urea levels, one study found that while milk LA was significantly elevated through 90 minutes postexercise following a maximal-intensity treadmill session, there was no significant increase following sessions at 50 percent or 75 percent VO_2 max, nor were there any significant differences in the other measures at any level of intensity [265]. Another study found that maximal exercise did not alter concentrations of phosphorous, calcium, magnesium, potassium, or sodium in breast milk at 10, 30, or 60 minutes postexercise [266]. A study concerning the effects of maximal exercise on immunoglobulin A (IgA) in breast milk found significantly decreased concentrations of IgA at 10 and 30 minutes postexercise, but levels at 60 minutes were similar to controls [267]. In addition, levels of IgA1 showed a significant decrease at 10 minutes postexercise, but returned to control concentrations at both 30 and 60 minutes. No significant changes in IgA2 concentrations were found at any time [267].

The effects of calorie restriction (as opposed to malnutrition) and maternal weight loss are also of interest. A review of research findings concluded that short-term energy deficit in conjunction with exercise and resulting weight loss did not adversely affect lactation, due perhaps to the increase in maternal plasma prolactin concentration associated with a negative energy balance [268]. A comparison of lactation-induced bone changes in women who participated in self-selected recreational exercise in the early postpartum period with those who did not found that exercise had no impact on the BMD loss associated with early postpartum lactation [269].

Respiration, Thermoregulation, and Metabolism Breathing returns to normal within a couple of months after giving birth, but the ribs may remain expanded for a year or more. The amount of time it takes to return to normal thermoregulation varies among postpartum women. In many women, six weeks is adequate. For others, especially those who are breastfeeding, it may take longer. The biochemistry of energy is also returning to a nonpregnant state. If the mother is not breastfeeding, her metabolic rate will be slowing, reducing the need to eat as much or as often. If she is breastfeeding, it is generally agreed that an additional 300 to 500 calories are needed, so the need for food and fluids will remain elevated during this time, and even more calories and fluids will be needed for exercise. Additional metabolic changes are beyond the scope of this chapter, but the changing endocrine status may affect inflammatory responses that produce tendonitis, affecting comfort during movement.

Biomechanics After giving birth, a woman undergoes a sudden and dramatic shift in her center of

gravity, without accompanying changes in bone alignment and neuromuscular adaptations. Postural reeducation in the postpartum period is a major concern. The midwife can suggest the following methods to achieve this:

1. Use the constructive rest position (see Figure 9-8) [227].
2. Strengthen abdominals, gluteals, pelvic floor, and upper back.
3. Stretch psoas, low back, and pectoral muscles.
4. Consciously adopt healthy alignment patterns in movement.

Among the common structural conditions that can arise as result of the changing body dynamics of pregnancy and the demands of birth are diastasis recti, separation of the symphysis pubis, broken coccyx, SI joint dysfunction, back pain, and lower limb problems. Postpartum women are also susceptible to tendonitis and aching joints of the hands, shoulders, low back, knees, ankles, and feet due to postpartum changes in the center of gravity, hormone shifts, and poor techniques of carrying and holding their infants. These can be alleviated by taking the following steps:

1. Carry the baby close to the central axis of the body, using the muscles proximal to the central axis to bear the weight.
2. When nursing in a seated position, support the baby with enough pillows or blankets to bring her/him to the breast; this relieves the weight at the shoulders, reduces kyphosis in the thoracic spine, and frees the arms to manipulate the infant and the environment.
3. Wear socks and/or high-top exercise shoes to provide the ankle with cutaneous proprioceptor stimulus to help the brain re-image proper alignment in the leg.
4. Keep the hips, knees, and ankles slightly flexed and active when standing to provide mechanoreceptor stimulus to the brain.
5. Practice the hiss/compress abdominal exercise and splint the abdomen when doing curl-ups for the first few weeks until the abdominal muscles are strong enough to stabilize the trunk.

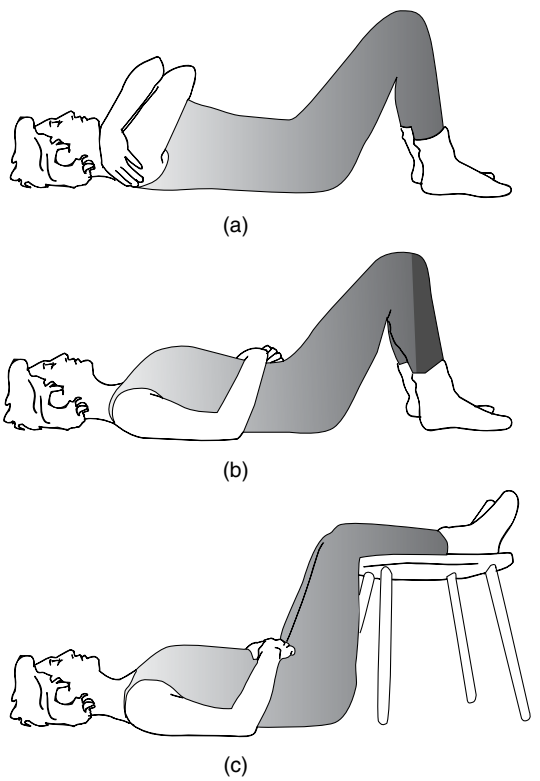

FIGURE 9-8 Constructive rest position. In this position, the pull of gravity assists in maximizing relaxation of skeletal muscles (a). If upper back and/or arms are tense when crossed over the chest, allow the elbows to slide to the floor and hands to rest on the abdomen (b). If the low back is tight, place the lower legs parallel to the floor with the knees directly over the iliofemoral joint (c).

Psychophysiological Interactions Mood and anxiety disorders following birth are receiving increasing attention from mental health professionals. The role of physical activity in establishing feelings of well-being make this a rich area for future research. From experience, we know that postpartum women report that their exercise group plays a significant role in their well-being [270]. There has been a small amount of research that helps us understand why this may be. Examining the psychological effects of an aerobic exercise session and a rest session on postpartum women, researchers concluded that both factors resulted in decreased anxiety and depression, and that the exercise was associated with significant decreases in total mood disturbance and significant increases in vigor [271]. Sampselle et al. [6] found two markers of postpartum well-being were significantly improved in women who participated in self-reported vigorous physical activity by six weeks postpartum. In the first marker—postpartum weight retention—women with higher levels of activity retained less weight than the inactive group. In the second marker—Lederman's postpartum maternal adaptation questionnaire—vigorous exercisers had better scores on all adaptation subscales. When combined with the

positive effects of group support and the health effects of regular physical activity, it becomes clear why postpartum group exercise produces positive psychological outcomes.

Management of Exercise in the Postpartum Period

The following steps can be incorporated into the management process during the postpartum period:

1. Establish a database
   a. prenatal fitness
   b. course of labor, birth, and first two weeks
   c. maternal-infant adjustment
2. Screen
3. Make exercise recommendations
   a. Kegels exercises
   b. abdominals
   c. walking
   d. returning to a regular exercise regimen
4. Assess and evaluate the exercise program
5. Return to mainstream exercise program

Establishing a Database

Prenatal Fitness. A woman's level of fitness going into birth will play a large role in her recovery. The same physiological augmentations that enhanced oxygen and nutrient delivery in the antenatal period will enhance tissue recovery in the period immediately following birth. The general rule is that the more fit a woman is going into the birth, the faster she will return to normal activity.

Course of Labor, Birth, and First Two Weeks. A fit woman with a relatively easy labor and no complications may be walking a mile or two every other day by the end of the second week postpartum. At the other end of the spectrum, an inactive woman with a difficult labor may not be able to execute all of her activities of daily living by the end of the second month. The range of variation is so great that it is critical to review the information on an individual woman's labor and birth, and to inquire about what activities the woman has been able to execute at her two-week visit.

Maternal-Infant Adjustment. For a first-time mother in today's world, bringing a baby home can involve a dramatic adjustment. To complicate matters, the baby's disposition as well as the adjustment of the new mother and baby will play a significant role in the commencement of a regular exercise program. If the baby is adjusting well and the mother is getting some regular periods of sleep, it is likely that some health and fitness activities can be started during the first few weeks. A difficult adjustment may prolong the start of activities other than essentials.

For women who find it difficult to adjust but who are connected with an ongoing exercise group, it can be very beneficial to return to the group for support, even if the actual exercising has to wait. Because exercise helps to alleviate depression, once it is resumed or even taken up for the first time, it is a great outlet for new mothers, including those who are adolescents.

Screening The midwife should assess the following prior to advising a woman about commencing a regular exercise regimen involving sustained activity:

1. Lochia should have stopped or nearly stopped; walking a mile should not cause an increase in bleeding the next day; there should be no bright red blood in any case.
2. The episiotomy or lacerations should be healed sufficiently that there is little or no discomfort.
3. The cesarean incision should be healed, intact, and with no evidence of infection.
4. Pelvic relaxation should have lessened and there should be no or minimum stress incontinence.
5. Milk production should be adequate for the infant's needs.

The following conditions are common results of the structural stresses of pregnancy and birth. The first item—diastasis recti—is almost universal, although negligible in many fit women. All of these conditions need to be checked for and if found, assessed for their impact on movement range and whether exercise restrictions are indicated.

1. *Diastasis recti:* A mild to moderate separation of abdominal muscles away from the linea alba will heal over time with careful exercise; the hiss/compress abdominal exercise and splinting for the first few weeks will be helpful.
2. *Separation of the symphysis pubis:* A wide lateral stance must be avoided for two or three months; if the condition does not gradually abate, medical attention is imperative.
3. *Broken coccyx:* Exercise may be restricted for six to eight weeks; the woman should sit directly on her ischial tuberosities and should not sit on a rubber donut as this will place weight directly on the broken coccyx (see Figure 9-9).
4. *Upper back pain:* Extreme shoulder tension or a difficult position held for a long time during

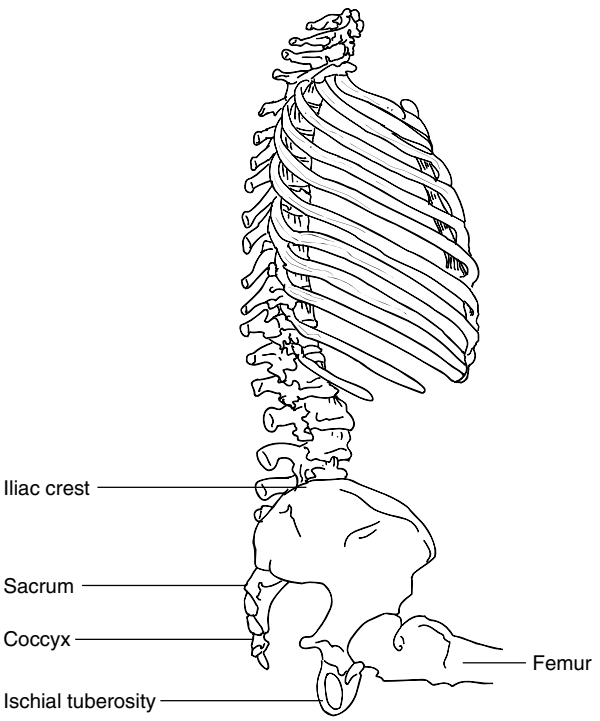

FIGURE 9-9 Sitting upright on the pelvis, not the coccyx. Three-dimensional view of pelvis and spine (with ribs represented). Notice that in the upright seated position, the weight is totally supported on the ischial tuberosities, not on the spinal column or the femur.

the second stage of labor will sometimes cause muscle spasms. Faulty positioning of the baby during nursing may also cause pain.

5. *Low back pain and/or mid-back pain:* Back pain is often related to biomechanics and abdominal strength; it may also be due to epidural discomfort; most back pain abates in the deeply folded position (see again Figure 9-6).
6. *Sacroiliac dysfunction or sciatica:* Such conditions may be caused by sacroiliac slippage, spasm in the medial gluteal or, if sciatica is suspected, spasm in the piriformis muscle.
7. *Slow-healing surgical closure:* If there is infection or the incision from a cesarean or episiotomy is slow to heal, delay start of exercise.

Figure 9-10 presents an example of a screening and assessment form that can be used at the six-week checkup—or whenever the woman is preparing to return to a regular, sustained exercise program.

Making Exercise Recommendations

Kegel Exercises. If there are no complications with a vaginal birth, the new mother may begin to try to tighten her pelvic floor muscles within a *few* hours of birth. Regaining control of these muscles is a very significant contribution to well-being.

Abdominals. Within a day or two of an uncomplicated vaginal birth, the new mother should be able to lie in the constructive rest position (see again Figure 9-8) and tighten her abdominal muscles by doing the hiss/compress exercise: inhaling through the nose and relaxing the abdomen, then exhaling with a hissing sound and tightening a few inches below the surface, pulling the abdomen toward the back of the waist. This activates the transverse abdominal muscle (described above). When well-toned, this muscle holds in the contents of the abdominal cavity and thereby aids in the protection of the low back. It lies beneath the abdominus recti, the internal obliques, and the external obliques—muscles responsible for motions of the abdomen such as the curl-up, spinal c-curve, oblique curl-up, and twisting motions.

During pregnancy, the transverse muscle, along with all the abdominal muscles, is stretched. When bearing down, or pushing the pelvic floor to open, this muscle can distend. It is not uncommon to find that postpartum women will begin a curl-up with this distending motion, probably due to effects of its stretching during pregnancy. It is imperative, therefore, to ensure that the new mother can maintain the contraction of the transverse muscle as she begins curl-ups or other motions that load the surface abdominal muscles. If the lower abdomen pops up or protrudes as she lifts her head or begins a curl-up, the transverse is not strong enough yet. She should continue with the hiss/compress exercise until she can maintain a flat abdomen when she lifts her head. Combining the Kegels contraction with the exhale and transverse contraction is also recommended.

After ensuring that the deep muscles are properly patterned (which may take from one day to a week or more), the new mother can begin loading the abdominus recti muscles by lifting her head and looking at her knees. If she can do this without pain and she has no persistent diastasis, she can begin abdominal strengthening exercises, paying attention to muscle fatigue and other kinesthetic cues such as pain or numbness. If she has a wide or a deep diastasis, she should splint her abdomen for a few weeks (see the description in the section on management in pregnancy) until it improves. If a diastasis does not improve, she should be referred to physical therapy for evaluation. Following cesarean birth, exercises for abdominal muscles may

Six-Week Postpartum/Return to Regular Exercise Medical Screening and Exercise Assessment

Fill this form out with your care provider and bring it to your instructor or trainer.

Name: _____ *Date: _____

Weeks postpartum: _____ Care Provider's Signature: _____

*Lochia (bleeding/flow due to the separation of the placenta): (circle one) Has ceased Has not ceased

What is the most vigorous activity you have done? _____

Any problems? _____

*Episiotomy: Discomfort? (circle one) Yes No

*Cesarean closure: Discomfort? (circle one) Yes No Numbness? (circle one) Yes No

*Pelvic relaxation: Are the pelvic bones stable? (circle one) Yes No

If not, describe: _____

Pelvic floor: Can you stop the flow of urine during a Kegel? (circle one) Yes No Don't know

Abdominal tone: Do this test: Inhale, relax abdomen. Exhale, hiss, and compress abdomen. Do a curl-up. Does your abdomen stay compressed? (circle one) Yes No, it bulges

*Conditions resulting from birth (and notes):

Diastasis _____

Symphysis separation _____

SI joint _____

Broken coccyx _____

Back pain _____

Lower body _____

Other _____

Milk production, if nursing: Any problems? _____

What do you do weekly in each of the following components:

Centering: _____

Cardiovascular or aerobic conditions: _____

Core strength: Hiss/compress _____ Curl-ups _____

Upper body strength: Upper back _____ Push-ups _____

Relaxation: _____

Realignment: _____

Mother-baby activities: _____

be delayed one or two weeks, due to the need for the closure to heal properly before strain is placed on it.

Walking. During the first week to ten days, short walks of five or ten minutes once or twice a day are feasible for most women, providing there is no discomfort. Attention to nutrition and hydration should also be given a high priority in preparation for more extensive activity. Some women will be walking, or even jogging, 20 to 30 minutes at a time by the end of the third week and may be ready to start a special mother-infant class.

Returning to a Regular Exercise Regimen. Once a new mother can do Kegels and simple curl-ups and can walk a mile with no discomforts or complications, she is ready to begin a more structured regimen. Going slowly, working at an intensity and duration that does not produce discomfort or fatigue is critical. In practice, we find that women who were fit during their pregnancies commonly return to exercise between three and six weeks postpartum. The form shown in Figure 9-10 will be useful in assessing a woman's readiness for regular, sustained exercise.

Assessing and Evaluating the Exercise Program If a woman is enjoying her activities and she is feeling that she is stronger, healthy, and benefiting from her exercising, then the program can clearly be assessed as successful. Some postpartum conditions that should be recorded in assessing the impact of the postpartum exercise program include complications, depression or psychosis, mother and infant adjustment, discomforts, and recovery of reproductive organs.

In more and more postpartum group exercise classes, she can be with her baby and even incorporate the baby into some activities. This situation allows her to enhance her own well-being while also being an attentive mother.

In practice, women and infants enrolled in a mother-baby program tend to thrive under the direction of a well-trained instructor. Most likely this results from the phenomenon already noted: Women who have the support of other women during difficult periods have a better prognosis than women who do not have this support.

Returning to a Mainstream Exercise Program For some women, mainstreaming as soon as possible is a high priority. They may be very active women who want to be away from what they perceive as their exercise peer group for as short a time as possible. Or they may be returning to work and feel they need to be with a similar group for their exercise activities. If they also feel the need for group support, a weekend "stroller aerobics" class or a mothers' support group may be available in the area. Group support during this time is important, especially for first-time mothers.

Essential Exercise for Menopause

The connections between menopause, aging and disease, and physical activity have become particularly interesting topics in recent years. As modern improvements in sanitation, health care, and women's rights developed, women began regularly outliving their fertility. For some time, the mean age for natural menopause in the West has been around 51 years of age [272–275]. Now that women are regularly living into their seventies, eighties, and beyond, we are asking many new questions. Is menopause just an aspect of aging? Is the underlying mechanism of aging separate from the mechanisms of disease? It has been suggested that the underlying rate of aging is a distinct phenomenon from disease and that it begins in one's thirties [276]. If exercise helps prevent disease and ameliorate the effects of aging, can it also help prevent the disorders of menopause?

Hormonal changes, gravity, and sarcopenia (loss of muscle mass) appear to be major mechanisms in the effects of functional aging on the human body. Physiologic adaptations to exercise can offset the effects of these mechanisms to a degree, but while exercise appears to have direct impact on aging, its impact on menopause is more complex.

The Impact and Benefits of Exercise and Menopause

To have a meaningful discussion of the impact of exercise on menopause, it is necessary to alter our perspective. Although we will still focus on potential, we will look more closely at how the long-range effects of physical activity history begin to show up in a midlife woman's state of health. The quality of life for a menopausal woman will be as much—or more—a result of how she has lived her life to this point as what she chooses to do in the future. While some women are protected from heart

disease or diabetes by their exercise histories, some are at risk because of inactivity. Some women are at risk of osteoporosis because their exercise and nutrition histories produced adverse changes in their fertility, while others will have benefited from maintaining an energy balance. The loss of powerful estrogens that protect the heart, muscles, bones, and brain enter onto a preset stage.

Hormone Loss, Hormone Replacement, and Exercise

The idea that menopause is reproductive aging in women, or the physiological decline in the function of the hypothalamic-pituitary-ovarian (HPO) axis, is a twentieth-century concept. The view that this condition can be cured or treated through medical intervention—much like a disease such as Type I diabetes—has also been a popular perspective since the 1960s when Wilson published *Feminine Forever* [277] and advocated the wholesale use of estrogen replacement. A wide range of conditions—from heart disease and osteoporosis to autoimmune disorders and Alzheimer's—have been attributed to the loss of estrogen during the perimenopausal process, and it was believed that hormone replacement therapy offered a degree of protection from these conditions. But there is a cascade of complex, sex-specific, metabolic events for each of these conditions. In coronary artery disease (CAD), for example, the adverse effects of dyslipidemia— independent of the loss of estrogen protection—has been demonstrated through research explicating the role of diabetes in causing CAD in premenopausal women [278]. In order to elevate HDL and lose central obesity—two risk factors for CAD associated with dyslipidemia—women require exercise, unlike men who require only a proper diet [279]. During menopause, if we add estrogen in order to elevate HDL, the risk of endometrial cancer increases, so we must also add progesterone or testosterone. But, although estrogen is protective of HDL, progesterone and testosterone have the opposite effect.

Health benefits of exercise extend to menopausal women as they do to all populations. Specific benefits that accrue to this group include reduction in the risk of cardiovascular disease resulting from obesity, poor lipid profiles, insulin resistance and high blood pressure; limiting of bone loss and increases in balance and strength contributing to the prevention of falls and fractures; some reduction in cancer risk; and improvements in cognition and mood.

Cardiovascular Disease and Exercise. Each year about a half million women die of cardiovascular disease, and most of them are postmenopausal. The issue of whether or not an adequate and ongoing exercise history obviates the need for HRT in relation to heart disease is controversial. Clearly, cardiovascular or aerobic conditioning extends its benefits to midlife women. Strength training with its ability to increase muscle mass thus improves metabolic functions and takes on increasing importance as women age. Barriers to exercise exist for women in their perimenopausal years. Employment history can have a detrimental impact on both exercise participation and health risk factors. In one study, women approaching menopause who were employed both at baseline and three-year follow-up had the lowest HDL profile at follow-up, and those employed at baseline were less likely to increase exercise and more likely to gain weight than those who were not employed at baseline [280]. Threshold levels for activity may be dependent upon the nature of an individual's risk. One group of researchers found that walking five times per week for 20 to 30 minutes provided a dose effect that reduced levels of excess stored iron in previously sedentary postmenopausal women (significant increases of stored iron following menopause and excess stored iron are risk factors for coronary artery disease) [281].

The effect of HRT and aerobic exercise on blood pressure is not symmetrical. Researchers measured maximum oxygen consumption, waist-to-hip ratio (central obesity), waist circumference, casual and 24-hour BP, and daytime and nighttime systolic and diastolic BPs. They found that in active women VO_2 max was higher, waist-to-hip ratio and waist circumference lower, and that there were lower levels of casual, 24-hour and daytime systolic BP, lower daytime systolic BP loads (percentage of recordings >140/90), lower daytime and nighttime BP variabilities, and a reduced systolic BP response to submaximal exercise [282]. Women on HRT tended to have lower levels of 24-hour and nighttime diastolic BP, and smaller daytime and 24-hour diastolic BP loads [282]. After stepwise multiple regression analysis, the researchers determined that waist circumference was the primary predictor of most of the systolic BP-related cardiovascular risk factors, and that HRT was the best predictor for diastolic BP loads [282]. Other studies have shown either none or a small but statistically significant decrease in BP on HRT [283–285], and one study

demonstrated that a few women on HRT experienced increased BP [273].

Osteoporosis and Exercise. The greatest long-term impact of exercise on bone is its capacity to facilitate optimal peak development of bone mineral density (BMD) during the premenopausal years [286–295]. Participation in high-impact activities in young, healthy athletes results in the highest peak BMD [296, 297]. The effect of exercise on BMD in the perimenopausal and postmenopausal periods has been more difficult to assess. It appears that loading specific bones through strength-conditioning exercises can help delay mineral loss in those bones or, in postmenopausal women, produce small increases over time, as well as reducing the risk of fractures by lowering the incidence of falls [298–301].

BMD loss is greatest in the perimenopausal years; women may experience nearly half their bone loss before menopause actually occurs [302]. In the United States the rate of fracture of the proximal femur for white women rises abruptly between ages 40 and 44 [303]. White women have a lifetime risk rate of 15 percent for what is usually termed a *hip fracture*, but is actually a fracture in the neck or trochanters of the femur [304], while risk rates for Asian and African-American women are much lower. However, researchers studying Australian women of Asian descent concluded that ethnicity was not related to BMD in this group, but that clinical and lifestyle factors were [305]. A study of Taiwanese women concluded that physical activity played a major role in BMD levels in postmenopausal women [306]. In a number of cultural settings, exercise has a positive association with the BMD level of women in midlife and older years [307–311]. However, the American College of Sports Medicine (ACSM) warns against making a false assumption that exercise, or exercise and diet, can substitute for hormone replacement [312]. While a decline in activity level clearly results in profound loss of bone mass, the results of increased activity are slower and less clear. The ACSM notes that the results of cross-sectional studies have demonstrated a more positive effect of exercise on bone than prospective studies [312].

Cancer and Exercise. Following the development of synthetic estrogen in 1938, replacement therapy for natural and surgical menopause grew in practice. Beginning in 1975, strong evidence of the increased risk of endometrial cancer among users of unopposed conjugated estrogens began to be published [313–315]. Progestogen was added to estrogen to combat this effect and the term *hormone replacement therapy* (HRT) was born. Estrogen-dependent cancers (breast, ovarian, and endometrial) have etiologies that are not totally understood, although it does appear that estrogen is implicated in a process that stimulates the expression of estrogen receptor sites [316–318].

Heavy exercise may play a role in decreasing the risk of breast cancer. Changes in 4-hydroxycatecholestrogen metabolism in response to heavy exercise include changes that may undermine fertility, while preventing free radicals and exposure of breast epithelium to endogenous estrogens [319]. One study followed 25,624 women aged 20 to 54 at entry into the program over a mean period of 13.7 years [320]. Findings included a correlation between recreational exercise and breast cancer showing that the greater the leisure-time activities of the participants, the lower the risk of breast cancer. In regular exercisers, the reduction of risk was greater in premenopausal than in postmenopausal women. Risk was lowest in lean women (<22.8 BMI) who exercised at least four hours per week. Risk also was reduced with higher levels of activity at work.

Brain, Mind, Mood, and Exercise. The impact of exercise on mood in midlife is profound. A review of mood and symptom reporting found that both chronic and acute exercise had a positive effect on mood and reduced the level of somatic and vasomotor symptoms compared with nonexercisers, regardless of menopause status or whether or not the women were taking hormone replacement [321]. The degree of a woman's psychosomatic symptoms in perimenopause has been found to be inversely related to the degree of exercise from age 30 on. These researchers also concluded that the greater the degree of exercise from age 40 on, the less the degree of her symptoms after menopause, and that exercising moderately from the subjective point of view in the perimenopausal period may alleviate symptoms [322].

Hot flashes, or vasomotor symptoms, are experienced at some point by perhaps 80 or 90 percent of women with a changing gynecological status in the West [302, 323, 324]. Temperature regulation requires integration of autonomic, endocrine, and skeletomotor responses in the hypothalamus [325]. The sensation of being overheated is related to the metabolism of the neurotransmitter norepinephrine, which is mediated by estrogen in the hypothalamus.

With estrogen at a low ebb, malfunctions in the body's thermostat occur. The condition is aggravated by stress, which results in increased norepinephrine, and generally abates postmenopausally. In addition, the increasing level of follicle stimulating hormone causes altered signals concerning the internal temperature set point. The ability of exercise to contribute to stress management may well be a factor for reduction of vasomotor symptoms.

It seems possible that adequate levels of estrogen in the female brain are necessary for memory storage and learning new tasks [326]. The parietal lobes of the cerebral cortex—important for organizational thinking—are affected in early menopause by a changing estrogen concentration, and probably account for the reports of "fuzzy thinking" by midlife women. Alzheimer's disease (AD), while clearly related to estrogen levels, has many more dimensions than fuzzy thinking. (AD is discussed in the section on senescence.)

The Importance of Gravity in Exercise Spaceflight has provided interesting insight into the relationship between aging and changes in reproductive status, as well as into why weight-bearing and resistance exercise play critical roles in lessening the effects of aging and menopause. The factor influencing endocrine function during spaceflight appears to be the absence of gravity acting on the body. This factor affects a number of endocrine subsystems as well as bone demineralization, anemia, insulin resistance, and the sympathetic system [327]. Some endocrine systems—particularly those regulating bone and muscle metabolism and reproduction—undergo changes that resemble functional aging; however, recovery always occurs within weeks or months of the return to gravity [327]. Malfunction also occurs in space with immune, neurosensory, and cardiovascular systems [327]. Over many thousands of years, the human body has adapted to function in the force field of gravity. Antigravity exertion affects biochemical and biomechanical functions, playing a mitigating role in the development of symptoms associated with aging and menopause. No significant relationship has been found between the degree of exercise in life stages and the age at menopause [323]. However, large doses of strenuous exercise at a young age may result in the female athlete triad (see the section on adolescence) and acceleration of aging symptoms such as osteoporosis. The first menstrual irregularities in a healthy woman frequently appear when she is in her late forties, but asymptomatic hormonal fluctuations and anovulatory cycles begin sooner, often in her thirties. By perimenopause, she may be well into the period that triggers the need for concerted antigravity exertion to fend off the effects of menopause and aging.

Management of Exercise in Perimenopause

To help women incorporate exercise into their lifestyle during their menopausal transition, the following steps can be included in management procedures:

1. Establish a database
   - **a.** establish needs and make medical referrals
   - **b.** menopause, health, and nutritional status
   - **c.** exercise history and preferences
   - **d.** activity domain(s)
2. Screen
   - **a.** criteria for a stress test
   - **b.** indications for myocardial perfusion scintigraphy
   - **c.** special screening procedures
3. Make exercise recommendations
   - **a.** bone-loading resistance and/or impact training
   - **b.** weight-bearing aerobic or cardiovascular conditioning
   - **c.** centering, relaxation, and other stress-management activities
4. Assess and evaluate the exercise program

Establishing a Database When midlife women begin to exercise or enter organized fitness programs for the first time, it is critical to do efficient data collection in order to ensure safety. It is even necessary to gather information about women who have been active prior to menopause; assessing their life stage may cause women to refocus the intent of their physical activities. While efforts need to be made to acquire as much information as possible for safety reasons, some women—especially those with high levels of psychosocial risks or time constraints—may not tolerate extensive data collection. Nonmedical information may not be essential at first, especially if these women are not initially involved with vigorous exercise forms, but rather with gaining a sense of kinesthesia, body acceptance, or starting at a very low level of activity.

Establishing Needs and Making Medical Referral. Sometimes group programs are formulated around specific

concerns, goals, or purposes—for example, women who have been abused or want to lose weight or have had various cancers. Notations should be made when women are referred to organized exercise for health-related purposes. Their group instructor or personal trainer may request a medical referral or supply a form letter for this purpose. If a woman is motivated to participate in an activity because she perceives potential health and/or social benefits, it is still a good idea for her to have a referral or approval from a health care provider as a first step in ensuring that regular exercise is appropriate to her health status or needs. An example of a form that can be used for this purpose is shown in Figure 9-11. In all cases, a woman's motivation for participation should be noted. As always, the keys to compliance lie within meeting the desire or need.

Menopause, Health, and Nutritional Status. There are issues around dose-effect that depend upon a woman's particular menopause status and health status. For example, a former runner who is postmenopausal with osteoarthritis and high levels of stored iron may be asked to walk five days a week, rather than jog three days a week. Before making any recommendations, the midwife will look closely at the reproductive and health history of the individual woman.

In addition, nutrition plays a critical day-to-day role for an active menopausal woman. Factors such as calcium turnover require attention to a nutrient-dense diet. Adequate levels of the three macronutrients—protein, carbohydrate, and fat—are necessary, with attention to whole foods containing high levels of micronutrients, including vitamins and minerals. Sources of isoflavones, or plant-derived estrogen precursors (phytoestrogens), include soybeans, cashews, peanuts, almonds, oats, corn, wheat, apples, and melons as well as most fruits and vegetables to a lesser degree [328–330]. Water and other hydrating fluids are also important to maintaining a high central blood volume. A food diary—kept for several days or a week—will enable the midwife to assess the food and fluid intake of her midlife patients.

Exercise History and Preferences. To make sure that activities are appropriate for a given woman, having an exercise history and a record of activity preferences are essential pieces of information. Questions similar to those asked in the form shown in Figure 9-2 can be asked of perimenopausal women. Her exercise history and the domain (sports/exercise, active living, occupational, and household/caregiving) in which she is most active will also produce variables affecting the type and amount of activity in which she participates [294].

Activity Domain. Health care providers who promote physical activity in midlife women need to take into account differences in the demographic and psychosocial correlates of activity domain. It can be extremely useful for creative purposes and for helping women develop self-efficacy to know in which arenas a woman has experienced being physically active. Habitual movement patterns form a rich base from which to expand a woman's activity vocabulary. Asking questions about her domains of activity will provide a starting point. Such a form is shown in Figure 9-12.

Screening An exercise stress test, health and fitness assessments, and nutritional status assessment are screening procedures that are standards of practice used by fitness professionals in developing an exercise prescription. Sometimes a participant must be restricted or turned away from a vigorous group activity on the basis of findings, and referred to a clinical exercise setting.

Criteria for a Stress Test. The leading cause of death in the United States is myocardial infarction, with 63 percent of the women who die suddenly from acute coronary events having no prior symptoms or coronary artery disease [331]. While regular aerobic activity promotes heart health, intense activity in persons with heart disease can be fatal. For women over 50 and those with multiple cardiac risk factors, the American College of Sports Medicine recommends an exercise stress test (EST) prior to starting a vigorous exercise program [332].

Indications for Myocardial Perfusion Scintigraphy. Women with an intermediate likelihood of coronary artery disease may be referred for myocardial perfusion scintigraphy, a nuclear imaging technique that has been developed to overcome the limitations of EST. A multicenter study of emergency room protocol in which myocardial perfusion nuclear imaging was used reduced the rate of myocardial infarction from 1.8 to 0.1 percent in patients discharged with chest pain [333]. While this procedure is invasive and still not readily available, for women with the resources and the risk factors, it may prove a helpful procedure. The technique is also useful for the diagnosis of hyperthyroidism, including Graves' disease and postpartum thyroiditis.

Health Care Provider's Referral

Dear Health Care Provider: _____ Date: _____

Your patient _____ has contacted me to help her develop a program of physical activity appropriate for the condition(s) you have identified. To ensure safety and effectiveness in this endeavor, I request that you fill in the needed information, sign the referral form, and return it in the envelope provided.

I am referring this patient for physical activity due to the following condition(s): _____

_____

_____

It is appropriate for this patient to participate in the following exercise components, as long as they are appropriate to her age and fitness level:

____ Cardiovascular conditioning activities ____ Strength or resistance training

____ Flexibility exercises ____ Activities to improve balance and coordination

____ Stress management techniques (such as relaxation)

Regarding cardiovascular health, I consider this patient:

____ Class I: Presumably healthy without apparent heart disease

____ Class II: Presumably healthy with one or more risk factors for heart disease

____ Class III: Patient is not eligible for cardiovascular conditioning

Does this patient have any preexisting medical/orthopedic conditions not described above requiring continued or long-term medical treatment or follow-up? (circle one) Yes No

If yes, please describe: _____

_____

Please list any currently prescribed medications: _____

_____

Referring Provider's Signature: _____ Date: _____

Thank you for your time. Please feel free to contact me at any time should you have questions.

Sincerely,

FIGURE 9-11 Health care provider's referral.

Activity Domain Questionnaire

1. Do you have children? How many? When were they born? How were the births?

2. What did you do when they were toddlers?

3. What are your favorite memories (trips, games, events, etc.) of playing with your children?

4. If you don't have children, have you been around children? What do you remember doing with them?

5. Do you provide care for children, elderly parents, or others? Describe these activities. How much time do you spend doing this on a daily basis?

6. What are your most favorite and least favorite household tasks?

7. How much time do you spend each week on household tasks?

8. Do you do the grocery shopping? Do you carry your own bags?

9. Do you work? Describe your work activities. Are they light, fairly light, somewhat hard, hard, or very hard physically?

10. Do you play sports? Which ones? How many days per week do you play each activity? How long is each session?

11. Do you participate in recreational exercise? Describe the activity, including information about how many days per week, how much time per session, and how hard you work.

FIGURE 9-12 Activity domain questionnaire.

Special Screening Procedures. When women have had surgery, chemotherapy, and/or radiation treatments for breast cancer or have had a hysterectomy or other invasive procedures, the midwife must rely on the particular medical specialist to approve any physical activity. There are specialized fitness professionals who are trained to provide appropriate exercise programs for a number of special medical conditions, such as cancer recovery, diabetes, autoimmune disorders, and cardiac rehabilitation.

Making Exercise Recommendations A woman's own view of her gynecologic status [334], awareness of her personal value system [335], and access to appropriate educational materials [334–336] allow her to be confident that the chosen menopause plan of action is appropriate and promotes high levels of adherence, whatever the treatment of choice [336]. There is a need for public education that helps women interpret the information on health risks [337] and on how to achieve a healthy, active lifestyle within their particular domain, time, family, and individual constraints [338].

The variety of activity histories, predispositions, lifestyles, and life situations encountered in midlife women result in a vast array of effective exercise regimens for this population. During adolescence, the goal is to introduce girls to the myriad possibilities for an active life. During childbearing, all participants—regardless of variations in exercise history and body type—are involved in the same athletic event (pregnancy, birth, and recovery). But, at midlife we are confronted by huge differences in skill, functional capacity, and will.

There are common essential fitness needs that face this population, regardless of history or body type. For an ideal activity program aimed specifically at the needs of midlife women, essential components include bone-loading resistance and/or impact training two or three days per week, weight-bearing moderate intensity aerobic activity for 20 to 30 minutes five days per week, and centering, relaxation, and other stress management techniques as needed. Beyond this, many women are capable of many things. Some will be capable of only the minimum, and reaching them will produce the greatest gain in public health.

Bone-Loading Resistance and/or Impact Training. A major determinant of bone strength, mass, and microarchitecture is age [339] as well as loading; consequently it is important to participate in bone-loading training throughout the aging years. There is a concomitant loss of muscle strength and bone density in women between 45 and 65 irrespective of HRT, with loss of lower-body strength 50 percent greater than loss of upper-body strength [340]. It is critical that women are participating in activities that load bone, especially the spine, pelvis, and femurs, by their forties, to help minimize bone and muscle loss. Stretching can easily be incorporated into the strength routine, where it is most effective.

Both high-load and high-repetition regimens—with high load defined in one study as 80 percent of the weight that could be lifted once, with 8 repetitions (80 percent 1RM, 8 reps) and high repetition as 40 percent 1RM, with 16 reps—were shown effective for increases in muscle strength and size in early postmenopausal women. Neither regimen had significant increases in spine or hip BMD over a six-month period, with calcium supplementation to 1500 mg daily [341]. The threshold for an intensity that has an effect on bone may be sensitive to genetics [342] and sex [343].

Bone is also responsive to impact activities. In a five-year follow-up study of jumping in weighted vests, researchers found that the program helped prevent significant loss of femoral neck, trochanter, and total hip BMD in older postmenopausal women [344]. An exciting finding of this particular study was the long-term compliance of participants [344], indicating that a high-intensity, impact activity involving coordination skills can be challenging and interesting enough to retain women in their mid-to-late sixties.

Weight-Bearing Aerobics or Cardiovascular Conditioning. For most women, 20 or 30 minutes, almost every day, of rhythmic, repetitive motion that propels the whole body through space supported by the feet is beneficial. Most women are doing some activity that involves moving on their feet, so there is always a starting point, whether it is making beds, stacking inventory, or delivering the mail. Figure 9-13 categorizes various activities by METs—metabolic equivalents—providing a useful tool to locate the intensity of a woman's preferred or habitual activities.

Delineating appropriate intensity levels for midlife women includes consideration of prior activity level and medication use. Medications that may alter heart rates require following medical instructions, and relevant guidelines for cardiovascular intensity are absolutely necessary. Other medications, such as insulin, may also indicate a need for careful exercise planning.

METs

METs are a useful starting point for assessing the level of physical activity for a given individual. They are also helpful for locating an appropriate perceived exertion for moderate activity—for example, saying "Do this as if you were changing the sheets!"

Home Maintenance or ADL

Light Activities: 1–3 METs
Daily bed making
Driving a car
Ironing
Kneading dough
Light auto maintenance
Light cleaning (dusting, picking up, wiping)
Light meal preparation
Loading and unloading dishwasher
Mowing lawn (riding)
Peeling vegetables
Polishing furniture
Scrubbing pots and pans
Setting and clearing the table
Short errands (in the car)
Sweeping the floor
Washing a few dishes
Washing small clothes by hand
Watering the yard

Moderate Activities: 3–4 METs
Beating carpets
Cleaning windows
Grocery shopping/carrying bags
Hanging wash
Laundry (light loads)
Light carpentry
Light gardening
Light home repairs
Meal preparation
Mopping floors
Mowing lawn (light power mower)
Pushing wheelbarrow (with a 100-lb load)
Stocking shelves
Taking out trash containers on wheeled carts
Vacuuming
Wringing clothes by hand

Moderate Activities: 4–6 METs
Auto repair (moderate)
Bed making (changing sheets)
Heavy carpentry
Heavy gardening
Hoeing
Laundry (heavy loads)
Lifting more than 20 lbs.
Paper hanging
Raking leaves
Sawing soft wood
Shoveling light soil
Washing or painting walls
Washing ceilings
Washing or polishing car

Moderate Activities: 6–7 METs
Auto repair (heavy)
Mowing lawn (by hand)
Shoveling light snow
Splitting wood

Heavy Activities: 7–9 METs
Digging ditches
Sawing hardwood
Shoveling heavy snow
Tending furnace

Occupational

Light Activities: 1–2 METs
Auto driving
Clerical work
Computer operator
Desk work
Drafting
Electric calculating, machine operator
Light assembly line
Setting type
Typing/keyboarding computer
Watch repair

Light Activities: 2–3 METs
Assembly work
Auto repair (light)
Bartending
Janitorial work
Machine work
Radio repair
Shoe repair
Television repair
Typing

FIGURE 9-13 METs.
Sources: See references 332, 377, 378.

Moderate Activities: 3–4 METs
Bricklaying
Driving trailer truck in traffic
Machine assembly
Plastering
Sheet metal work
Stocking shelves (light objects)
Welding (medium load)

Moderate Activities: 4–5 METs
Auto repair (moderate)
Carpentry (light)
Hairstyling
Masonry
Painting
Paper hanging

Moderate Activities: 5–7 METs
Auto repair (heavy)
Carpentry (heavy)
Pneumatic tools
Sawing soft wood

Heavy Activities: 7–9 METs
Carrying up to 80 lbs
Digging ditches
Planing
Sawing hardwood
Tending furnace
Using a pick and shovel

Heavy Activities: 9 METs and over
Heavy labor
Lumberjack

Recreational

Light Activities: 1–2 METs
Attending a concert
Crocheting
Desk work
Flying in airplane
Knitting
Listening to music
Making a mosaic
Motorcycling
Movies
Needlework
Painting
Playing cards
Puzzles
Reading
Sewing
Table games
Television
Typing
Writing

Light Activities: 2–3 METs
Billiards
Block printing
Bowling
Calisthenics (very light)
Canoeing
Darts
Golfing
Horseback riding (walk)
Leather carving and stamping
Light woodworking
Macrame
Model building
Photography
Playing a musical instrument
Playing with children
Powerboat driving
Shuffleboard
Singing
Walking (level, 2 mph)

Moderate Activities: 3–4 METs
Archery
Badminton
Calisthenics (light)
Ceramics
Croquet
Cycling (light)
Fly fishing (standing with waders)
Golfing
Horseback riding (trot)
Horseshoes
Playing musical instruments (energetic)
Pottery
Rug hooking
Sailing (small boat)
Walking (3 mph)
Weaving (floor loom)
Woodworking (moderate)
Volleyball

Moderate Activities: 4–5 METs
Badminton (singles)
Calisthenics (many)
Cycling (8 mph)

FIGURE 9-13 METs. (*continued*)

Dancing
Golfing
Swimming
Table tennis
Tennis (doubles)
Walking (3.5 mph)

Moderate Activities: 5–6 METs
Backpacking (light)
Canoeing
Cycling (10 mph)
Gymnastics (moderate)
Hiking
Horseback riding
Ice skating (9 mph)
Roller skating (9 mph)
Soccer (light)
Softball
Stream fishing
Walking

Moderate Activities: 6–7 METs
Badminton (competitive)
Cycling (11 mph)
Dancing (vigorous)
Skiing
Ski touring (cross country)
Tennis (singles)
Walking (5 mph)
Water skiing

Heavy Activities: 7–9 METs
Basketball (moderate)
Canoeing (5 mph)
Cycling (12 mph)
Horseback riding (gallop)
Ice hockey
Jogging (5 mph)
Mountain climbing
Paddleball
Scuba diving
Skiing (vigorous downhill)
Sledding (tobogan)
Snowshoeing (slow)
Swimming (moderate)
Touch football

Heavy Activities: 8–9 METs
Basketball (vigorous)
Cycling (13 mph)
Fencing
Handball, squash
Rope jumping
Running (5.5 mph)
Ski touring (vigorous)

Heavy Activities: 10 METs and Over
Backpacking
Handball, squash (competitive)
Running (6 mph)
Ski touring (5 mph)
Snowshoeing (vigorous)

FIGURE 9-13 METs. (*continued*)

The moderately or highly fit woman may know her preferred heart rate and it may be above her age-predicted maximum, although well within an appropriate perceived exertion range. Medical clearance and liability waivers are necessary in this case. For a woman who has never exercised, learning certain skills is necessary, including recognizing signs of exertion (breathing changes, heat, alterations in awareness, fatigue), how to take her own pulse, and the assessment of her own level of exertion. Once her functional capacity has been assessed, appropriate intensities can be determined.

Centering, Relaxation, and Other Stress-Management Activities. Some women need to take a few minutes to center and clear their minds every day, while others only need relaxation activities on the weekend or to take an occasional yoga class. One study demonstrated that jogging and progressive relaxation, in eight-week programs, each independently reduced trait anxiety and improved self-efficacy for working women significantly and nondifferentially, with both benefits maintained at an eight-week follow-up [345].

Searching for clues to why different women experience more or less discomfort from the physiologic changes associated with menopause, psychosocial factors and their association with physical activity come to the fore [346–348]. Individuals who were successful at maintaining weight loss reported regular physical activity, self-monitoring, and coping skills [349] as their methodology. They also reported that there was a triggering event that precipitated the weight loss and that they often used structured programs to help them develop coping mechanisms [349]. While they have been criticized for not always being scientifically rigorous, socially oriented group weight

loss programs have the best record for enabling this long-term behavior change. Fitness professionals are borrowing from this model to effect positive physical activity changes for midlife women. One study has demonstrated that by reframing the psychosocial context, physical activity interventions can be made more relevant and thereby more effective for midlife women [350].

Assessing and Evaluating the Exercise Program For a woman with a history of exercise who is currently active, there may still be changes in her routine that will bring about greater health benefits. Perhaps she has osteoporosis but prefers swimming, or has urogenital prolapse problems but likes to play basketball. Are the changes necessary? How difficult will they be to make? Will they dramatically affect her quality of life? On the other hand, for women who are relatively inactive almost any increase in frequency, intensity, or duration of activity will bring benefits.

To determine if a program of activity is working for an individual woman, basic health issues may be the first step of assessment. Has health been maximized? Whatever the health risk factors are, have they been minimized? The second step may be to ask about quality of life issues. Is this woman as comfortable and as able as possible to cope with her life stressors and daily hassles? The evaluation of outcomes may take a little longer. To determine if midwives—together with other health care providers and fitness professionals—are promoting the health of midlife women will require epidemiologic assessment.

Exercise in the Senior Years

Following menopause a woman's body continues to make adjustments. During the later years of life, the aging process—sometimes referred to as *senescence* in this period—poses yet another set of challenges. An anthropological perspective on the changing body was given impetus by research conducted on postmenopausal women of the Hadza tribe in Tanzania. The theory proposed was that menopause is an evolutionary adaptation with advantages for women, their offspring, and the community, and that senior females who are not fertile provide a hunter-gatherer community with a desirable evolutionary advantage for offspring survival. By not tying the older females' contribution to their direct lineage, the researchers demonstrated that the superior ability of postmenopausal women to gather edible food and to maintain information that is useful over the long run (wisdom), benefited children in the extended family and the larger community [351].

The researchers' observations involved the ability of the older women to spend seven or eight hours a day in the strenuous job of gathering food. Once children become independent, if life is vigorous, might the need for the protection that estrogen provides during the childbearing and nurturing years (when physical activity is lessened for nursing infants and overseeing children's welfare) be unecessary? Given the contemporary trend toward sedentary existence, one is forced to inquire into the nature of postmenopausal disorders such as heart disease, loss of muscle mass, osteoporosis, and diabetes. Can these be as much disorders of aging in an unhealthy, sedentary population as the result of a change in reproductive status?

The Impact and Benefits of Exercise During Senescence

Of all groups, the elderly may respond more dramatically to the enhancements offered by physical conditioning than any other group. Aerobic and resistance (strength) training—especially in combination—result in significant gains in functional capacity, muscle mass, bone density and spontaneous activity [352]. Cardiovascular exercise significantly improves cardiovascular disease risk profiles in postmenopausal women, while results of HRT are somewhat mixed [353]. Increases in muscle mass through resistance training positively affect metabolism by slowing age-related sarcopenia. The basic muscle cell aging processes that result in sarcopenia, especially mitochondrial production of free radicals and their secondary effects, may help explain other adverse cellular changes [354]. Basic cell aging results from intrinsic changes in the cell but also from shifts in hormonal and neurotransmitter signals, affecting the response of skeletal muscle to exercise [354]. Consequently, both exercise and hormone replacement may be important mechanisms for slowing the age-related decline in protein turnover [355, 356].

Exercise and Muscle Enhancement Understanding the more subtle effects on muscle of acute or chronic exercise in the elderly is largely limited to studies on men, but these do provide some insight. Two studies tell us about the relationship of endurance

versus power (or speed) as men age. One study of sedentary men demonstrated that older males (ages 60 to 75) had significantly lower maximum oxygen uptake than their younger comparison group (age 30 or younger); however, endurance-related parameters were less diminished with aging than maximal capacity, and the researchers found age was associated with an increase in the relative magnitude of moderate submaximal exercise [357]. These findings concur with other findings that progressive resistance training in elderly men increases muscle cell size, strength, contractile velocity, and power in both slow- and fast-twitch muscle fibers; however, the changes are more pronounced in the slow-twitch, or endurance-related, muscle fibers [358]. Because activities of daily living (ADL) primarily involve slow-twitch muscle fibers, or endurance patterns of activity, the greater preservation of this function in the aging process may indicate a preference for slower or more fluid motion as a person ages. Unfortunately, quick or powerful motions, such as preventing a fall if one trips on a rug, become less quick or powerful in this scenario. Fortunately, these studies provide insight into the fact that quick motions can be improved by exercise, as we see in the case of reductions in falls when the elderly—including women—exercise.

Exercise and Relief of Discomforts The capacity of physical activity to relieve physical discomfort is exemplified by its beneficial effect on fibromyalgia—a condition primarily affecting midlife and older women in which tendons, ligaments, and muscles are painfully tender and that often involves fatigue and stiffness. Its symptoms are somewhat characteristic of autoimmune or inflammatory disorders. Maintaining one position for long periods is poorly tolerated by this population [359], so that movement is necessary. Exercise seems the most effective therapy [360], with stretching, strength training, and moderate cardiovascular activities proving helpful [361]. In addition, both land-based and aquatic exercise programs for individuals ages 45 to 70 with osteoarthritis of the knee produce improvements in range of motion, thigh strength, time for one-mile walk, and decreases in overall pain [362].

Collagen is responsible for the elastic quality of connective tissue in muscles and tendons, and persons with low levels are subject to connective tissue plasticity due to forced stretching, as well as reduced flexibility due to tightness. One study found low levels of collagen in the urogenital organs and skin of women with genital prolapse [363]. The postmenopausal women with prolapse also had impairment of pulmonary function and researchers concluded that the associating factor may be lack of collagen, as the lungs depend on abundant connective tissue for their capacity to expand and contract [363]. Another study looked at the effect of endurance exercise on passive stiffness via the alteration of elastic properties of collagen in older mice [364]. Our understanding of these factors is sufficient to make us aware that extreme stiffness, tightness, or damage from overstretching may be indications to check for prolapse and refer appropriate cases to physical therapy. In any case, pelvic floor exercises are indicated for older women, while high-impact activities may not be.

Exercise and the Brain That group exercise improves cognitive function and mood in older women as a transient phenomenon has been demonstrated [13]. Whether chronic exercise provides protection for disorders such as Alzheimer's remains to be elucidated. There are indications that estrogen is protective for Alzheimer's disease [302, 365–368]. It is well-accepted that there is an association between Alzheimer's and premature menopause. Because early menopause can be an autoimmune disorder, described by Northrup [302], this raises questions about whether estrogen loss is a cause of Alzheimer's or the ovarian failure that leads to both menopause and Alzheimer's are related to an autoimmune/inflammation disorder. The inflammatory component of AD, demonstrated by the protective role of NSAIDs [369–372], along with vascular pathologies and neurotoxic metabolism [371, 373, 374], join genetics as cofactors in this complicated disease.

Management of Exercise in Older Women

The steps involved in management of exercise in menopausal women can be used in the management of exercise for senior women. Tools are available to help determine the activity levels of older women [375]. When older, frail women are being referred to structured rehabilitation programs or research studies, screening and assessment will occur in the clinical setting. When making recommendations for activity, it is helpful to remember that for older women, developing muscle strength best predicts continued participation in structured exercise [376].

Summary

Throughout her life cycle, a woman who participates in regular, moderate exercise is providing herself with one of the best available defenses against disease and debilitation, as well as a chance to feel involved in wholesome and meaningful action. A midwife who understands how exercise protects health, and who develops the ability to support and monitor an adequate level of activity for each of the women in her practice, provides an important element in state-of-the-art care. During adolescence, pregnancy, the postpartum period, menopause, and senescence, women undergo physical and psychosocial experiences unique to each of these phases. For the midwife, each woman represents the opportunity to help an individual harness her growth potential by identifying needs and motivations, and by supporting the methods and rewards of being an active participant in life.

213. Both unpublished data and anecdotal accounts covering 1982–1993 in the Dancing Thru Pregnancy®, Inc. program evaluation files give clear indication of the importance of the group setting for prenatal exercise. More than 95 percent of clients responding to confidential evaluation forms and interviews report that being with other pregnant women was one of the most important parts of the program. As part of the same surveys, reports of complications, as measured by need for cesarean birth, were well below local and national percentages for all time periods surveyed.

CHAPTER

10

Pharmacology and Midwifery

MARY C. BRUCKER, CNM, DNSc, FACNM
MARY ANN FAUCHER, CNM, PhD

Introduction

Throughout history, midwifery, like pregnancy, has been intertwined with myths. Among the modern myths is the one that midwives eschew the use of drugs and only use, at most, herbal remedies. In reality, knowledge of pharmacology is necessary for the practice of midwifery in the twenty-first century so that midwives can use agents appropriately. Moreover, herbal agents are pharmaceutical agents themselves and should be subject to the same scrutiny as any drug. As an increasing number of midwives attain prescriptive privileges, knowledge of pharmacology becomes even more important. Although midwives may use a wide repertoire of nonpharmaceutical approaches, there are conditions and situations in which no effective substitutes exist for pharmacological treatments.

Throughout this book, specific therapeutic agents are discussed as treatments for various conditions. However, the field of pharmacology is so expansive that midwives can benefit from a pharmacological overview. This chapter focuses on such an overview, and it includes discussion of specific situations such as the use of common drugs in the primary care of women when the woman is either pregnant or breastfeeding. Moreover, although many examples are included in the chapter as illustrations, it should not be assumed that they are exhaustive. Additionally, certain terms—including drugs, agents, medications, and pharmaceuticals—are terms used interchangeably throughout the chapter. The word *drug* should not connote an illicit substance or a licit substance being abused. Drugs with abuse potential will be designated as such. In this chapter, drugs will be listed by generic name, accompanied by the most common brand name(s). Readers who desire additional information about the basics of pharmacology are directed to any of the standard pharmacology textbooks.

The Lexicon of Pharmacology

As knowledge in pharmacology has expanded, so has the lexicon. Knowledge of the terms is helpful as midwives are faced with an increasing amount of information in the field. A prerequisite to understanding drug actions and effects is the midwife's ability to define the various terms used in pharmacology. Some of the terms are old and established. *Pharmacology* itself means the study of drugs in all their aspects. However, there are several more specific terms employed in the field. Pharmacokinetics describes the absorption, distribution, metabolism (biotransformation), and excretion (clearance) of drugs. These factors then determine the amount of the agent available at the target sites for action. Pharmacodynamics refers to the receptor-mediated action of drugs, rather than drug effects that occur when agents are free, unbound, and not ionized. The pharmacodynamic action of a drug results from the drug's binding relationship at the receptor site as either an *agonist* or an *antagonist*. Pharmacotherapeutics is the field focusing on treatment effects of drugs. Additional terms can be found in the pharmacology glossary presented in Table 10-1.

TABLE 10-1	A Brief Glossary of Pharmacology
Agonist	A drug that binds to a receptor and activates it, producing a pharmacological response.
Antagonist	A drug that attenuates the effects of an agonist. Antagonism can be competitive and reversible (i.e., it binds reversibly to a region of the receptor in common with the agonist) or competitive and irreversible (i.e., the antagonist binds covalently to the agonist binding site, and no amount of agonist can overcome the inhibition).
Cardiovascular pharmacology	Pharmacotherapeutic uses of agents on specific areas of the cardiovascular system.
Chemotherapeutics	Agents used to kill microorganisms such as bacteria, viruses, and parasites; includes antimicrobial agents.
Cosmeceutical	Cosmetic products that have medicinal or druglike benefits.
Ecopharmacology	Drugs derived from plants, especially those found in the rain forest, as well as exploration of pharmacological implications of pollutants in water that exert pharmaceutical-like effects, most often estrogenic in nature. The latter also have been called ecoestrogens or xenoestrogens.
Half-life	The period of time required for the concentration or amount of drug in the body to be reduced to exactly one-half of a given concentration or amount.
Immunotherapy	Treatment of disease by inducing, enhancing, or suppressing an immune response.
Loading dose	A larger than normal dose administered as the first in a series of doses, the others equal to each other, but smaller than the first. A loading dose is administered in order to achieve a therapeutic amount in the body more rapidly.
Molecular pharmacology	Study of the molecular mechanisms that define drug action.
Neuropharmacology	Pharmacotherapeutic uses of agents on specific areas of the nervous system.
Nutriceuticals, or functional foods	Food or supplements like folic acid that have specific health benefits.
Pharmacodynamics	How drugs produce their effects, such as interactions at a receptor site.
Pharmacoeconomics	A blending of pharmacology and economics that applies cost-benefit, cost-effectiveness, cost-minimization, and cost-utility analyses to compare the economics of different pharmaceutical products or to compare drug therapy to other treatments. Several sources include in this definition factors such as quality of life and impact of the drug on the recipient, caregivers, and society in general.
Pharmacoepidemiology	The study of the utilization and effects of drugs in large numbers of people. To accomplish this study, pharmacoepidemiology borrows from both pharmacology and epidemiology.
Pharmacogenetics	The study of how drugs interact with genetic makeup of an individual or the genetic response to a drug; this may be one of the first clinical applications derived from the Human Genome Project.
Pharmacogenomics	Studies that illustrate similarities and differences in pharmacodynamic and pharmacokinetic mechanisms among various individuals and people of different ethnic backgrounds.
Pharmacokinetics	The movement of drugs in the body, specifically encompassing the study of factors that determine the amount of chemical agents at their sites of biological effect at various times after the agent is administered. Pharmacokinetics is composed of four specific factors of absorption, distribution, metabolism (biotransformation), and excretion (clearance).
Pharmacotherapeutics	The field concentrating on the treatment effects of drugs. There are several subsections within pharmacotherapeutics.
Pharmacovigilance	The monitoring of untoward pharmacologically induced effects.
Psychopharmacology	The study of agents used for mental conditions such as depression.
Steady state	On a fixed dosage schedule, steady state or a steady concentration of the drug is reached after about 4 half-lives. In case of a long half-life, it may therefore take some time for the drug to reach a therapeutic concentration. To reach the window more rapidly, one would use a loading dose.
Toxicology	The branch of pharmacology that deals with the nature, effects, and treatments of poisons.

Newer terms in the field of pharmacology have emerged and more are likely to follow. *Nutriceuticals*, or functional foods, is a term coined by the De Felice of the New York Foundation for Innovative Medicine, a group founded in 1976 and dedicated to accelerate medical discovery by establishing a more productive clinical research community. Nutriceuticals (alternatively spelled Nutraceuticals) refer to foods or supplements like folic acid that have specific health benefits [1, 2]. While the Food, Drug, and Cosmetic Act does not recognize the term *cosmeceutical*, the cosmetic industry uses this word to refer to cosmetic products that have medicinal or druglike benefits [3]. *Ecopharmacology* is a term that recognizes drugs derived from plants, especially those found in the rain forest, as well as exploration of pharmacological implications of pollutants in water that exert pharmaceutical-like effects, most often estrogenic in nature. The latter have also been termed *ecoestrogens* or *xenoestrogens* [4].

Pharmacogenetics—the study of the genetic response to a drug, or how drugs interact with the genetic makeup of an individual—may be one of the first clinical applications derived from the Human Genome Project [5, 6]. Pharmacogenetic studies illustrate similarities and differences in drug effects among various individuals and people of different ethnic and racial backgrounds. *Pharmacogenomics* is the study of DNA sequencing and is theorized as one basis of the creation of designer drugs, or agents specifically made to decrease various adverse effects [7–9]. *Pharmacoeconomics* is a blending of pharmacology and economics that applies cost-benefit, cost-effectiveness, cost-minimization, and cost-utility analyses to compare the economics of different pharmaceutical products or to compare drug therapy to other treatments. Several sources include in this definition such factors as quality of life and impact of the drug on the recipient, caregivers, and society in general [10]. *Pharmacoepidemiology* has been defined as the study of the utilization and effects of drugs in large numbers of people. To accomplish this study, pharmacoepidemiology borrows from both pharmacology and epidemiology. Pharmacoepidemiological studies explore probability of beneficial effects in populations, or the probability of adverse effects in populations and other parameters relating to drug use using epidemiological methodology. A term even exists for the monitoring of untoward pharmacologically induced effects—namely, pharmacovigilance [11].

Drugs in Modern Society

More than 1.3 billion prescriptions are written each year in the United States, according to the National Association of Chain Drug Stores. Appendix A at the end of this chapter lists the 200 most commonly prescribed drugs in 2001 [12]. Each prescription filled can result in a 20 percent profit to the manufacturer, making the area highly profitable. In addition to prescription drugs, over-the-counter drugs are popular purchases.

In 2002, the National Slone Survey found that most American adults take at least one medication, and many take multiple pharmaceuticals daily [13]. Rates of use increased according to age group, and women used more agents than men in every age group, except for people aged 65 or older, where there was no gender difference for those using 10 agents or more. Some ethnic variations were also discovered, with Whites and Native Americans using the most pharmaceutical agents. Four of the five most popular agents were over-the-counter drugs; in order, they were acetaminophen (Tylenol), ibuprofen (Motrin or Advil), aspirin, and pseudoephedrine hydrochloride (Sudafed). The prescription drug, conjugated estrogens (Premarin) were ranked fifth. Approximately 40 percent of study participants had taken a vitamin and/or mineral supplement in the week before the survey; most commonly a multivitamin, vitamins E and C, calcium, or magnesium. Folic acid was ranked seventh among these agents. Fourteen percent of the population had taken at least one herbal agent or supplement in the preceding week, such as ginseng, ginkgo biloba extract, allum sativum, glucosamine, and St. John's wort.

The use of pharmaceuticals is thus seen to be prevalent in American society today. The increase in the use of drugs is related to several factors: the increase in their availability; the comfort of the public in safety of drugs, especially over-the-counter products; and the plethora of health care providers, pharmacies, and other outlets. These multiple options mean that an individual may receive drug prescriptions and/or recommendations from providers at various sites who may be unaware of other prescribers. Advertising directed to consumers exposes many more individuals to prescription drugs and proposed therapeutic options of which they might have been previously unaware [14]. Medications are widely marketed and there appears to be a shift among the generations in the country, from an older approach to avoid pharmaceuticals unless ab-

solutely necessary, to a newer, relatively liberal use of drugs. In addition to public acceptance of drugs to treat illnesses, there is a growing appreciation of agents for prophylaxis against various diseases or for general health maintenance.

Even individuals living in developed countries who avoid taking specific drugs or agents may constantly be exposed to pharmaceuticals through the food chain or in their daily environment [15]. Such exposure and other issues in reproductive toxicology are beyond the scope of this chapter, although the area is likely to grow, and studies should provide findings of clinical importance, perhaps even in the near future [16–20].

Practicalities and Issues Involving Drugs

Drugs are often listed in various ways. Agents can be described by a physiochemical property of the drug (e.g., an acid) or by phamacotherapeutic indication (e.g., sedative). Sometimes they are described by regulation. Pharmaceuticals are regulated in the United States by the Food and Drug Administration (FDA), one of 12 agencies within the U.S. Department of Health and Human Services. The FDA also regulates medical devices like intrauterine contraceptive systems (ParaGuard, Mirena) and biologic agents such as vaccines. The FDA has some post-marketing responsibility regarding safety of dietary supplements such as St. John's wort but does not regulate them by law in the same manner as pharmaceuticals. Similarly, the FDA may require labeling to designate that safety has not been established for cosmetics, but recall of cosmetics is voluntary by the manufacturer [21].

The pharmaceuticals for which the FDA does have authority may be obtained by prescription or over the counter. The regulation of drugs is administered by the Center for Drug Evaluation and Research (CDER), a subgroup within the FDA that oversees the research, development, manufacture, and marketing of drugs, both prescription and over the counter. If unexpected risks are detected after approval, CDER takes action to inform the public, change a drug's label, or, when necessary, remove a product from the market. The FDA does not develop, manufacture, or test drugs. Drug manufacturers submit full reports of a drug's studies, which are called *clinical trials*, so that the Center can evaluate its data and determine if the drug should be approved for a specific indication. This approval commonly is termed FDA labeling. The clinical trials are intended to be appropriately large to determine safety and effectiveness. However, sometimes the FDA approves a drug, only to remove it from the marketplace later due to issues that emerge in larger groups, when individuals use the drug for longer periods of time, or when used in conjunction with other agents. Midwives should be aware of the FDA MedWatch hotline (800-FDA-1088) where adverse reactions can be reported, although such reporting is not legally mandated at this time. Table 10-2 lists the sequencing of FDA phases or trials and Figure 10-1 illustrates the process [22].

The FDA has been regulating drugs for decades. However, women have not been participants in most drug development studies due to ethical, practical, and liability concerns [23]. Even when women have participated, it has been rare that an analysis of gender differences has been published. Moreover, clinical trials for contraceptives generally do not include many adolescents, as women under the age of 18 are considered pediatric patients. Pediatrics itself is a difficult area in which to conduct clinical trials because of the inherent issues with informed consent.

In relation to everyday usage, problems are emerging with the current mobile society. According to federal and most state regulations, drugs bought legally by a person in other countries,

TABLE 10-2 Phases or Trials of the Food and Drug Administration

FDA Phase	Description
1	Designed to determine drug dynamics and identify drug metabolites. This phase is usually small, and may be omitted if extensive international study has been conducted.
2	Controlled clinical trials to verify effectiveness and basic safety.
3	Randomized clinical trials, usually placebo controlled.
4	Post-marketing clinical trials, usually to gather information about adverse reactions, morbidity, and mortality that can be obtained only in larger groups.

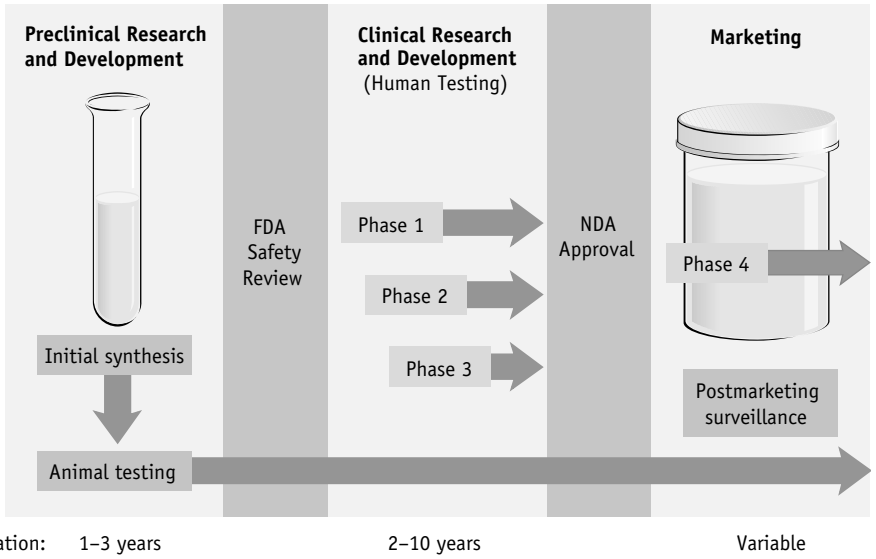

FIGURE 10-1 Steps required by the FDA for reviewing a new drug.

Source: Hanson, G.R., Venturelli, P.J., and Fleckenstein, A.E. *Drugs and Society*, 7th ed. Sudbury, MA: Jones and Bartlett Publishers, Inc., 2002.

such as Canada and Mexico, generally are considered illegally imported when the same individual uses them in the United States [24].

Perhaps most importantly, FDA labeling does not mean that off-label use is ineffective. Such use describes clinical practice for indications for which a drug is not labeled [25]. Examples abound regarding off-label use. The most commonly used tocolytic in the United States is magnesium sulfate, yet only ritodrine (Yutopar) is FDA labeled for the indication. Methotrexate (Rheumatrex), a folic acid antagonist used as a chemotherapeutic, has a marked predilection for destruction of trophoblastic tissue and is used off label for medical treatment of an unruptured ectopic. Midwives should recognize that off-label use, albeit common, should not be undertaken capriciously. Both medical and legal implications are involved, especially if the drug is not yet widely accepted in practice.

Some prescription drugs have a higher risk of abuse than others. The U.S. Drug Enforcement Administration (DEA) was established in 1973 within the Department of Justice. This agency has a special role in the regulation of prescription drugs under the 1970 Controlled Substance Act (CSA). The CSA has categorized potentially abused pharmaceuticals regulated under existing federal law into one of five schedules based upon the substance's medicinal value, harmfulness, and potential for abuse or addiction. Schedule I is reserved for the most dangerous drugs that have no recognized medical use, such as LSD or heroin. Schedule V is the classification used for the least dangerous drugs, such as brand name antitussives containing small amounts of codeine. Meperidine (Demerol) is a Schedule II agent. Knowledge of these schedules is important for midwives seeking prescriptive authority. Table 10-3 lists the five schedules for controlled substances.

Approximately 48 states grant some type of prescriptive authority to Certified Nurse-Midwives [26]. Prescriptive authority remains less common for Certified Midwives, as their credential is newer and their numbers fewer. Prescriptive authority is controlled on the state level and ranges from very limited to relatively broad. Many states limit prescriptive authority according to the aforementioned schedule of drugs, often making it difficult for midwives to offer opiate analgesics to laboring women. Some laws are based on delegation or practice site, which also can be barriers for midwives to provide appropriate care to women.

A registration number issued by the DEA is needed in order to prescribe a controlled substance. In 1993, the DEA published a regulation that established a new category under which health care providers other than physicians, dentists, veterinarians, or podiatrists would receive individual DEA registration numbers granting controlled substance privileges consistent with the authority granted them under state law (including authorization through joint practice agreements, protocols, and guidelines)

TABLE 10-3	FDA Classification of Controlled Substances
Schedule	**Interpretation**
I	High potential for abuse and no current accepted medical use. Examples are heroin and LSD.
II	High potential for abuse. Use may lead to severe physical or psychological dependence. Examples are opioids, amphetamines, short-acting barbiturates, and preparations containing codeine. Prescriptions must be written in ink or typewritten and signed by the practitioner. Verbal prescriptions must be confirmed in writing within 72 hours and may be given only in a genuine emergency. No renewals are permitted.
III	Some potential for abuse. Use may lead to low-to-moderate physical dependence or high psychological dependence. Examples are barbiturates and preparations containing small quantities of codeine. Prescriptions may be oral or written. Up to five renewals are permitted within six months.
IV	Low potential for abuse. Examples include chloral hydrate, phenobarbital, and benzodiazepines. Use may lead to limited physical or psychological dependence. Prescriptions may be oral or written. Up to five renewals are permitted within six months.
V	Subject to state and local regulations. Abuse potential is low; a prescription may not be required. Examples are antitussive and antidiarrheal medications containing limited quantities of opioids.

[27]. According to this regulation, midlevel practitioners such as Certified Nurse-Midwives were given authority for controlled substances by the state or jurisdiction in which they practice. However, because of state and local barriers, the majority of midwives do not have separate DEA numbers.

Midwives with prescriptive authority have the legal ability to write prescriptions. Although many prescriptions are phoned to a pharmacy or, increasingly, transmitted by electronic means, a midwife needs to know the components of a prescription. All handwritten prescriptions must be legibly written in indelible ink. Every prescription includes the midwife's name, address, and contact information for the pharmacist should questions arise. It is optimal to have the midwife's prescriptive authority number or other identifying information either on the top of the prescription or adjacent to the midwife's signature. All prescriptions are dated, and information about the prescription is placed in the woman's record so that if she loses the prescription, changes pharmacies, or moves, it can be easily retrieved. Only one drug is written on each prescription blank. Refills, if any, are noted, especially since certain health plans limit coverage of monthly drugs. Some authorities have lists of abbreviations, such as TID for "three times a day," although many sources recommend actively avoiding any abbreviations.

The section of the prescription specific to the medication consists of four parts: (1) superscription, (2) inscription, (3) subscription, and (4) signature. The superscription includes the symbol "Rx," although according to WHO guidelines, it is more proper to use the Latin "R/" [28]. In any case, the symbol is derived from the Latin for "recipe" or "take." The inscription specifies the ingredients and their quantities (e.g., nitrofurantoin 100 milligram capsules). The subscription informs the pharmacist how to compound or dispense the medication (e.g., dispense 10 capsules). The midwife should avoid decimals and, where necessary, write words in full to avoid misunderstanding. For example, the midwife should write "levothyroxine 50 micrograms," not "0.050 milligrams" or "50 μg." The signature, or "sig," is not that of the prescriber, but represents the Latin "signa" or "mark" that are the instructions that enable the woman to understand dosages and when to take a drug. The sig should include route, frequency, duration, and any other specific information—for example, "Take 1 capsule by mouth at bedtime for 10 days."

Generally it is recommended that the generic or nonproprietary name be used when a prescription is written. Use of generic names enables the pharmacist to maintain a more limited stock of drugs, and/or dispense the least expensive drug. However, if there is a particular reason to prescribe a special brand, the trade name can be added. Some areas allow generic substitution by the pharmacist and require the addition "Do not substitute," "Dispense as written," or "Brand medically necessary" if that brand, and no other, is to be dispensed. When a specific brand is required, the midwife should document such in the woman's chart with rationale. The documentation is not only for completeness, but also may be necessary for the prescription to be covered by a public program like Medicaid, various managed care groups, or other types of health insurance. Figure 10-2 illustrates a sample prescription written by a midwife.

Adverse Drug Reactions/Adverse Drug Events

Although the federal government has attempted to address the issue of drug abuse through the CSA and DEA activities, society can be harmed in different ways by drugs. In 1998, a meta-analysis by Lazarou et al. of adverse drug reaction (ADR) in hospitals culminated in major concerns about drugs [29]. Based on the research, it was estimated that in 1994 more than two million hospitalized patients had serious ADRs and more than 100,000 had fatal ADRs. These statistics indicated that ADRs ranked in the top six causes of death. Since that time, professional organizations such as the American Medical Association and various nursing and medical state boards have been in dialogue to develop strategies to avoid ADRs, recognize the reactions promptly, and promote methods to develop drugs with fewer risks.

Adverse drug reactions do not include drug calculation errors, overdoses, or problems with compliance. Some authors categorize these as adverse drug events (ADEs), a more inclusive phrase connoting any injury resulting from the administration of a drug. This broader terminology means that the overall effect of drug injuries would be higher than those estimated by Lazarou and colleagues. Midwives need to be aware of the increased scrutiny about drugs and to be prepared to expect additional outside regulations or controls as institutions and organizations attempt to address issues of drug safety. Part of the move toward electronic transmittal of prescriptions and computer charting is an attempt to decrease medication errors [30].

Drug Resistance

Within four years after drug manufacturers began mass production of penicillin in the 1940s, resistant *Staphylococcus aureus* began to appear. By the late 1960s, additional resistant bacteria were found in the Pacific. The spread of resistance was rapid [31]. Between 1979 and 1987, only 0.02 percent of strains of pneumococcus were reported as resistant by the CDC; by 1994, 6.6 percent were reported to be resistant. Several factors account for the development and rapid rise of drug-resistant strains. One factor is the human complacency that developed in the 1980s when many scientists and clinicians began to view a bacterial infection as an easily curable condition. Antimicrobial use was liberal, even for conditions for which they were not indicated, such as the common cold.

When susceptible bacteria were eradicated, the few left were the resistant ones. With natural selection, these microbes often became the predominant microorganism. Resistant microbes have several mechanisms of action. For example, penicillin resistance is the result of gene action. Since penicillin destroys cell walls, some of the organisms can alter cell walls so that the antibiotic cannot bind to it, or they can produce enzymes to destroy the penicillin. Alternatively, resistance to quinolones involves altering the ability of the drug to penetrate its target [32].

There are three ways in which bacteria can acquire genes that provide resistance: (1) spontaneous DNA mutation—e.g., drug resistant tuberculosis; (2) transformation in which one bacterium assumes DNA from another bacterium—e.g., penicillin resistant gonorrhea; and (3) resistance acquired from a small circle of DNA called a plasmid that can fit from one type of bacterium to another—e.g., shigella. The latter is the most troublesome, since with plasmid acquisition, the bacteria may simultaneously become resistant to several types of drugs. The rise in drug resistance directly correlates with the rise in use of antimicrobials. Therefore, midwives are advised to use good hand-washing techniques with regular soap to avoid spread of disease, to use antimicrobials only when they are clearly indicated, and to attempt to use narrow-spectrum agents when the microorganism is known. Midwives should also educate women about the appropriate use of antimicrobials, including avoidance of antibacterial soaps and cleansers that may contribute to the problem. Adding antibacterial agents to a variety of substances, such as soaps, lotions, and cleaning supplies, can act like antibiotics in the selection of resistant strains of microbes and are no more effective than similar agents without the antibacterial additives [33].

Drug-to-Drug Reactions

Although certain drugs are therapeutic when used alone, when they are used concomitantly with other agents, untoward effects may result. Recent research has been conducted in the area of drug to drug and even drug to herb interactions.

Many agents are metabolized through the cytochrome P-450 pathway. This pathway tends to affect the metabolism of drugs by slowing or accelerating drug clearance. It has been found that some individuals have mutations called polymorphisms in the cytochrome P-450 pathway in the liver. Approximately 10 percent of Caucasians have the polymorphism that inhibits metabolism of some agents, and facilitates others. It is probable that more mutations may be discovered in the future. An example of a drug-to-drug reaction is cardiac arrhythmias that may occur when the macrolide erythromycin (e.g., e-base or Eryc, azithromycin or Zithromax, clarithromycin or Biaxin) and the antifungal ketoconazole (Nizoral) are taken simultaneously. Gene testing for the cytochrome P-450 mutation is on the horizon. Until then, since no one can identify which women specifically are at risk, all women should be advised about potential interactions. Thus, it is important that midwives know all the medications, including herbs [34], that a woman is taking before prescribing or recommending others.

One of the greatest challenges to the midwife in clinical practice is maintaining current information about drug indications, doses, side effects, and contraindications. Now providers additionally need to be aware of drug-to-drug/herb interactions. Various publications, both in print and electronic media, have emerged to help with maintaining the information, and also updating it as new discoveries emerge. Prominent among these innovations are applications for personal digital assistants (PDAs), which can download programs containing information about all FDA approved medications, including doses, contraindications, cautions, interactions, adverse reactions, cost, and pregnancy categorization [35]. This information can be accessed rapidly regardless of location [36, 37].

Drug Costs

Health care costs are a major component of the gross national index, and pharmaceuticals remain a large part of the costs. Today, the high cost of many drugs exceeds the personal savings of individuals, if they are not able to obtain assistance through public programs such as Medicare or Medicaid. Midwives should be aware that many pharmaceutical companies have patient assistance programs for women with an annual income less than $12,000, or a family income less $15,000 and nonavailability of prescription drug payment from public or private third-party sources. Most of these programs require a prescription and a letter of verification, and usually they will provide a three-month supply subject

to re-review at that time [38]. Midwives may contact the pharmaceutical manufacturers directly, access information via the Internet, or contact social services at local institutions.

Drugs and Herbs

Hippocrates documented the use of more than 200 herbal remedies. Today, more than three-quarters have been refined, synthesized, or packaged as modern pharmaceuticals. However, many other herbs and botanicals are sold today, although their actions and safety may remain unknown. Herbal preparations can be found in a variety of forms and are listed as dietary supplements by the FDA. The FDA regulates dietary supplements differently than it does prescription and over-the-counter agents. Under the Dietary Supplement Health and Education Act of 1994 (DSHEA), the manufacturer must ensure that a dietary supplement is safe before it is marketed [39]. The FDA is responsible for taking action against any unsafe dietary supplement product after it reaches the market. Generally, manufacturers do not register with the FDA nor do they get FDA approval before producing or selling dietary supplements. The FDA's postmarketing responsibilities include monitoring safety, such as voluntary dietary supplement adverse event reporting. The FDA must also monitor product information, such as labeling, claims, package inserts, and accompanying literature. The Federal Trade Commission regulates dietary supplement advertising.

For years herbal therapy has been outside the mainstream of American life. However, it is apparent that today many individuals take nutritional supplements and herbs, often as a complementary therapy to pharmaceutical therapies. The National Center for Complementary and Alternative Medicine (NCCAM), founded in 1998, is one of the 27 institutes and centers that compose the National Institutes of Health (NIH) within the U.S. Department of Health and Human Services (DHHS).

Because herbal therapy has been outside the mainstream, it has not been subjected to the same rigorous investigation as pharmaceuticals—but such lack of research has in turn kept it from being in the mainstream. This paradox is unfortunate because many of the agents are inexpensive and easily available but financial backing has been unavailable to conduct studies. However, with the advent of the research under the auspices of NCCAM and evidence-based research emerging from abroad, it is becoming apparent that herbs can be effective therapies.

The use of herbs is challenging for modern midwives, as much of the information available on the Internet or in journals remains anecdotal or strictly opinionated. Some evidence-based information can be obtained, and it should be sought by any midwife planning to recommend herbal therapy. In 1978, a regulatory agency was established in Germany to evaluate the effectiveness of herbal remedies. Called the German Commission E, the group of 24 scientists evaluated studies (clinical, case, field), and prepared scientific monographs. The current plans are that by 2004 only herbs that the German Commission E have found to be effective, and of low risk of adverse effects, will be available in Germany. The American Botanical Council, based in Texas, has published an English translation of the German monographs [40]. Although the work generally has been lauded, many common North American herbs are not included [41]. Currently, the NCCAM has approximately two dozen studies in process that compare herbal remedies to conventional pharmaceutical treatments for specific conditions, such as endometriosis. Data from these U.S. studies should expand knowledge in the area. At the present time, however, midwives must be cautious about claims involving therapeutic uses of herbs. Many sources simply are lists of possible indications without accompanying data.

Pregnancy and Drug Use

Pharmacokinetics in Pregnancy

As previously mentioned, pharmacokinetics describes the absorption, distribution, metabolism, and excretion of an agent. The basics of pharmacokinetics can be found in various pharmacology texts. However, during pregnancy, the myriad physiological changes in a woman's body also affect the pharmacokinetics of any drugs and herbs she uses [42].

Absorption

Gestational nausea and vomiting are common and impair absorption of drugs from the gastrointestinal system. Decreased gastric emptying, probably associated with increased levels of progesterone, results in drugs remaining in the stomach for approx-

imately twice as long as in a nonpregnant woman. Decreased gastric motility also results in a possible increase in absorption of drugs in the small intestine and may increase absorption of hydrophilic drugs that tend to cross the gastrointestinal epithelia slowly. In addition, the pH of the stomach increases during pregnancy, becoming more alkaline. Drugs that are weak bases have increased absorption because less of the drug is ionized and more of the agent passively diffuses out of the stomach. The opposite effect occurs with weak acids; more drug is ionized in the stomach and less is passively diffused. However, even with these changes affecting oral bioavailability, the therapeutic windows of most agents are wide enough that modifications in drug dosing are not needed.

Modifications in drug absorption in pregnancy also occur with other routes of administration, including inhalation through the respiratory tract. By the twentieth week of pregnancy, tidal volume is increased, residual volume decreased, and respiratory rate is either unchanged or slightly increased. By term, alveolar ventilation is increased by approximately 70 percent. These changes, especially the alveolar ventilation, lead to increased particle uptake and diffusion of aerosols and bronchodilators. Thus, less drug may be needed to obtain the same therapeutic effect found in a nonpregnant woman.

During pregnancy, the increase in cardiac output significantly increases skin perfusion. Thus, there is enhanced absorption of most transdermal and subcutaneous drugs, especially water-soluble ones. Theoretically, some local anesthetics, such as lidocaine, can have enhanced absorption when administered during pregnancy, although it is likely that such a reaction would be mediated by differences in the distribution and rate of elimination. Intramuscular injections may result in more rapid reactions because of increased cardiac output and enhanced blood flow; conversely, if the injection site is in an area of major edema, decreased absorption may occur.

Bioavailability/Drug Distribution

Distribution of a drug is related to a variety of factors including protein binding, lipid solubility, ionization, and affinity with tissue. Protein binding initially buffers the action of a drug but also has the effect of prolonging its half-life. Drugs bound to protein are not free and active in solution until the concentration gradient diminishes, causing the release of the drug from the protein. By the last few weeks of pregnancy, the intravascular volume expansion results in a lower serum albumin concentration. Therefore, more free drug is available at lower plasma concentrations since less albumin binding of the drug exists. Binding varies inversely with pregnancy—i.e., the more advanced the pregnancy, the lower the serum concentration of protein. Drugs that generally are highly bound to albumin, such as antiepileptic drugs and selective serotonin reuptake inhibitors, tend to demonstrate an increased effect because of this physiological phenomenon.

Drug distribution is complex during pregnancy because of four separate compartments that exist: (1) the fetus, (2) the amniotic fluid, (3) the placenta, and (4) the mother. Each of the compartments impacts movement of drugs, and occasionally certain drugs can have higher concentration in a specific compartment. For example, although studies of placental transfer are less than optimal, it appears that most transplacental movement of drugs from the mother to the fetus occurs by simple diffusion [43]. In general, increased drug distribution is associated with the 50 percent increase in blood volume during pregnancy. Drug transfer is facilitated by lipid solubility, since the placenta is lipoid in character. A nonionized state also facilitates transfer. Transfer can occur both ways, although sometimes ion trapping can result. When ionized modules cross the placenta via active transport, they can accumulate in the fetal liver and adrenal glands and become ion trapped in the fetus because of the more acidic fetal circulation.

Drugs are more easily transferred in the third trimester. Table 10-4 lists the major factors that influence the enhanced drug transfer of late pregnancy.

Placental transfer of drugs can be accomplished by any of the traditional drug transfer methods, whether passive or active. Passive transfer includes simple diffusion and facilitated diffusion. Neither of these two methods requires energy, or allows an agent to be transferred across the membrane to an

TABLE 10-4 Factors Influencing Increased Drug Transfer in Late Pregnancy

- Increased unbound drug available for transport
- Increased uteroplacental blood flow
- Increased placental surface area
- Decreased thickness of semipermeable lipid membranes between placental capillaries
- Greater physical disruption of placental membranes
- More acidic fetal circulation to trap basic drugs

area of higher drug concentration. Most drugs transfer across the placenta by simple diffusion, although some are carrier mediated, or use facilitated diffusion. Active transport requires energy; the most common method is pinocytosis, a process during which a portion of the plasma membrane engulfs the drug molecule, creating a type of intracellular vesicle. Because of the energy and time required for pinocytosis, few drugs cross the placenta using that method in any appreciable amount.

Certain factors dictate the method available for transport. Most drugs have a small molecular weight, usually less than 500 MW, so they are more likely to be transferred easily across the placenta, especially when compared with drugs like heparin or insulin, with a greater than 1000 MW. However, even large molecules can be transported, although it is a more difficult process.

Once a drug passes the placenta, it is free to bind with proteins in the fetal plasma, especially since albumin concentrations in the fetal compartment are higher than in the maternal compartment. Thus, some drugs like diazepam (Valium) may have an increased fetal effect when compared with maternal effects. Other factors associated with maternal fetal drug transfer include conditions that influence drug distribution and metabolism, such as preeclampsia and hepatitis.

Metabolism

Most drug metabolism occurs in the liver. Lipid-soluble drugs are converted into water-soluble ones to enhance elimination, especially by the urinary system. Pharmaceutical agents may be categorized as high extraction or low extraction. High extraction agents like lidocaine (Xylocaine) and meperidine (Demerol) depend on liver blood flow for metabolism. In spite of general increases in blood flow, there is no evidence that hepatic blood flow is increased significantly during pregnancy. Therefore, metabolism of high extraction drugs is similar to that in the nonpregnant state.

Low extraction drugs are dependent upon liver enzymes. Examples include phenytoin (Dilantin), theophylline (Theolair), and fluoxetine (Prozac, Sarafem). The most important metabolic pathway is the one that enables drugs to be oxidized in order to facilitate clearance. The liver enzyme most prominently involved is cytochrome P-450, discussed earlier in this chapter in relation to drug-to-drug interactions.

All hepatic enzymes fluctuate in pregnancy, probably due to increased production of steroidal hormones. In particular, estrogen and progesterone have been found to inhibit some enzyme activity in the liver, resulting in increased drug accumulation or decreased elimination of agents like caffeine. Additional studies are ongoing regarding other hormonal influences.

The placenta can also accomplish metabolism of drugs. The organ has cytochrome P-450 pathways. It has been found that the placenta contains approximately half the amount of liver enzymes as the maternal liver, although the effect of these enzymes remains poorly understood.

Elimination/Clearance

Major changes can occur with drugs that use the urinary system for clearance of the agent itself or its metabolites. In general, excretion includes glomerular filtration, especially for water-soluble drugs, active tubular secretion, and passive absorption. In the urinary tract, protein bound drugs are not easily absorbed while lipophilic drugs usually are reabsorbed.

Renal clearance is influenced by some of the changes in pregnancy. Renal blood flow increases by 80 percent in early pregnancy, then decreases until it approximates the nonpregnant state at term. The glomerular filtration rate increases by 50 percent during pregnancy, allowing water-soluble drugs to be cleared more rapidly. Creatinine clearance tends to mimic changes in the glomerular filtration rate and reaches a maximum at 34 weeks. Thus, renally excreted drugs like beta-lactam penicillins and aminoglycosides like gentamicin (Garamycin) are cleared more rapidly during pregnancy.

In conclusion, pharmacokinetics are impacted directly by physiological changes in pregnancy. However, most commonly used agents possess wide therapeutic windows and need little, if any, change in administration. Thus, even if these pharmacokinetic changes are known, they often do not impact clinical practice today. However, as pharmaceutical designs and delivery systems become more sophisticated, additional knowledge may be needed in the area to compensate for changes in pregnancy.

At this time, there are a few agents that midwives should be aware could theoretically need

dosage adjustments. Midwives should monitor women carefully for therapeutic effects particularly with the use of aminoglycosides like gentamicin (Garamycin) or other agents such as ampicillin (Omnipen, Polycillin, Principen), and cefazolin (Rochephin), since serum concentrations appear to be decreased in pregnancy. The clinician may also need to decrease theophylline (Theolair) doses for the asthmatic woman as its serum concentrations rise in pregnancy.

Teratology and Drugs During Pregnancy

Although women are aware that they should not take drugs during pregnancy—be they licit or illicit—the majority of women report taking several drugs during pregnancy. One of the major issues specific to pregnancy is whether or not the agents ingested are teratogenic.

In today's common use, teratology essentially is the study of congenital anomalies. Contrary to popular belief, the vast majority of birth defects either are idiopathic or due to genetic/chromosomal influences. It is estimated that approximately 2 to 5 percent of all births result in a baby with a birth defect [44, 45]. This percentage is often called the "background risk" upon which additional risks are calculated based on family history, past history, and environmental exposure. Only 10 percent of birth defects can be associated with environmental factors, and even then the majority of environmental factors are not pharmaceuticals. The etiology of congenital anomalies includes maternal infections and illnesses such as rubella, pregestational diabetes, and exposure to radiation. Drug agents, including agents such as mercury and pesticides, account for approximately 45 percent of the environmental factors involved in congenital anomalies, or an estimated 4 to 5 percent of all birth defects.

The unique fact about teratogenic medications is that avoiding the teratogen can prevent the associated congenital anomaly. Thus, knowledge about teratogenic drugs is essential for the practicing midwife. Fortunately, the number of these agents is relatively low, and even fewer are in common use. The period of organogenesis—between 3 to 8 weeks postfertilization or 5 to 10 gestational weeks—is the most critical period for exposure to teratogens.

Using a strict definition, a teratogenic agent is one that, when administered during the first trimester, causes permanent structural or behavioral changes to the fetus. Some sources advocate using the term fetotoxic for agents, like tobacco, that cause changes when administered in the second or third trimester. Others might term it a trophogen, as an agent that alters growth. Yet most clinicians apply the term teratogenic to agents culminating in intrauterine insults, regardless of gestational timing [46].

In 1980, the FDA published a list of pregnancy risk categories for prescription and nonprescription drugs, including those with known teratogenic effects. These categories can be found in Table 10-5 [47]. The FDA does not directly categorize drugs it-

TABLE 10-5 FDA Pregnancy Risk Categories for Prescription and Nonprescription Drugs

A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.
B	Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) or there are no controlled studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
X	Studies in animals or human beings have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Source: From the *Federal Register*, 44:37434–37467, 1980.

self and in most cases the drug manufacturer performs that action [48]. Few drugs can be placed in Category A since the conduct of controlled studies in pregnancy not only is difficult but also is probably unethical. Category B contains agents such as acetaminophen and penicillin where both animal and noncontrolled human studies have failed to demonstrate any teratogenic effects. Category C encompasses two distinct concepts: either data are lacking about safety of the drug, most likely because it is new to the marketplace, or there is some evidence of animal teratogenic effects, although no similar human effects have been found. More than two-thirds of current drugs fall into Category C [49]. Categories D and X are both teratogens but differ according to risks and benefits. For example, some Category D drugs are antiepileptic drugs (AEDs) with known teratogenic effects. However, these AEDs may be prescribed during pregnancy if they are the only agents effective in controlling seizure activity. Isotretinoin (Accutane) is a Class X drug since it is used to treat acne, a non-life-threatening event. At the time of this writing, the FDA is considering updating the categorization [50].

Occasionally the term *litogen* is used in the literature. Although litogens are not classified as teratogens, they are agents that have been found to be of risk in court—i.e., in litigation [51]. For example, a combination of doxylamine succinate and vitamin B_6 was marketed for years under the brand name Bendectin, a remedy for gestational nausea [52]. Parents of infants born with limb defects argued that there was an association with the drug. In spite of a large volume of expert testimony to the contrary, the court awarded a major finding in at least one case, causing the manufacturer to remove the drug from the marketplace not as a teratogen but as a litogen.

Additionally, the FDA has created a Web site to provide information directly to women and to encourage pregnant women using selected drugs to participate in surveillance registries. The women are actively enrolled and asked to periodically participate in surveys and other data-collecting methods. Prominent among the drugs are antiepileptic agents (AEDs). General information about teratogens is included and a link to the Organization of Teratology Information Services (OTIS) is part of the Web site. OTIS is of value not only to pregnant women but particularly to midwives who are seeking information about the safety of an agent for a woman. The Pregnancy Registry is a separate page that can be accessed through the FDA Web site at www.fda.gov/womens/registries.html. Other drug registries, such as the antiretroviral registry, are maintained by manufacturers. Appendix B at the end of this chapter lists teratology information systems by location.

Most human teratogens are identified *ex post facto*—after the results are apparent in clinical practice. Sometimes the information proves to be circumstantial, and, ultimately, no association is found. Generalizability is an issue for data from animal studies. Different species have various responses to the same drug. Moreover, there exists the issue of animal rights, the cost of primate studies, which provide the most similar response to humans, and problems with inconsistency among species. In general, animal studies demonstrating teratogenicity can be helpful, although rarely definitive. The absence of reports of birth defects does not imply safety, nor is the converse true. A drug may consistently cause defects in animal species but not in humans. Some basic criteria for identifying a teratogen includes exposure to the agent; epidemiological studies that establish linkage; biological plausibility; and consistent manifestation of a specific defect, especially if it is a rare anomaly [53]. Epidemiological studies are particularly challenging as studies often are of small size, nonrandomized, and conducted by recall from mothers with affected children [54, 55]. Table 10-6 lists drugs and chemicals that are known to be teratogens.

Another problem emerges once a teratogen is identified. In the United States, one of two approaches is followed: The agent may be removed from the marketplace, as thalidomide (Thalomid) was initially withdrawn; or it may be retained with various public safeguards [56]. For example, isotretinoin (Accutane) uses explicit and detailed printed warnings, includes drawings of malformed children, and has a detailed informed consent form for women. Still a substantial number of fetuses have been exposed, and as many as one-third of the women did not use any method of contraception, believing they were not fertile [57, 58].

Embryologists and other scientists specializing in this area have published much of the information about teratology, and these professionals tend to use postconceptional dating. Since midwives are more familiar with gestational weeks, rather than postconceptional or postfertilization weeks, they should read the literature about teratology and embryology carefully.

Teratogenic effects such as a cleft palate may be obvious. However, some may be subtle and sub-

TABLE 10-6 Drugs and Chemicals That Are Known Teratogens

Agent	Teratogenic Associations	Comments
Alcohol	Growth restriction Mental retardation Atypical facial appearance Renal and cardiac defects Spontaneous abortion Microcephaly	Women who ingest six drinks per day are at a 40% risk of developing some features of fetal alcohol syndrome (FAS), but the threshold remains unclear. Nutritional deficiencies, smoking, and polypharmacy activities confound the data.
Androgens and testosterone derivatives (including Danocrine)	Virilization of females Advanced genital development of males	Dose dependent and based on critical period. Brief exposure rarely is significant. Before 9 weeks' gestation, labioscrotal fusion is common. Incidental, brief exposure usually has minimal risk.
Angiotensin converting enzyme (ACE) inhibitors	Growth restriction Oligohydramnios Renal failure Decreased skull ossification Renal tubular dysgenesis	Risk of growth restriction is approximately 25% with fetal morbidity approximately 30%. Risk of effects increase in second and third trimester (probably due to decreased utero placental flow).
Antithyroid drugs	Fetal and neonatal goiter Hypothyroidism Aplasia cutis (with methimazole)	Methimazole should be avoided. Propylthiouracil is agent of choice, subject to close monitoring since high doses can effect fetal thyroid.
Coumarin	Bone defects Growth restriction CNS defects Developmental delays	15–25% risk when anticoagulants that impair vitamin K are used, especially between 6–9 weeks of gestation. Later use in pregnancy associated with abruption, CNS defects, stillbirth, and hemorrhage of the fetus/newborn.
Carbamazepine	Neural tube defects Minor craniofacial defects Developmental delays Growth restriction	Risk of neural tube defect is increased, especially when used with other antiepileptic drugs.
Folic acid antagonists	Spontaneous abortion Various anomalies	Includes cytotoxic drugs like aminopterin (not currently in clinical use) and methotrexate. Malformation in first trimester is 30%, among those that survive. Some authors include trimethoprim, trimterene, carbamazepine, phenytoin, phenobarbital, and primidone. Some suggest that risk can be decreased with FA in multivitamins.
Cyclophosphamide	CNS malformations Secondary cancers	Chemotherapeutic and antirheumatic drug that is not in common usage.
Diethylstilbestrol (not currently in clinical use)	Clear cell adenocarcinoma of vagina and cervix Vaginal adenosis Possible infertility or subfertility in females and males	Vaginal adenosis found in 50% of females whose mothers took these drugs before 9 weeks' gestation. Data suggest that males exposed in utero may have up to 25% incidence of epididymal cysts and abnormal tests and spermatozoa.
Finasteride	Male genital abnormalities	Marketed most commonly as Propecia, a hair loss treatment for men. Can be absorbed through broken tablets.
Hypoglycemic drugs	Neonatal hypoglycemia	Insulin is a macromolecule and little if any passes the placenta and is the hypoglycemic agent of choice to avoid fetal effects associated with oral hypoglycemic agents.
Lead	Spontaneous abortion Stillbirths	Theorized that CNS development is adversely affected.
Lithium	Congenital heart disease (Ebstein)	Low risk, but Ebstein's has been found and not found with SSRIs and TCAs. Exposure in last month of pregnancy linked to toxic effects on thyroid, renal, and musculoskeletal systems.

TABLE 10-6 Drugs and Chemicals That Are Known Teratogens (continued)

Agent	Teratogenic Associations	Comments
Misoprostol, mifepristone (RU-486)	Abortion Moebius sequence (brain stem ischemia, vascular disruption) for misoprostol	Primarily used for abortion. When used alone for abortion, each is less effective.
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Theorized premature closure of the ductus arteriosus Necrotizing enterocolitis	Sulindac probably does not have the effect on the ductal constriction. Also associated with post-term pregnancy.
Organic mercury	Cerebral atrophy Microcephaly Mental retardation and blindness	Exposure is usually due to fish and/or grain contaminated with methylmercury. Note that mercury thermometers are being withdrawn from the marketplace.
Phenytoin	Growth restriction Mental retardation Craniofacial dysmorphia	Full syndrome less than 10% of fetuses exposed. Degree of expression may be associated with a mutant gene that decreases production of epoxide hydrolase, an enzyme necessary to decrease the teratogen phenytoin epoxide.
Streptomycin and kanamycin	Hearing loss Eighth nerve damage	No ototoxicity has been found with gentamicin or vancomycin.
Tetracycline	Abnormalities of teeth	No known effect unless exposure occurs in second or third trimester.
Thalidomide	Limb deficiencies Cardiac and GI abnormalities	20–30% risk during critical period (very potent). Used for years before teratogenic effects became obvious. Has caused the belief that all drugs have the potential to be a new thalidomide. Back on market for oral lesions in HIV, Hansen's disease, TB, and multiple myeloma. STEPS (System for Thalidomide Education and Prescribing Safety) available on-line from manufacturer, Celgene Corporation.
Trimethadione and paramethadione	Growth restriction Cleft lip/palate Mental retardation Facial dysmorphia Ophthalmic, limb, and GU problems	In first trimester, risk of spontaneous abortion is 60–80%. Characteristic facies associated with use. These antiseizure drugs rarely used today, especially during pregnancy since other agents are available.
Valproic acid	Neural tube defects Minor facial defects	Incidence is approximately 1%. Exposure must be in first trimester, before closure of neural tube.
Vitamin A and derivatives	Spontanous abortion CNS defects Cardiovascular, facial dysmorphia Mental retardation Cleft lip/palate	Use before pregnancy of isotretinoin is not a risk since it is not stored in tissue. However, etritinate has a long half-life and may present a problem. Note that 30% of affected infants according to Retinoid Pregnancy Prevention Program are conceived by women who did not use a contraceptive method, assuming they were not fertile since they had not conceived during periods of months or years when they had not used contraceptive methods. In addition to no contraception, issues of using leftover medications, and even a physician obtaining drug from friend so she could treat her oily skin, etc., have been found.

lethal. For example, decreased intelligence, but not necessarily mental retardation, has been implicated with the use of certain agents such as phenobarbital or cocaine [59].

Fetal age, drug potency, and drug dose all matter in teratology. For women who are exposed to agents prior to tissue differentiation (usually less than 20 days postfertilization or up to approximately four to five gestational weeks), the teratogenic agents tend to result in either a spontaneous abortion, or no effect at all. This phenomenon is termed the all-or-none effect [60]. The susceptibility to teratogenesis depends upon the host susceptibility, involving the mother, embryo, or fetus and the environment (including concomitant use with other drugs), so that prediction of degree of effect becomes an inexact science.

After tissue differentiation occurs, organ systems develop with different timing. (See the section on intrauterine growth and development in Chapter 21.) Exposure to teratogens may result in different manifestations based on timing. When thalidomide (Thalomid) was ingested during the critical period for limb development, phocomelia, or flipper-like limbs, resulted. With some agents, as the dosage increases so does the resulting manifestation. With the dose effect, the result may range from no effect to a totally lethal level. If there is a level known below which there is no effect, and at or above which there is effect, it is called a threshold. For example, the threshold is unknown for alcohol. In some parts of the world alcohol is not proscribed for pregnant women, but suggested in moderation. In the United States, since the threshold is not known, all pregnant women are admonished to abstain from drinking.

Once organogenesis has been completed, drugs still remain a potential problem. Agents such as ACE inhibitors have been linked to low birth weight infants. As mentioned earlier, these agents are fetotoxic, as opposed to true teratogens, although the distinction usually is not emphasized in clinical practice.

Commonly Used Pharmaceuticals

The typical woman in today's society may take medications for a variety of conditions, and a single chapter cannot address all the potential agents she may be confronted with. However, certain drug classifications are commonly used among women, such as antimicrobials, analgesics, and hormones. Midwives need to be aware of these drugs, particularly if the woman is pregnant or could become pregnant. Fortunately, most agents that midwives prescribe are not teratogenic. Lists of teratogenic agents include pharmaceuticals as well as environmental agents. For example, organic mercury can have profound untoward effects but certainly no one prescribes or recommends it. However, some common pharmaceutical agents can be teratogenic and should be viewed cautiously for the pregnant or preconceptional woman. The sections that follow discuss categories of pharmaceuticals from which midwives often prescribe or recommend treatments for nonpregnant women. Agents that should be avoided because of risk in pregnancy are indicated as such. Some common agents that are preferred for use during pregnancy are also included.

Antimicrobials

It is well known that antimicrobials should not be used without indication. Drug resistance has become a major threat to well-being because of the inappropriate and liberal use of these agents in the past [61]. However, there are specific instances in which an antimicrobial agent is necessary. Many agents, like penicillins, are reasonable options for the pregnant woman. However, tetracyclines, (tetracylcine or Acromycin, doxycycline or Vibramycin, minocycline or Minocin) should be avoided as, after crossing the placenta, they concentrate in bones and teeth. Children exposed in utero to tetracyclines may have yellowed teeth with poor enamel and vulnerability to caries as well as problems with bone growth. Other agents should be chosen for the pregnant woman.

The aminoglycosides, streptomycin, and kanamycin (Kantrex) are ototoxic drugs, causing permanent eighth cranial nerve damage. These agents are reserved for grave situations in which the benefits may outweigh the risk, and peak and trough levels should be drawn with administration of multiple doses to ensure the drug plasma level is within the therapeutic window.

Cephalosporins (e.g., cefaclor or Ceclor, cefixime or Suprax, ceftriaxone or Rocephine) are among the most common antimicrobials in treatment of various female reproductive infections. Few studies of cephalosporins have been conducted in the first trimester, but no adverse effects have been reported and cephalosporins, like penicillin, belong to the beta-lactam classification of antimicrobial agents. However, since the penicillins and erythromycin (e.g., e-base or Eryc, azithromycin or

Zithromax, clarithromycin or Biaxin) have been studied extensively and not found to be associated with teratogenic effects, many scientists advocate using them as first-line therapies whenever possible.

Sulfonamides are not teratogenic but require attention to timing. These agents are highly protein bound and can displace bilirubin from binding sites. The most commonly used agents in this category are a combination of sulfamethoxazole and trimethoprim (Bactrim, Septa). Since the placenta clears bilirubin, administration of sulfonamides becomes problematic when it is administered near delivery and the free bilirubin is in the newborn's system where the immature liver is unable to compensate. Kernicterus may result from these high levels. Thus, sulfonamides should be avoided in the third trimester. One sulfonamide, sulfasalazine (Azulfidine), appears to be an exception. This drug is used primarily for the treatment of ulcerative colitis and Crohn's disease and has a weak, if any, effect on bilirubin.

Quinolones are an FDA Category C but are usually considered contraindicated in pregnancy and for young children. Animal studies have demonstrated drug accumulation in the joints with subsequent damage [62].

Metronidazole (Flagyl) is a well-established antiprotozoal agent and is the treatment of choice for *Trichomonas vaginalis* and bacterial vaginosis. No teratogenic effect has been found with metronidazole, even though its mechanism of action involves bacterial mutation [63]. The drug is assigned to FDA Category B. Yet many providers are hesitant to administer it during the first trimester. Although evidence does not support withholding the drug, the conditions for which it is used generally are not life threatening and many providers fear that should a malformed infant be born the drug could be implicated as a litogen. Once labeled as a litogen, it would likely be withdrawn from the marketplace. Since metronidazole is the most effective drug for the treatment of trichomoniasis, these providers avoid its prescription in early pregnancy in order to avoid the risk of litogen labeling.

Sex Hormones

Diethylstilbestrol (DES) is a synthetic nonsteroidal estrogen that was used during the mid-twentieth century to prevent spontaneous abortion, preterm labor, and preeclampsia. Although found not to be efficacious for the above indications, DES nonetheless had a profound effect on many women and their families. The drug became the first one recognized as being capable of transplacental carcinogenesis in humans. Daughters exposed in utero to DES not only were vulnerable to reproductive cancers but often had abnormal uteri, unexplained spontaneous abortions, and preterm labor. Even sons exposed to in utero DES were more likely to have abnormalities of male genitalia. Today, the individuals exposed to DES are perimenopausal or beyond reproductive age. However, women exposed to DES continue to require close health care attention, especially regarding vaginal and cervical cancers and abnormalities [64].

Approximately three million women conceive while actively using contraception, including those using combination oral contraceptives [65]. In most cases of failure with oral contraceptives, it is due to a pill-taking error. Nevertheless, women are concerned that they have exposed their children to estrogen and progesterone. No evidence exists linking any hormonal contraceptives to teratogenic effects.

Vitamins

Vitamin A Vitamins are not always positive supplements. Vitamin A in large doses can be a teratogen. Initially, the threshold was thought to be above 25,000 IU daily. However, a more recent study has found cranial neural crest anomalies occurring with as little as 10,000 IU daily [66]. Midwives should know that routine supplementation of vitamin A is unnecessary, and, if supplementation is used, it should not exceed 5000 IU daily. Typical prenatal multivitamins contain at least 800 IU of vitamin A. Women should be cautioned not to double or triple multivitamins in an attempt to get additional folic acid or calcium. Increasing a multiple vitamin increases all constituents, including vitamin A.

Isotretinoin (Accutane), a vitamin A analog, is a popular agent to minimize acne. Its metabolite, etretinate (Tegison), is used for psoriasis, yet both are known to carry a risk of anomalies of approximately 25 percent.

Folic Acid Through a variety of studies, it has been proved that preconceptional folic acid has positive effects for both primary and secondary prevention of neural tube defects [67]. Numerous cohort studies have suggested that folate, also known as vitamin B_9, may have other prophylactic effects in regard to cardiac disease and colon cancer as well as other diseases [68, 69].

Vaccinations Immunizations are an excellent example of primary care prevention. However, pregnant

women, or those at risk of pregnancy, should not be given live virus vaccines such as the rubella vaccine. Other vaccinations, such as hepatitis A and B, influenza, polio, and rabies may be given during pregnancy if necessary [70].

Analgesics Nonsteroidal anti-inflammatory drugs include a variety of over-the-counter agents and, strictly speaking, include acetylsalicylic acid or aspirin. All these agents have been implicated in disruption of the prostaglandin cascade involved in initiation of labor and are thus linked to post-term pregnancy. Theoretically, they also may be linked with premature closure of the ductus arteriosus as they are employed neonatally for that specific therapeutic effect. Aspirin has been associated with some bleeding issues throughout pregnancy as well as competition with bilirubin for albumin binding sites. All of these agents should be avoided in pregnancy. An alternative agent without anti-inflammatory action is acetaminophen (Tylenol) [71]. Acetaminophen is an FDA Category B and is the analgesic of choice for minor pain during pregnancy.

Opiate analgesics have not been implicated as having teratogenic effects. Caution for use in pregnancy is based upon fear of addiction, not teratogenicity.

Lifestyle Agents Although increasingly unpopular from a social standpoint, smoking remains a relatively common activity during pregnancy, estimated at slightly less than 15 percent nationwide [72]. Although nicotine is not a known teratogen, both nicotine and its metabolite cotinine are fetotoxic, and linked to low birth weight infants, reduced uteroplacental blood flow, placental abruption, and possibly preterm birth. Postnatally, the child of a smoker is more likely than a child of a nonsmoker to die of sudden infant death syndrome (SIDS) [73].

Caffeine is an agent that remains controversial in spite of years of study. It has been established that the half-life of caffeine is tripled during pregnancy. However, linkage with teratogenic effects is more elusive. Early studies failed to account for the confounding bias with smoking. Research studies involving high levels of caffeine have been associated with spontaneous abortion and skeletal anomalies. Studies of women drinking approximately one cup of coffee daily failed to demonstrate any association. Thus, the exact amount that should be recommended to women remains unclear [74, 75]. Theoretically, decaffeinated drinks pose little if any effects on the embryo or fetus.

Many women query their midwives on the advisability of adding a nonnutritive sweetener to their coffee, or ask if they should drink diet soft drinks. Aspartame (Equal, Nutrasweet) is a sugar substitute whose major metabolite is phenylalanine. Although extremely high levels of phenylalanine theoretically can result in toxic fetal levels, as commonly used, aspartame results in fetal phenylalanine levels that are far below toxicity [76]. Obviously, if the mother has phenylketonuria, aspartame is contraindicated.

Almost half of all women between the ages of 15 and 44 years of age have used illicit drugs at least once in their lives. Illicit drug use most commonly has been reported in 7.5 to 15 percent of pregnant women [77]. Although some studies have implicated cocaine with prune-belly syndrome, the evidence is not clear regarding congenital anomalies. Cocaine is associated with abruptio placentae and preterm labor as well as long-term deficits in mental skills [78]. Most illicit drugs are difficult to link with teratogenic effects because of polypharmacy effects, hesitancy regarding disclosure, and variations in potency of the agent. Chapter 12 discusses drug abuse in more detail.

Drugs for the Treatment of Various Medical Conditions

Approximately 25 years ago, midwifery care of high-risk women was a controversial area [79]. Today, the definitions of low and high risk have become less distinct. Many midwives collaboratively care for women who have various medical conditions. Therefore, the midwife needs to appreciate the potential teratogenic issues that accompany some treatments. The following are examples of some conditions that usually require pharmaceutical interventions.

Pregnant women with seizure disorders pose a distinct challenge to the health care provider [80]. Some speculation exists that the disease itself contributes to teratogenic outcomes. Several antiepileptic drugs (AEDs) carry a major risk of teratogenesis, although the absolute risk of congenital malformations following prenatal exposure to most psychotropics is low.

For example, trimethadione is a potent teratogen involving cardiac anomalies, intrauterine growth restriction, and microcephaly. Trimethadione (TMO; Trimethadionum, Trimethinum, Troxidone) is not

commonly used in general and should not be used during pregnancy. Phenytoin (Dilantin) appears to have some teratogenic effect, although perhaps overestimated in years past. Carbamazepine (Tegretol) can result in a dysmorphic pattern of minor anomalies. Phenobarbital (Solfoton) has been associated with potential teratogenic effects. Newborns exposed in utero to phenytoin, carbamazepine, or phenobarbital are at risk of coagulation problems secondary to drug induced vitamin K deficiency, and need prompt supplemental vitamin K.

Many mechanisms have been proposed to explain teratogenicity of anticonvulsant agents. Several of the drugs appear to have antifolate characteristics, and some authorities recommend that women on AEDs should be treated with 4 mg of folic acid preconceptionally and in early pregnancy [81]. The midwife should work closely with maternal fetal specialists when caring for a woman with a seizure disorder as treatment requires the choice of the least risky drug, at the lowest dose that controls seizures.

Depression and other psychiatric conditions are not uncommon in pregnancy. Diazepam (Valium) remains the most common anxiolytic or antianxiety drug and current evidence about benzodiazepines has presented a controversy about whether or not they are associated with cleft palate. Based on the data, if an association does exist, it is very small [82]. However, when administered late in pregnancy or during labor, significant doses of diazepam may result in neonatal irritability, tremors, and hyperreflexia.

Tricyclic antidepressants (TCAs) such as amitriptyline (Elavil), imipramine (Tofranil), and protriptyline (Vivactil) as well as selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft) have not been found to be teratogens [83]. Although the FDA classifies TCAs as Category D, they are commonly prescribed, and almost two decades of experience suggests these drugs are not potent teratogens. Cases of first-trimester exposure have failed to indicate a significant association with high rates of congenital malformations [84]. The SSRI most studied is fluoxetine and in 450 exposed pregnancies, no fetal anomalies or neurobehavioral effects were demonstrated [85]. Data are sparse or lacking regarding various other antidepressant agents, and monoamine oxidase inhibitors (MAOIs) like phenelzine (Nardil) or tranylcypromide (Parnate) as well as St. John's wort are not recommended for use in pregnancy.

Mood stablizers, such as lithium (Eskalith, Lithobid, Lithonate), usually are used for the treatment of bipolar disease. Lithium appears to be linked with cardiovascular anomalies, including Ebstein's anomaly, a malattachment of tricuspid valve leaves. However, the birth defect is relatively rare, with an estimated incidence of 1 in 20,000 births in the general population. The risk of Ebstein's anomaly is approximately eight times more common among pregnant women taking lithium [86]. Polyhydramnios also has been associated with the use of lithium in pregnancy. Alternatives to lithium generally include anticonvulsant agents like carbamazepine (Tegretol), although these drugs are also problematic.

Untreated hyperthyroidism itself has been linked to spontaneous abortion. However, treatment with radioactive iodine, although useful for the nonpregnant woman, is contraindicated in pregnancy. The agent not only can destroy the maternal thyroid, but it can cross the placenta and destroy the fetal thyroid. Traditionally, propylthiouracil (PTU) has been the drug of choice for hyperthyroidism in pregnancy as methimazole (Tapazole) has been linked to aplasia cutis in the newborn. However, the neonatal association has been called into question [87]. Moreover, propylthiouracil may result in fetal hypothyroidism when the drug is used in high doses, so close monitoring is warranted. The common treatments for hypothyroidism are supplementation with thyroid and, thus, not associated with any known teratogenic effects.

For the woman with chronic hypertension, ACE inhibitors such as captopril (Capoten) and enalapril (Vasotec) should be avoided [88]. Use in second and third trimesters is associated with low birth weight, oligohydramnios, and hypoplastic fetal lung development. In studies on the long-term effect of beta-adrenergic antagonists in pregnancy, atenolol (Tenormin) has been associated with intrauterine growth restriction (IUGR). Propanolol (Inderal) has been associated with neonatal hypoglycemia, IUGR, fetal and neonatal bradycardia, although it is unknown whether the fetal effects are due to the disease process, the drug, or an interaction between the two. The alpha-adrenergic antagonists (e.g., prazosin or Minipress) are commonly used in pregnancy since they effectively can control hypertension and have not been linked with fetal growth restriction. The use of calcium channel blockers has not demonstrated harmful fetal effects. Current studies are being conducted for nifedipine (Adalat, Procardia) both as a tocolytic and as an

agent for treatment of preeclampsia and chronic hypertension in pregnancy. Nicardipine is more effective and has fewer side effects for treating hypertension in pregnancy than metoprolol (Lopressor) [89].

If a woman needs an anticoagulant during pregnancy, heparin, either regular or low molecular weight, remains the drug of choice [90]. Coumarins, including warfarin (Coumadin), easily cross the placenta and approximately one-fourth of the embryos are born with fetal warfarin syndrome (nasal hypoplasia, optic atrophy, and mental retardation). When the fetus is exposed, the results may include cataracts, microcephaly, and microphthalmia, as well as fetal and maternal hemorrhage.

Tocolytics are reserved for treatment in the late second or third trimester, avoiding the classic teratogenic period. However, magnesium sulfate, as a tocolytic or treatment for preeclampsia, may result in an infant who is lethargic and hypotonic at birth. Tachycardia, both maternal and fetal, is a common side effect of beta-adrenergic tocolytics (e.g., terbutaline or Brethine and ritodrine or Yutopar). None of these agents have been identified as teratogenic [91].

The pregestational diabetic woman often controls her disease by the use of oral hypoglycemic agents. Oral hypoglycemics have been implicated with profound neonatal hypoglycemia since placental transfer is relatively easy. Intrauterine fetal death has also been reported. In contrast to oral hypoglycemic agents, insulin is a large molecule and has difficulty crossing the placenta. Therefore, it has been the drug of choice for management of diabetes mellitus during pregnancy [92]. Ongoing current studies are investigating glyburide (DiaBeta, Micronase), a second generation hypoglycemic. When administered during pregnancy, glyburide has neither been found in cord blood nor associated with neonatal effects. If further trials are consistent with these findings, this drug may change management of diabetes in the future [93, 94].

Fortunately, cancer is relatively rare for a reproductive-aged woman. However, when it does occur, chemotherapeutic agents generally pose great risk to the fetus [95]. Trophoblastic and embryonic tissue grows rapidly and anticancer drugs may target them as they do cancerous cells. Methotrexate, for example, interferes with folic acid metabolism. Depending upon when they are administered, chemotherapeutic agents can cause spontaneous abortions or major teratogenic manifestations. Because of its predilection for trophoblastic tissue, methotrexate is often used for the medical treatment of unruptured ectopic pregnancy.

Fetal Drug Therapy

Perhaps the opposite of the study of teratology, or the study of drugs with adverse effects, is the study of fetal drug therapy, or the use of drugs specifically for fetal therapeutics [96]. Fetal drug therapy is the administration of an agent for the purpose of treating a fetal disorder in order to improve capacity for later intrauterine or neonatal adaptation. It is based on knowledge of fetal pharmacokinetics and placental transfer. This area of study is in its infancy, yet several examples already exist, including steroidal treatment of the preterm fetus in order to mature the lungs, folic acid to reduce neural tube defects, antiviral treatment of HIV positive women to decrease mother to child transfer, and even antiarrhythmic drugs for fetal arrhythmia. More study can be anticipated in this area in the future.

Pharmaceuticals and Breastfeeding

No doubt exists that breastfeeding is the best method of feeding newborns and young infants. For many women, the need to take a medication during this time presents a dilemma [97]. Often they fear that there are untoward effects for their child, and their provider may or may not be able to address those fears. Sometimes they discontinue breastfeeding without discussing it with a provider because of fear. A midwife needs to know how drugs transfer into breast milk, reliable resources specific to breastfeeding and drug compatibility, and several key questions [98, 99]. The first question is whether the breastfeeding mother really needs to be medicated. How much of the drug is excreted in breast milk, and does it present a risk to the baby?

The difficulty in answering these questions lies in the fact that there is a meager knowledge base in the area, and data are often conflicting. Essentially all milk secretion and synthesis studies have been conducted on animals. Much of the general knowledge is extrapolated from those studies, adding anecdotal findings and plausibility based on known maternal and neonatal pharmacokinetics. For the majority of drugs, less than 1 percent of the maternal plasma level of the drug crosses into the breast milk. In addition, binding to the milk proteins or onto the surface of the milk fat globule deters neonatal exposure further, since

bound drugs do not passively diffuse out of the newborn's stomach [100].

In order for drugs to come into contact with breast milk, they must pass the mammary membrane. The mammary membrane is semipermeable, and transfer is more difficult than transfer across the placenta. However, just as placental drug transfer is dependent upon a variety of factors, so is the amount of an agent transferred through breast milk. Factors that increase the likelihood of drug transfer into breast milk include lipid solubility, low molecular weight, long half-life, and the capacity to remain unbound and nonionized in the maternal plasma.

Timing also influences drug transfer into breast milk. The excretion of drugs into breast milk primarily involves passive diffusion. However, in addition to diffusion, drugs may pass by secretory methods though the capillary walls into the alveolar cell lining of the milk buds and through both walls to the alveolar cells to penetrate milk. During the first one to two weeks postpartum, large gaps exist between alveolar cells, facilitating easy transfer of various agents including immunoglobulins. As milk production is established and the alveolar cells expand, the intracellular gaps tend to close, making drug transfer more difficult [101]. Also, since the majority of milk is produced at the time of feeding and blood flow to the breast is maximized at this time, women should be educated about time for peak plasma levels of the drug and counseled to avoid breastfeeding during these times.

One of the most popular approaches used in clinical practice to evaluate drug concentration in breast milk is the milk plasma ratio (MPR). This ratio varies over time as both drug amount and type of milk varies over time, so most drug kinetics are based on a time-averaged ratio or range [102]. The MPR has been calculated for many agents. The majority of drugs have an MPR of 1 or less, indicating that the level of drug in the breast milk is the same or less as in maternal plasma. For example, an MPR of 0.10 indicates that the breast milk contains 10 percent of the amount of the drug in maternal plasma. Although the MPR can be helpful, it is not clinically relevant unless other factors are considered. For example, a drug with a high MPR, may not indicate a problem if the drug poses no harm to the infant. Conversely, a low MPR may be problematic if drug clearance is slow in the neonate or the half-life of the drug is unusually long, exposing the baby to the pharmaceutical over a longer period of time.

In 2001, the American Academy of Pediatrics Committee on Drugs published an evidence-based listing of drug information for breastfeeding that included approximately 400 primary research references [103]. This group currently uses a list of seven categories for licit and illicit drugs. Six of the categories include those licit and illicit drugs that are contraindicated, requiring temporary cessation, of possible concern, to be used with caution, and compatible. The additional category includes food and environmental agents. (See the AAP tables in Appendix C at the end of this chapter.)

The Breastfeeding and Human Lactation Study Center at the University of Rochester is a repository of breastfeeding information. Midwives with specific questions can contact the center during the week at (716) 275-0088.

Midwives should note that most of the drugs felt to be harmful to the breastfeeding couplet are uncommon ones. Fortunately, many other common drugs are compatible with breastfeeding. Although more research is needed regarding many agents, drug transfer is rarely a reason to discontinue breastfeeding, and the midwife should be encouraged to seek out the most current and reliable information when counseling a woman about safety. The following section describes agents or groups of drugs that midwives may find themselves considering for management of conditions that a breastfeeding woman may experience. Agents that should be avoided because of risk are indicated as such. Some common agents that are preferred for the breastfeeding woman also are included in the discussion.

Selected Drugs and the Breastfeeding Woman

Antimicrobials

Penicillins (e.g., ampicillin or Omnipen and amoxicillin or Amoxil) and related cephalosporins (e.g., cefaclor or Ceclor, cefixime or Suprax, ceftriaxone or Rocephine) are considered compatible for the breastfeeding dyad [104]. Concern about sensitivity is more theoretical than actual. Sulfa drugs such as the combination of sulfamethoxazole with trimethoprim (Bactrim, Septa) should be avoided during the first month of life because of the issue of competing for albumin-binding sites with bilirubin. When the liver is mature enough that the infant

could have pediatric use of sulfa, there is no need to restrict it from the breastfeeding woman.

Midwives may remember that women should not take tetracyclines such as tetracycline (Acromycin), doxycycline (Vibramycin), or minocycline (Minocin) with dairy products as it inhibits the therapeutic effect. In a like manner, tetracyclines tend to bind with breast milk, causing only a small amount to be transferred to the infant. Studies of dosing regimens lasting 10 days or less have failed to demonstrate any adverse neonatal effects. However, since long-term use may have bone or dental impact, alternative antimicrobials are generally advised. Quinolones are usually discouraged for a woman who is breastfeeding due to the theoretical risk of arthropathies, although the AAP states that is compatible with the lactating mother. Quinolones include ofloxacine (Floxin), levofloxacin (Levaquin), and ciprofloxacin (Cipro, Baycip, Ciflox, Ciplox).

Erythromycin (e.g., e-base or Eryc, azithromycin or Zithromax, clarithromycin or Biaxin) is one of the agents that is more highly concentrated in breast milk than in maternal plasma—i.e., it has an MPR > 1.0. Many clinicians defer prescribing it until the baby is mature enough to take the drug directly, although the AAP lists it as compatible with breastfeeding. The most commonly discussed problem with this macrolide is drug-to-drug interactions with other agents, like some nonsedating antihistamines. Therefore, as usual, the midwife should consult with the woman about all her current use of drugs and herbs.

The use of metronidazole (Flagyl) by a breastfeeding woman is controversial [105]. Some authorities, including the American Academy of Pediatrics, have recommended that when a 2-gram dose is used, it is followed by manual expression/pumping for 24 hours, during which the breast milk would be discarded. However, metronidazole is a drug in pediatric use and it has an MPR close to 1.0 with a 400 mg dose given three times a day. It is the side effects that make most scientists advise temporary cessation of breastfeeding. These adverse effects have included neonatal vomiting and potential blood dyscrasias. If the woman needs the medication for treatment of bacterial vaginosis, metronidazole in vaginal gel form (MetroGel) should pose no need to cease breastfeeding as the level in breast milk is undetectable.

Aminoglycosides like kanamycin (Kantrex) are agents that are given directly to newborns. These drugs are compatible with breastfeeding.

Sex Hormones

The puerperium is a critical period for most women. Postpartum women must decide if they want more children and, if so, when. Therefore, contraception is a major area of discussion. Breastfeeding women may use the lactational amenorrhea method (LAM) with excellent results if they are exclusively breastfeeding. Modern culture is not supportive of breastfeeding and many women find themselves at work in an unsupportive environment. For them, exclusivity of breastfeeding may not be feasible. The most popular temporary method of contraception in the United States is combination oral contraceptives (COCs). These agents have been found to have a moderate inhibitory effect on breast milk, especially the older agents with 50 micrograms or more of estrogen [106]. Some of the hormones may be transferred to the newborn, and no long-term effects have been found, although women who use COCs breastfeed their infants for a shorter period of time than women who use other contraceptive methods. Therefore, most sources recommend progesterone only methods, such as progestin only pills (POPs) or medroxyprogesterone acetate in oil (DepoProvera). Progestin methods do not inhibit milk volume, and according to some research, may even increase the volume. Nonsteroidal methods such as barriers and copper intrauterine devices are compatible with breastfeeding. Data are lacking on newer methods such as vaginal rings, transdermal patches, and estrogen/progesterone injections. However, each is composed of estrogen and progesterone and should be viewed as comparable to COCs.

Analgesics

Codeine and meperidine (Demerol) appear in low levels in breast milk and generally do not warrant cessation of either the drug or breastfeeding for the couplet. Nonsteroidal anti-inflammatory drugs are considered reasonable choices while breastfeeding because negligible amounts have been found in breast milk. However, when large amounts of opiates are administered during labor, the baby may be sleepy and hypotonic at birth, causing some difficulty in initiating breastfeeding. Slower initiation of breastfeeding has been reported for primigravidas when meperidine was administered 1 hour to 4 hours prior to birth [107]. Similar concerns about neonatal disorganization after intrapartum epidurals have been proposed, although no clear data exist to address these concerns.

Gastrointestinal Drugs and Antihistamines

Cimetidine (Tagamet) is an antisecretory antihistamine in popular use for maternal pyrosis, or heartburn. However, it has antiandrogenic effects and possesses an MPR higher than 1, whereas antacids can also be used for heartburn and are compatible with breastfeeding. Many sources suggest that any antihistamine, whether indicated for respiratory or gastrointestinal reasons, should be used with caution, or avoided, during breastfeeding because of concerns regarding anticholinergic side effects and possible diminished milk supply rather than any direct effects on the newborn.

Miscellaneous

Recent studies indicate that heparin, low molecular weight heparin, and warfarin are compatible with breastfeeding. For the woman with hyperthyroidism, propylthiouracil (PTU) is the drug of choice and methimazole (Tapazole) should be avoided.

Lifestyle Drugs

As previously noted, smoking can have major negative effects on the newborn such as an increased risk of sudden infant death syndrome (SIDS). Nicotine use previously was cited as a contraindication to breastfeeding. However, today smoking is viewed as a risk-benefit issue, since there is a greater appreciation of the benefits of breastfeeding for babies of smokers. Breastfeeding has been demonstrated to ameliorate the risk of SIDS as well as to decrease the incidence of respiratory infections in children of smoking mothers compared to bottle fed babies of smoking mothers [108]. Beer and wine are often part of breastfeeding management in European countries. Although not contraindicated during lactation, alcohol changes the odor and taste of the breast milk and infants tend to consume less milk as the concentration of alcohol in milk increases [109].

Caffeine accumulates in the infant. Moderate use, such as one to two daily cups of coffee, rarely is problematic. However, caffeine tends to be ubiquitous in modern food. A woman who drinks coffee, soft drinks containing caffeine, and even caffeine-enhanced bottled water may intake large amounts. Her breastfed baby may be wide awake and hyperactive. Smoking may enhance this effect. Discontinuation or at least a major decrease of caffeine will remedy the situation.

In summary, every effort should be made to support breastfeeding. Obviously drugs should not be casually prescribed or recommended. When a drug is needed, the midwife should choose one for which data exist and one that poses the least possibility of an adverse neonatal reaction. Moreover, midwives should initiate a discussion of drugs and breastfeeding with all lactating women, including the reassurance that it would be rare to discontinue breastfeeding, but that a woman should make certain that all her providers and her infant's providers know that she is lactating. Such a proactive discussion also should decrease the chance that the woman herself might wean the baby of her own volition. Table 10-7 provides a summary of guidelines for breastfeeding and the use of medications.

Galactagogues

The most common reason for premature weaning is the assumption by the mother that she has inadequate breast milk [110]. Although this assumption may not be accurate, there are times in which a woman's milk supply may be low. Nonpharmaceutical interventions such as hydration and frequent nursing may remedy the situation. However, there are some agents, both prescription and herbal, that are called *galactagogues* and may be of therapeutic help. For example, metoclopramide

TABLE 10-7 Guidelines for Breastfeeding and Medication Use

- Reserve the use of pharmaceuticals for situations where they are necessary.
- Delay the use of pharmaceuticals as long as possible since maturation of the infant includes ability to better metabolize agents.
- Use the lowest dose for the shortest time that is therapeutic.
- Whenever possible, choose an agent that
  - Is used in pediatrics
  - Has a short half-life
  - Has a milk plasma ratio of 1 or less
  - Is not sustained release
- Manipulate timing so that the lowest amount is in the milk—usually immediately after a feeding or before the baby has a long sleep period.
- Observe the baby for any changes, including behavior or physical signs like a rash.
- Teach a woman about manual expression or use of a breast pump if the only drug available is contraindicated for the baby.
- Encourage the woman to continue to breastfeed and not see use of medications as a reason she must wean her baby.

Source: Adapted from Riordan, J., and Auerbach, K. *Breastfeeding and Human Lactation*, 2nd ed. Sudbury, MA: Jones and Bartlett, 1999.

(Reglan) is a dopamine antagonist used for gastrointestinal indications. A side effect of the drug is galactorrhea and it is used off label to help women increase their milk supply. Metoclopramide tends to have a number of side effects, including fatigue, mental exhaustion, and even extrapyramidal effects, so generally it is used for a limited duration. Herbal galactagogues are common. For example, fenugreek (*Trigonella foenum-graecum L.*) has been used for years and is well accepted in many countries, yet data demonstrating its efficacy remain elusive. Studies are ongoing in several areas of the world regarding efficacy of various galactagogues and other herbal remedies.

Conclusion

Pharmaceutical agents are part of modern life. Today's midwife should be knowledgeable about them. Like any other intervention in the midwife's repertoire, drugs and herbs should be used appropriately and monitored for therapeutic as well as adverse effects. Pharmacology is an essential area in women's health care, and it is one that continues to grow and challenge providers and women alike.

Top 200 Drugs by Rank, by Generic Name, and by Brand Name

TABLE 10A-1 Top 200 Drugs, 2001: By Rank

Rank	Generic Name	Brand Name	Manufacturer
1	Hydrocodone w/APAP	Hydrocodone w/APAP	Various
2	Atorvastatin	Lipitor	Parke-Davis
3	Conjugated Estrogens	Premarin	Wyeth-Ayerst
4	Atenolol	Atenolol	Various
5	Levothyroxine	Synthroid	Knoll
6	Azithromycin	Zithromax	Pfizer
7	Furosemide	Furosemide	Various
8	Amoxicillin	Amoxicillin	Various
9	Amlodipine	Norvasc	Pfizer
10	Alprazolam	Alprazolam	Various
11	Albuterol	Albuterol Aerosol	Various
12	Loratadine	Claritin	Schering
13	Hydrochlorothiazide	Hydrochlorothiazide	Various
14	Omeprazole	Prilosec	AstraZeneca
15	Sertraline	Zoloft	Pfizer
16	Paroxetine	Paxil	SK Beecham
17	Triamterene/HCTZ	Triamterene/HCTZ	Various
18	Lansoprazole	Prevacid	Tap Pharm
19	Ibuprofen	Advil, Motrin, Nuprin	Various
20	Celecoxib	Celebrex	Searle
21	Simvastatin	Zocor	Merck

Diltiazem HCl	Diltiazem	Various	92
Diovan	Valsartan	Novartis	88
Diovan HCT	Valsartan/HCTZ	Novartis	137
Doxazosin	Doxazosin	Various	100
Doxycycline Hyclate	Doxycycline	Various	80
Effexor XR	Venlafaxine	Wyeth-Ayerst	66
Elocon	Mometasone	Schering	195
Enalapril	Enalapril	Various	72
Estradiol	Estradiol	Various	81
Evista	Raloxifene	Lilly	101
Flomax	Tamsulosin	Abbott	130
Flonase	Fluticasone	Glaxo Wellcome	61
Flovent	Fluticasone Propionate	Glaxo Wellcome	77
Fluoxetine	Fluoxetine	Various	158
Folic Acid	Folic Acid	Various	103
Fosamax	Alendronate	Merck	44
Furosemide	Furosemide	Various	7
Gemfibrozil	Gemfibrozil	Various	115
Glipizide	Glipizide	Various	141
Glucophage	Metformin	B-M Squibb	23
Glucophage XR	Metformin	B-M Squibb	163
Glucotrol XL	Glipizide	Pfizer	197
Glucovance	Glyburide/Metformin	B-M Squibb	162
Glyburide	Glyburide	Various	65
Humulin 70/30	Human Insulin 70/30	Lilly	142
Humulin N	Human Insulin NPH	Lilly	90
Hydrochlorothiazide	Hydrochlorothiazide	Various	13
Hydrocodone w/APAP	Hydrocodone w/APAP	Various	1
Hydroxyzine HCl	Hydroxyzine	Various	119
Hyzaar	Losartan/HCTZ	Merck	121
Ibuprofen	Ibuprofen	Various	19
Imitrex Oral	Sumatriptan	Glaxo Wellcome	118
Indomethacin	Indomethacin	Various	191
Isosorbide Mononitrate	Isosorbide Mononitrate S.A.	Various	64
K-Dur	Potassium Chloride	Key Pharm	75
Klor-Con	Potassium Chloride	Upsher-Smith	127
Lanoxin	Digoxin	Glaxo Wellcome	53
Lescol	Fluvastatin	Novartis	168

TABLE 10A-3 Top 200 Drugs, 2001: By Brand Name (continued)

Brand Name	Generic Name	Manufacturer	Rank
Levaquin	Levofloxacin	McNeil	67
Levothroid	Levothyroxine	Forest	116
Levoxyl	Levothyroxine	Jones Medical Ind	34
Lipitor	Atorvastatin	Parke-Davis	2
Loestrin Fe	Norethindrone/Ethinyl Estradiol	Parke-Davis	117
Lorazepam	Lorazepam	Various	37
Lotensin	Benazepril	Novartis	78
Lotrel	Amlodipine/Benazepril	Novartis	86
Macrobid	Nitrofurantoin	Procter and Gamble	159
Meclizine	Meclizine	Various	120
Medroxyprogesterone	Medroxyprogesterone	Various	68
Methylphenidate	Methylphenidate	Various	156
Methylprednisolone	Methylprednisolone	Various	87
Metoclopramide	Metoclopramide	Various	133
Metoprolol Tartrate	Metoprolol	Various	36
Metronidazole	Metronidazole	Various	138
Miacalcin	Calcitonin Salmon	Novartis	179
Minocycline	Minocycline	Various	134
Mircette	Desogestrel/Ethinyl Estradiol	Organon	165
Monopril	Fosinopril	B-M Squibb	109
Motrin	Ibuprofen	McNeil	19
Naproxen	Naproxen	Various	48
Naproxen Sodium	Naproxen Sodium	Various	194
Nasacort AQ	Triamcinolone Acetonide	Hoech Mar R	189
Nasonex	Mometasone	Schering	79
Necon	Ethinyl Estradiol/Norethindrone	Watson	143
Neurontin	Gabapentin	Parke-Davis	49
Nexium	Esomeprazole	AstraZeneca	172
Nifedipine ER	Nifedipine	Various	187
Nitroglycerin	Nitroglycerin	Various	199
Nortriptyline	Nortriptyline	Various	174
Norvasc	Amlodipine	Pfizer	9
Nuprin	Ibuprofen	B-M Squibb	19
Nystatin	Nystatin	Various	146
Ortho Tri-Cyclen	Norgestimate/Ethinyl Estradiol	Ortho Pharm	30
Ortho-Cyclen	Norgestimate/Ethinyl Estradiol	Ortho Pharm	150
Ortho-Novum	Norethindrone/Ethinyl Estradiol	Ortho Pharm	102
Oxycodone/APAP	Oxycodone/APAP	Various	110
Oxycontin	Oxycodone	Purdue	105
Paxil	Paroxetine	SK Beecham	16
Penicillin VK	Penicillin VK	Various	104
Phenazopyridine	Phenazopyridine	Various	200
Phenergan	Promethazine	R.P.R.	190
Phenobarbital	Phenobarbital	Various	193
Plavix	Clopidogrel	Sanofi	84
Plendil	Felodipine	AstraZeneca	180
Potassium Chloride	Potassium Chloride	Various	71
Pravachol	Pravastatin	B-M Squibb	47
Prednisone	Prednisone	Various	29
Premarin	Conjugated Estrogens	Wyeth-Ayerst	3
Prempro	Conjugated Estrogens/Medroxyprogesterone	Wyeth-Ayerst	28

TABLE 10A-3 Top 200 Drugs, 2001: By Brand Name (continued)

Brand Name	Generic Name	Manufacturer	Rank
Prevacid	Lansoprazole	Tap Pharm	18
Prilosec	Omeprazole	AstraZeneca	14
Prinivil	Lisinopril	Merck	56
Promethazine	Promethazine	Various	112
Promethazine/Codeine	Promethazine/Codeine	Various	148
Propoxyphene N/APAP	Propoxyphene N/APAP	Various	27
Propranolol	Propranolol	Various	85
Protonix	Pantoprazole	Wyeth	126
Prozac	Fluoxetine	Lilly	39
Ranitidine HCl	Ranitidine	Various	40
Remeron	Mirtazapine	Organon	154
Risperdal	Risperidone	Janssen	97
Roxicet	Oxycodone/APAP	Roxane	151
Serevent	Salmeterol	Glaxo Wellcome	108
Serzone	Nefazodone	B-M Squibb	153
Singulair	Montelukast	Schein	62
Skelaxin	Metaxalone	Elan	173
Spironolactone	Spironolactone	Various	128
Synthroid	Levothyroxine	Knoll	5
Tamoxifen	Tamoxifen	Various	178
Temazepam	Temazepam	Various	106
Tequin	Gatifloxacin	B-M Squibb	186
Terazosin	Terazosin	Various	113
Tetracycline	Tetracycline	Various	184
Theophylline	Theophylline	Various	183
Tiazac	Diltiazem	Forest	164
Toprol-XL	Metoprolol	AstraZeneca	38
Trazodone	Trazodone	Various	60
Triamcinolone Acetonide	Triamcinolone	Various	140
Triamterene/HCTZ	Triamterene/HCTZ	Various	17
Tricor	Fenofibrate	Abbott	176
Trimox	Amoxicillin	Apothecon	35
Triphasil	L-Norgestrel/Ethinyl Estradiol	Wyeth-Ayerst	167
Trivora-28	Levonorgestrel/Ethinyl Estradiol	Watson	181
Ultram	Tramadol	McNeil	58
Valtrex	Valacyclovir	Glaxo Wellcome	155
Veetids	Penicillin VK	Apothecon	131
Verapamil HCl	Verapamil	Various	52
Viagra	Sildenafil Citrate	Pfizer	46
Vicoprofen	Hydrocodone/Ibuprofen	Knoll	196
Vioxx	Rofecoxib	Merck	24
Warfarin	Warfarin	Various	73
Wellbutrin SR	Bupropion HCL	Glaxo Wellcome	55
Xalatan	Latanoprost	Pharmacia/Upjohn	94
Zestoretic	Lisinopril/HCTZ	Zeneca	132
Zestril	Lisinopril	Zeneca	25
Zithromax	Azithromycin	Pfizer	6
Zocor	Simvastatin	Merck	21
Zoloft	Sertraline	Pfizer	15
Zyprexa	Olanzapine	Lilly	114
Zyrtec	Cetirizine	Pfizer	32

Appendix B

Teratology Information Systems by Location

ALABAMA

Alabama Birth Defects Surveillance
University South Alabama
(800) 423-8324 or (334) 460-7691
Department Medical Genetics
307 University Blvd., Rm. 214, CC/CB
Mobile, AL 36688-0002
Geographic Area Served: AL, MS, FL
Hours: 8:00 AM to 5:00 PM, M-F

ARIZONA

Arizona Teratogen Information Program
(888) 285-3410 or (520) 626-3410 (in Tucson)
University of Arizona
PO Box 245079
Tucson, AZ 85724-5079
Geographic Area Served: AZ/National
Hours: 8:00 AM to 5:00 PM, M-F

ARKANSAS

Arkansas Teratogen Information Service
(800) 358-7229 or (501) 296-1700
University of Arkansas for Medical Sciences
Department of Obstetrics and Gynecology
Arkansas Genetics Program
4301 West Markham - Slot 506
Little Rock, AR 72205
Geographic Area Served: AR
Hours: 8:00 AM to 4:30 PM, M-F

CALIFORNIA

California Teratogen Information Service and Clinical Research Program
(800) 532-3749 (CA Only) or (619) 543-2131
UCSD Medical Center, Department of Pediatrics
200 W. Arbor Drive #8446
San Diego, CA 92103-8446
Geographic Area Served: CA
Hours: 9:00 AM to 4:00 PM, M-F

CANADA

IMAGE: Info-Medicaments en Allaitement et Grossesse
(514) 345-2333
Pharmacy Dept. Ste. Justine Hospital
Montreal (Quebec) H3T1C5 Cn.
Geographic Area Served: Province of Quebec
Hours: 9:00 AM to 12:00 PM, 1:00 PM to 4:00 PM, M-F

Motherisk Program
(416) 813-6780
Hospital for Sick Children
555 University Ave.
Toronto, Ont. CN M5G 1X8
Geographic Area Served: Ontario (although calls accepted from across Canada)
Hours: 9:00 to 5:00 PM, M-F EST

CONNECTICUT

Connecticut Pregnancy Exposure Information Service
(800) 325-5391 (CT only) or (860) 679-8850
University of Connecticut Health Center
Division of Human Genetics MC6310
263 Farmington Ave.
Farmington, CT 06030-6310
Geographic Area Served: CT
Hours: 8:00 AM to 4 PM, M-Th,
8:00 AM to 12:00 PM, F

DISTRICT OF COLUMBIA (MARYLAND)

Reproductive Toxicology Center, a Non-Profit Foundation
(301) 620-8690 or (301) 657-5984
7831 Woodmont Ave., #375
Bethesda, MD 20814
Geographic Area Served: Unrestricted

FLORIDA

Florida Teratogen Information Service
(800) 392-3050 (FL only) or (352) 392-3050
University of Florida Health Science Center
Box 100296
Gainesville, FL 32610-0296
Geographic Area Served: Priority to FL calls; open to all callers
Hours: 8:00 AM to 5:00 PM, M-F

Florida Teratogen Information Service
(305) 243-6006
University of Miami
P.O. Box 016820
Miami, FL 33101
Geographic Area Served: South Florida
Hours: 9:00 AM to 4:30 PM, M-F

Teratogen Information Service
(813) 259-8852
University of South Florida Birth Defects Center
Department of Pediatrics
17 Davis Blvd.
Tampa, FL 33606
Geographic Area Served: Central Florida
Hours: 7:30 AM to 4:30 PM, M-F

ILLINOIS

Illinois Teratogen Information Service
(800) 252-4847 (IL only) or (312) 981-4354
680 N. Lake Shore Dr., Suite 1230
Chicago, IL 60611
Geographic Area Served: IL
Hours: 8:00 AM to 5:00 PM, M-F

INDIANA/KENTUCKY/OHIO

Indiana Teratogen Information Service
(317) 274-1071
Indiana University Medical Center
Department of Medical and Molecular Genetics 1B130
975 W. Walnut St.
Indianapolis, IN 46202-5251
Geographic Area Served: Priority to IN callers; Also serves IL, KY, OH
Hours: 8:00 AM to 5:00 PM, M-F

MASSACHUSETTS/MAINE/NEW HAMPSHIRE/ RHODE ISLAND

Massachusetts Teratogen Information Service (MaTIS)
(800) 322-5014 (MA only) or (781) 466-8474
Pregnancy Environmental Hotline
40 Second Ave., Suite 520
Waltham, MA 02451
Geographic Area Served: MA, NH, ME, RI
Hours: 9:00 AM to 2:00 PM, M-F

Genetics and Teratology Unit, Pediatric Service
(617) 726-1742
Massachusetts General Hospital
Warren Building 801
55 Fruit St.
Boston, MA 02114-2696
Geographic Area Served: Eastern Massachusetts
Hours 9:00 AM to 5:00 PM, M-F

MICHIGAN

Michigan Teratogen Information Service
(877) 52-MITIS (64847) or (313) 966-9368
4160 John R. St., Suite 616
Detroit, MI 48201
Geographic Area Served: MI and surrounding states
Hours 9:00 AM to 4:00 PM, M-F

MISSOURI

Missouri Teratogen Information Service
(800) 645-6164 or (573) 884-1345
University of Missouri Hospital and Clinics
1 Hospital Dr., DC058.00
Columbia, MO 65212
Geographic Area Served: MO
Hours: 9:00 AM to 4:00 PM, M-F

NEBRASKA

Nebraska Teratogen Project
(402) 559-5071
University of Nebraska Medical Center
985440 Nebraska Medical Center
Omaha, NE 68198-5440
Geographic Area Served: NE
Hours: 8:00 AM to 4:30 PM, M-F

NEW JERSEY/DELAWARE/PENNSYLVANIA

Pregnancy Healthline
(888) 722-2903 (NJ) or (856) 665-6000
Southern New Jersey Perinatal Cooperative
2500 McClellan Ave., Suite 110
Pennsauken, NJ 08109-4613
Geographic Area Served: NJ, DE, PA
Hours: 10:00 AM to 3:00 PM, M-F

NEW YORK

Pregnancy Risk Network
(800) 724-2454 (then press 1) (NY only)
or (716) 882-6791 (then press 1)
976 Delaware Ave.
Buffalo, NY 14209
Geographic Area Served: NY
Hours: 8:30 AM to 4:00 PM, M-F

PEDECS
(716) 275-3638
University of Rochester Medical Center
Department of Obstetrics and Gynecology
601 Elmwood Ave.
Rochester, NY 14642-8668
Geographic Area Served: NY
Hours: 8:30 AM to 4:00 PM, M-F

NORTH DAKOTA

North Dakota Teratogen Information Service
(701) 777-4277; Fax: (701) 777-3220
e-mail: ebertwsi@medicine.nodak.edu
UND School of Medicine and Health Science
Department of Pediatrics, Division of Medical Genetics
P.O. Box 9037
Grand Forks, ND 58202-9037
Geographic Area Served: ND
Hours: 8:30 AM to 4:30 PM, M-F

TEXAS

Texas Teratogen Information Service
(800) 733-4727 or (940) 565-3892
UNT Department of Biology
P.O. Box 305220
Denton, TX 76203-5220
Geographic Area Served: TX
Hours: 9:00 AM to 4:00 PM, M-F

MONTANA

Pregnancy RiskLine
(801) 328-2229 or (800) 822-2229
Utah Department of Health
P.O. Box 144691
Salt Lake City, UT 84114-4691
Geographic Area Served: UT, MT
Health Care Professionals served only from ID, NM, WY
Hours: 8:30 AM to 4:30 PM, M-F

VERMONT

Pregnancy Risk Information Service
800-531-9800 (VT only) or 800-932-4609
Vermont Regional Genetics Center
1 Mill St., Box B-10
Burlington, VT 05401
Geographic Area Served: VT and Upstate NY
Hours: 1:00 PM to 5:00 PM, Tu and F

WASHINGTON/ALASKA/IDAHO

CARE Northwest
(900) 225-2273 ($8/call)
University of Washington
Box 357920
Seattle, WA 98195-7920
Geographic Area Served: AK, ID, OR, WA
Hours: 8:00 AM to 4:00 PM, M-F

WEST VIRGINIA

West Virginia University Hospitals
(304) 293-1572
Physician Office Center
PO Box 782
OBGYN Clinic
Morgantown, WV 26507
Geographic Area Served: WV and surrounding area

WISCONSIN

Wisconsin Teratogen Information Service
(800) 442-6692
347 Waisman Center
1500 Highland
Madison, WI 53705
Geographic Area Served: WI
Hours: 9:00 AM to 3:00 PM

Appendix C

The Transfer of Drugs and Other Chemicals into Human Milk*

TABLE 10C-1 Cytoxic Drugs That May Interfere with Cellular Metabolism of the Nursing Infant

Drug	Reason for Concern, Reported Sign or Symptom in Infant, or Effect on Lactation
Cyclophosphamide	Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia
Cyclosporine	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Doxorubicin*	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Methotrexate	Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia

* Drug is concentrated in human milk.

TABLE 10C-2 Drugs of Abuse for Which Adverse Effects on the Infant During Breastfeeding Have Been Reported*

Drug	Reported Effect or Reasons for Concern
Amphetamine†	Irritability, poor sleeping pattern
Cocaine	Cocaine intoxication: irritability, vomiting, diarrhea, tremulousness, seizures
Heroin	Tremors, restlessness, vomiting, poor feeding
Marijuana	Only 1 report in literature; no effect mentioned; very long half-life for some components
Phencyclidine	Potent hallucinogen

* The Committee on Drugs strongly believes that nursing mothers should not ingest drugs of abuse, because they are hazardous to the nursing infant and to the health of the mother.

† Drug is concentrated in human milk.

TABLE 10C-3 Radioactive Compounds That Require Temporary Cessation of Breastfeeding*

Compound	Recommended Time for Cessation of Breastfeeding
Copper 64 (64Cu)	Radioactivity in milk present at 50 hr
Gallium 67 (67Ga)	Radioactivity in milk present for 2 wk
Indium 111 (111In)	Very small amount present at 20 hr
Iodine 123 (123I)	Radioactivity in milk present up to 36 hr
Iodine 125 (125I)	Radioactivity in milk present for 12 d
Iodine 131 (131I)	Radioactivity in milk present 2–14 d, depending on study
Iodine 131	If used for treatment of thyroid cancer, high radioactivity may prolong exposure to infant
Radioactive sodium	Radioactivity in milk present 96 hr
Technetium 99m (99mTc), 99mTc macroaggregates, 99mTc O4	Radioactivity in milk present 15 hr to 3 d

* Consult nuclear medicine physician before performing diagnostic study so that radionuclide that has the shortest excretion time in breast milk can be used. Before study, the mother should pump her breast and store enough milk in the freezer for feeding the infant; after study, the mother should pump her breast to maintain milk production but discard all milk pumped for the required time that radioactivity is present in milk. Milk samples can be screened by radiology departments for radioactivity before resumption of nursing.

Source: The 7 tables in this appendix are from the American Academy of Pediatrics, Committee on Drugs. The transfer of drugs and other chemicals into human breast milk. *Pediatrics*. 2001; 108:776–789 or go to: http://www.aap.org/policy/0063.html.

TABLE 10C-4 Drugs for Which the Effect on Nursing Infants Is Unknown but May Be of Concern*

Drug	Reported or Possible Effect
Antianxiety	
Alprazolam	None
Diazepam	None
Lorazepam	None
Midazolam	-
Perphenazine	None
Prazepam†	None
Quazepam	None
Temazepam	-
Antidepressants	
Amitriptyline	None
Amoxapine	None
Bupropion	None
Clomipramine	None
Desipramine	None
Dothiepin	None
Doxepin	None
Fluoxetine	Colic, irritability, feeding and sleep disorders, slow weight gain
Fluvoxamine	-
Imipramine	None
Nortriptyline	None
Paroxetine	None
Sertraline†	None
Trazodone	None
Antipsychotic	
Chlorpromazine	Galactorrhea in mother; drowsiness and lethargy in infant; decline in developmental scores
Chlorprothixene	None
Clozapine†	None
Haloperidol	Decline in developmental scores
Mesoridazine	None
Trifluoperazine	None
Others	
Amiodarone	Possible hypothyroidism
Chloramphenicol	Possible idiosyncratic bone marrow suppression
Clofazimine	Potential for transfer of high percentage of maternal dose; possible increase in skin pigmentation
Lamotrigine	Potential therapeutic serum concentrations in infant
Metoclopramide†	None described; dopaminergic blocking agent
Metronidazole	In vitro mutagen; may discontinue breastfeeding for 12–24 hr to allow excretion of dose when single-dose therapy given to mother
Tinidazole	See metronidazole

* Psychotropic drugs, the compounds listed under antianxiety, antidepressant, and antipsychotic categories, are of special concern when given to nursing mothers for long periods. Although there are very few case reports of adverse effects in breastfeeding infants, these drugs do appear in human milk and, thus, could conceivably alter short-term and long-term central nervous system function.

† Drug is concentrated in human milk relative to simultaneous maternal plasma concentrations.

TABLE 10C-5 Drugs That Have Been Associated with Significant Effects on Some Nursing Infants and Should Be Given to Nursing Mothers with Caution*

Drug	Reported Effect
Acebutolol	Hypotension; bradycardia; tachypnea
5-Aminosalicylic acid	Diarrhea (1 case)
Atenolol	Cyanosis; bradycardia
Bromocriptine	Suppresses lactation; may be hazardous to the mother
Aspirin (salicylates)	Metabolic acidosis (1 case)
Clemastine	Drowsiness, irritability, refusal to feed, high-pitched cry, neck stiffness (1 case)
Ergotamine	Vomiting, diarrhea, convulsions (doses used in migraine medications)
Lithium	One-third to one-half therapeutic blood concentration in infants
Phenindione	Anticoagulant: increased prothrombin and partial thromboplastin time in 1 infant; not used in United States
Phenobarbital	Sedation; infantile spasms after weaning from milk containing phenobarbital, methemoglobinemia (1 case)
Primidone	Sedation, feeding problems
Sulfasalazine (salicylazosulfapyridine)	Bloody diarrhea (1 case)

* Blood concentration in the infant may be of clinical importance.

TABLE 10C-6 Maternal Medication Usually Compatible with Breastfeeding*

Drug	Reported Sign or Symptom in Infant or Effect on Lactation
Acetaminophen	None
Acetazolamide	None
Acitretin	—
Acyclovir†	None
Alcohol (ethanol)	With large amounts, drowsiness, diaphoresis, deep sleep, weakness, decrease in linear growth, abnormal weight gain; maternal ingestion of 1 g/kg daily decreases milk ejection reflex
Allopurinol	—
Amoxicillin	None
Antimony	—
Atropine	None
Azapropazone (apazone)	—
Aztreonam	None
B_1 (thiamin)	None
B_6 (pyridoxine)	None
B_{12}	None
Baclofen	None
Barbiturate	See Table 10C-5
Bendroflumethiazide	Suppresses lactation
Bishydroxycoumarin (dicumarol)	None
Bromide	Rash, weakness, absence of cry with maternal intake of 5.4 g/d
Butorphanol	None
Caffeine	Irritability, poor sleeping pattern, excreted slowly; no effect with moderate intake of caffeinated beverages (2–3 cups per day)
Captopril	None
Carbamazepine	None
Carbetocin	None
Carbimazole	Goiter
Cascara	None
Cefadroxil	None
Cefazolin	None
Cefotaxime	None

TABLE 10C-6 Maternal Medication Usually Compatible with Breastfeeding* (continued)

Drug	Reported Sign or Symptom in Infant or Effect on Lactation
Cefoxitin	None
Cefprozil	—
Ceftazidime	None
Ceftriaxone	None
Chloral hydrate	Sleepiness
Chloroform	None
Chloroquine	None
Chlorothiazide	None
Chlorthalidone	Excreted slowly
Cimetidine†	None
Ciprofloxacin	None
Cisapride	None
Cisplatin	Not found in milk
Clindamycin	None
Clogestone	None
Codeine	None
Colchicine	—
Contraceptive pill with estrogen/progesterone	Rare breast enlargement; decrease in milk production and protein content (not confirmed in several studies)
Cycloserine	None
D (vitamin)	None; follow up infant's serum calcium level if mother receives pharmacologic doses
Danthron	Increased bowel activity
Dapsone	None; sulfonamide detected in infant's urine
Dexbrompheniramine maleate with d-isoephedrine	Crying, poor sleeping patterns, irritability
Diatrizoate	None
Digoxin	None
Diltiazem	None
Dipyrone	None
Disopyramide	None
Domperidone	None
Dyphylline†	None
Enalapril	—
Erythromycin†	None
Estradiol	Withdrawal, vaginal bleeding
Ethambutol	None
Ethanol (cf. alcohol)	—
Ethosuximide	None, drug appears in infant serum
Fentanyl	—
Fexofenadine	None
Flecainide	—
Fleroxacin	One 400-mg dose given to nursing mothers; infants not given breast milk for 48 hr
Fluconazole	None
Flufenamic acid	None
Fluorescein	—
Folic acid	None
Gadopentetic (Gadolinium)	None
Gentamicin	None
Gold salts	None
Halothane	None
Hydralazine	None
Hydrochlorothiazide	—
Hydroxychloroquine†	None

TABLE 10C-6 Maternal Medication Usually Compatible with Breastfeeding* (continued)

Drug	Reported Sign or Symptom in Infant or Effect on Lactation
Ibuprofen	None
Indomethacin	Seizure (1 case)
Interferon-α	–
Iodides	May affect thyroid activity; see iodine
Iodine	Goiter
Iodine (povidone-iodine—for example, in a vaginal douche)	Elevated iodine levels in breast milk, odor of iodine on infant's skin
Iohexol	None
Iopanoic acid	None
Isoniazid	None; acetyl (hepatotoxic) metabolite secreted but no hepatotoxicity reported in infants
Ivermectin	None
K1 (vitamin)	None
Kanamycin	None
Ketoconazole	None
Ketorolac	–
Labetalol	None
Levonorgestrel	–
Levothyroxine	None
Lidocaine	None
Loperamide	–
Loratadine	None
Magnesium sulfate	None
Medroxyprogesterone	None
Mefenamic acid	None
Meperidine	None
Methadone	None
Methimazole (active metabolite of carbimazole)	None
Methohexital	None
Methyldopa	None
Methyprylon	Drowsiness
Metoprolol†	None
Metrizamide	None
Metrizoate	None
Mexiletine	None
Minoxidil	None
Morphine	None; infant may have measurable blood concentration
Moxalactam	None
Nadolol†	None
Nalidixic acid	Hemolysis in infant with glucose-6-phosphate dehydrogenase (G6PD) deficiency
Naproxen	—
Nefopam	None
Nifedipine	—
Nitrofurantoin	Hemolysis in infant with G6PD deficiency
Norethynodrel	None
Norsteroids	None
Noscapine	None
Ofloxacin	None
Oxprenolol	None
Phenylbutazone	None
Phenytoin	Methemoglobinemia (1 case)
Piroxicam	None

TABLE 10C-6 Maternal Medication Usually Compatible with Breastfeeding* (continued)

Drug	Reported Sign or Symptom in Infant or Effect on Lactation
Prednisolone	None
Prednisone	None
Procainamide	None
Progesterone	None
Propoxyphene	None
Propranolol	None
Propylthiouracil	None
Pseudoephedrine†	None
Pyridostigmine	None
Pyrimethamine	None
Quinidine	None
Quinine	None
Riboflavin	None
Rifampin	None
Scopolamine	—
Secobarbital	None
Senna	None
Sotalol	—
Spironolactone	None
Streptomycin	None
Sulbactam	None
Sulfapyridine	Caution in infant with jaundice or G6PD deficiency and ill, stressed, or premature infant; appears in infant's milk
Sulfisoxazole	Caution in infant with jaundice or G6PD deficiency and ill, stressed, or premature infant; appears in infant's milk
Sumatriptan	None
Suprofen	None
Terbutaline	None
Terfenadine	None
Tetracycline	None; negligible absorption by infant
Theophylline	Irritability
Thiopental	None
Thiouracil	None mentioned; drug not used in United States
Ticarcillin	None
Timolol	None
Tolbutamide	Possible jaundice
Tolmetin	None
Trimethoprim/sulfamethoxazole	None
Triprolidine	None
Valproic acid	None
Verapamil	None
Warfarin	None
Zolpidem	None

* Drugs listed have been reported in the literature as having the effects listed or no effect. The word "none" means that no observable change was seen in the nursing infant while the mother was ingesting the compound. Dashes indicate no mention of clinical effect on the infant. It is emphasized that many of the literature citations concern single case reports or small series of infants.

† Drug is concentrated in human milk.

TABLE 10C-7 Food and Environmental Agents: Effects on Breastfeeding

Agent	Reported Sign or Symptom in Infant or Effect on Lactation
Aflatoxin	None
Aspartame	Caution if mother or infant has phenylketonuria
Bromide (photographic laboratory)	Potential absorption and bromide transfer into milk; see Table 10C-6
Cadmium	None reported
Chlordane	None reported
Chocolate (theobromine)	Irritability or increased bowel activity if excess amounts (>16 oz/d) consumed by mother
DDT, benzene hexachlorides, dieldrin, aldrin, hepatachlorepoxide	None
Fava beans	Hemolysis in patient with G6PD deficiency
Fluorides	None
Hexachlorobenzene	Skin rash, diarrhea, vomiting, dark urine, neurotoxicity, death
Hexachlorophene	None; possible contamination of milk from nipple washing
Lead	Possible neurotoxicity
Mercury, methylmercury	May affect neurodevelopment
Methylmethacrylate	None
Monosodium glutamate	None
Polychlorinated biphenyls and polybrominated biphenyls	Lack of endurance, hypotonia, sullen, expressionless facies
Silicone	Esophageal dysmotility
Tetrachloroethylene cleaning fluid (perchloroethylene)	Obstructive jaundice, dark urine
Vegetarian diet	Signs of vitamin B_{12} deficiency

CHAPTER

11

Health Issues of Lesbian and Bisexual Women

LAURA ZEIDENSTEIN, CNM, MSN

Background

Lesbianism has a much broader meaning than the narrow dictionary definition of a woman who is sexually attracted to other women. The concept comprises an identity based on a woman's choices as well as on a sexual orientation, psychological responses, cultural values, and societal expectations. Psychosocial and biomedical aspects of health care are influenced by a woman's sexual activity with women; thus midwives need to understand how lesbians are unique with respect to sexually transmitted diseases (STDs), HIV, cancer risk and screening, childbearing and family formation. It is important to every woman's well-being that health care providers use language free of heterosexual assumptions.

Most lesbians defy stereotypes; any female client can be lesbian or bisexual. Lesbian identity and sexual practices cross all divisions of socioeconomic, racial, ethnic, regional, religious, geographic, and age groups. Surveys estimate that 2 to 10 percent of the population are women sexually active with women. Lesbian sexual practices range from celibacy to sexual activity that may include both men and women. According to research studies, the majority of lesbians have at some point participated in heterosexual coitus [1–9].

Although lesbians have always existed as a marginal group in society, they have become increasingly visible in the mainstream since the 1990s. This visibility is a result of both the women's movement of the 1970s and 1980s and the media coverage of the HIV/AIDS epidemic with its devastating effect on the gay male population. Language changed in public media: the *New York Times* first printed the words *gay* and *lesbian* instead of *homosexual* after years of active lobbying from various gay and lesbian groups. The mainstreaming of language began to legitimize lesbian and gay issues as worthy of the civil and human rights that were granted to the heterosexual population.

This more open social climate had a positive effect on lesbian childbearing as more lesbians incorporated children into their families. Popular culture began to openly portray a particular view of lesbian "culture" in fashion, TV sitcoms, and advertisements. Movies that included empathetic portrayals of lesbians and the realities of discrimination have won national awards.

As public visibility increases, however, homophobia, expressed in various forms including extreme violence, continues to occur. Hate crimes against lesbians are also on the rise. Antigay hate crimes accounted for 11.6 percent of the statistics collected by the FBI in 1996, making this the third largest category following racial hate crimes and crimes based on religions. Most lesbians have experienced public verbal attacks because they were lesbian [8].

Lesbians are often afraid to disclose their sexual orientation/practices to their health care provider for fear of negative treatment. In general, lesbians do not feel safe in the clinical setting and thus are more likely to delay health care that includes preventive screening. Understanding a

client's culture is essential to developing appropriate assessments and interventions. Thus, midwives need to expand their competency in cultural issues by gaining knowledge and respect for the complexity of lesbian health care.

The reasons lesbians may not seek or receive routine health care include fear of discrimination from health care providers; a feeling of detachment and invasion when questioned about sexual history, birth control, and marital status in a homophobic manner; a societal misperception that lesbians do not need the same tests and procedures as heterosexual women; and the lack of lesbian-sensitive and lesbian-knowledgeable health professionals. Access to health care is often blocked or delayed for financial reasons because of inequitable wages and because domestic partner benefits are seldom offered [3, 4, 10–14].

Combating Heterosexist Attitudes

Homophobia is culturally constructed. The existence of lesbians calls into question the normative societal ideology about women. This norm identifies heterosexuality as universal, superior, and natural for all women. In a study that explored the cultural roots of homophobia in order to provide a better midwifery service for lesbian clients [15], five themes underlying cultural expression of homophobia were identified:

1. Anxiety about sexual difference
2. Fear of female sexuality
3. The sexualization of lesbianism
4. The characterization of lesbianism as "sick" or "unnatural"
5. The inability to identify lesbians with any certainty

In the context of midwifery, these themes are particularly powerful. The provision of safe and respectful care that honors each individual woman and her family is a component of midwifery care; midwives are thus in a unique position to provide sensitive and effective care to lesbians and bisexual women.

The American College of Nurse-Midwives has designated hallmarks that characterize the art and science of midwifery. They include cultural competency and proficiency as well as care to vulnerable populations [16]. The quality of health care is dependent upon the relationship between the midwife and the client. Research indicates that many lesbians believe their care is compromised because of negative attitudes held by health care practitioners. Disclosure of lesbian identity is known to evoke a wide array of negative reactions from health care providers, ranging from embarrassment to overt hostility. Reported responses include fear, ostracism, refusal to treat, cool detachment, shock, pity, voyeuristic curiosity, demeaning jokes, avoidance of physical contact, insults, invasions of privacy, rough physical handling, and breaches of confidentiality [8, 14, 15, 17].

Heterosexist health care structures make lesbians feel invisible and unwelcome. The assumption that heterosexuality is the norm is apparent in health brochures and posters, intake financial forms, health intake and history forms, interviews, comments, and other forms of communication. In hospital-based facilities, preventive services for women are located almost exclusively in birth control and obstetric clinics and outreach to lesbian communities is largely nonexistent.

There is no validation for lesbians in the health care system. Repeated negative experiences often influence lesbians to delay their health care needs until they can no longer be ignored. Lesbians and women who partner with women may also delay care because of insufficient finances, lack of insurance, past negative experiences, or failure to see themselves at risk for illnesses such as sexually transmitted infections, breast cancer, and cervical cancer.

Midwives need to involve themselves in exploring the unique health care needs of lesbians by communicating an openness to care. It is both the process of communication and the content of the message that demonstrate a provider's ability to provide care to lesbians. Lesbian clients must be able to trust that their life experiences and identities are not beyond the routine of a competent midwife. All midwives should acquire basic knowledge about the health care needs of lesbians, bisexual, and transgender (male-to-female) lesbians and of available resources (see the appendix at the end of this chapter). Midwives must practice with an open attitude in order to provide good health care.

Clinical Research on Lesbian Health Issues

For the first time in U.S. history, improved data collection and analysis around lesbian, gay, bisexual, and transgender (LGBT) health issues will be a goal of the U.S. government. *Healthy People 2010* (*HP 2010*), a publication of the U.S. Department of Health and Human Services (HHS), is the government's public health plan focused on the elimination of health disparities across racial, ethnic,

regional, gender, age, and (for the first time) sexual orientation lines [11, 12]. The unique aspect that has emerged in the development of *HP 2010* is the recognition that sexual orientation also affects access to, and utilization of, health services. In the past, the federal government had focused its lesbian and gay health concerns on HIV. The Gay and Lesbian Medical Association (GLMA) and the Center for Lesbian, Gay, Bisexual and Transgender Health at Columbia University's Joseph L. Mailman School of Public Health, with the support of the Health Resources and Services Administration (HRSA), created the *White Paper: LGBT Health: Findings and Concerns*, which summarized the research and pointed to the need for data on lesbian, gay, bisexual, and transgender health needs [10].

Research is needed to identify health disparities in order to address them and eradicate them. Lesbians are difficult to recruit for clinical studies because they feel unsafe in the clinical setting. Like other socially or legally stigmatized populations, lesbians may feel that research findings will be used against them. Nonetheless, sampling a vulnerable and hidden population is necessary in order to ascertain their diverse characteristics. Current research has often failed to look for information on lesbian experiences across race, culture, socioeconomic groups, geographic area, and age.

Research, clinical services, and community advocacy are most effective when they nurture one another [2, 8, 14, 18]. When lesbians feel safe in seeking health care, the clinical setting will become more conducive to conducting clinical research to identify health care needs and necessary interventions.

Data Collection

History/Interview Skills

The initial barrier to inclusive care that the lesbian client encounters is often the heterosexist structure of the health care setting. Informational brochures about Pap smears, breast exam, and STDs usually reflect heterosexual experience. Posters on the wall depict heterosexual families and coupling. In maternity areas of hospitals, signs may read, "visiting hours for fathers only." If the environment is perceived as completely unsafe, questioning by the provider will elicit an inaccurate history. Midwives should be aware that excellent educational materials focusing on LGBT care are available from various health care centers [35].

Financial intake and health history forms often reflect heterosexist assumptions in their language. For example, intake forms often ask women whether they are married, divorced, widowed, or single. They ask about a spouse's income and health insurance coverage. Health history intake forms need to be written with open-ended language. Questions about significant others should not assume gender. Many lesbians feel uncomfortable if the intake form does not allow them to indicate a same-sex relationship. If the only option for emergency contact is for a "husband, wife, or spouse," many lesbian clients assume it is unsafe to list a lesbian partner [36].

An atmosphere of silence about lesbianism provides little evidence to clients that the midwife has the knowledge base and awareness of the diversity of lesbian life experience. The client must have a sense that the provider understands lesbian partnerships, family and friendship networks, sexual practices, cultural and community resources, health care concerns, and local laws regarding domestic partnership, marriage, and parenting/adoption [3, 4, 8, 14, 18] in order to actively participate in an effective interview. A midwife can convey understanding with both verbal and nonverbal language that conveys open-minded respect as well as a basic knowledge base.

Lesbian clients report that interviewing frequently ceases once the provider ascertains through questioning that her client is a lesbian [3, 4, 14]. Often, on a traditional health history questionnaire, the sexual history appears after the obstetrical, gynecological, and contraceptive histories. This order of questioning may promote assumptions about a client's sexuality. Questions related to sexual activity should not assume heterosexual activity. The following example of assumed heterosexuality with uncomfortable results is not uncommon:

Q: Are you using birth control?
A: No.
Q: Are you sexually active?
A: Yes.
Q: Do you need birth control today?
A: No.
Q: Are you planning a pregnancy?
A: No.

If the client is brave enough, she may add, "I am a lesbian" or "My partner is a woman." The usual response by the health care provider after this revelation is silence and awkwardness; the client is left on the defensive and distrustful.

It is imperative that information from an open-ended sexual history be known by the provider before the obstetric, gynecological, and contraceptive histories are taken. A midwife has to transcend biases and stereotypes in order to embrace the humanity of her client's experience and conduct an interview that is respectful and effective for assessing health. Table 11-1 provides examples of phrasing sociosexual questions in a way that allows a lesbian to reveal her health needs in an affirmative manner.

Gynecological Exam

The gynecological exam provides a unique opportunity to share information in a sensitive manner. Lesbian couples may accompany each other to exams, which enables family-centered education to occur. It is always important to take a history that includes the sexual practices of your lesbian client and to ascertain whether vaginal entry from heterosexual intercourse or hands or sex toys has occurred in order to know how to proceed with both the speculum and bimanual exam. Some lesbians have never practiced vaginal entry of any sort. It is also important to know whether there has been a history of sexual abuse. This also impacts on methods for bimanual and speculum exams. If vaginal entry is a concern for your client, teaching exercises to relax and stretch the vaginal introitus may be appropriate. In some cases a pediatric speculum may be needed. Teaching your client about her anatomy and also teaching her and/or her partner to insert the speculum may foster a sense of control over her body. The pelvic exam may even be postponed to another date if that seems to put the lesbian client at ease.

Breast care has been a neglected area in lesbian health care. Some lesbians have had negative experiences with health care providers that involved their breasts. This may be due to a false assumption that lesbians know more about breast care because their sexuality involves the breasts of another woman. Awareness of each individual's history and needs, as well as sensitivity in performing the breast exam are key. For a lesbian, a positive experience with a gynecological exam may prove truly empowering.

TABLE 11-1 Phrasing Sociosexual Questions

With whom do you live? (alone / friend / partner / husband / children / pets / other)
Who is your emergency contact?
Do you currently have a sexual partner?
Have you ever had a sexual partner?
Is your current sexual partner female / male / both / transgender / none?
Have your sexual partner(s) in the past been male / female / both / transgender?
Do you have a need for birth control at this time?
Have you ever used contraception?
What methods have you used?
Are you currently using any birth control method?
Do you identify as heterosexual / lesbian / bisexual / transgender / celibate / other?
Do you experience orgasm?
Does your sexual activity include vaginal entry?
Do you have pain with vaginal entry?
Are you aware of safer sex practices?
Do you use safer sex practices?
If yes, please list the methods you are currently using.
Have you ever had sex without your consent?

Management of Health Care Issues

There are several areas of health care management in which lesbians may have specific differences from their heterosexual counterparts: sexual practices and safer sex; cancer screening; STD transmission, and HIV.

Lesbian Sexual Practices

Lesbian sexual practices span a wide range. Intimacy and sexual activity may be distinct or intertwined. Stereotypes and myths portray lesbian couples as less sexual than gay male couples and heterosexual couples. It is important for midwives to be competent in sexuality counseling to make accurate assessments and appropriate interventions. This requires both a thorough knowledge base and a projected attitude of comfort and nonjudgment. Sexual practices are often less proscribed than heterosexual coitus and may range from affectionate, nongenital contact to genital and/or anal entry. They vary according to the preferences of each partner and perceptions of erotic behaviors; these behaviors and preferences may change over time. Sexual practices may include mutual masturbation involving vagina/vagina, mouth/vagina, mouth/anus, hand/vagina, or hand/anus contact. Arousal of breast tissue may be integrated into sexual activity. Both partners or only one may desire vaginal or anal entry. Vaginal entry with

fingers, tongue, fist, or sex toys and/or anal entry with fingers, tongue, or sex toys may be included. Sex toys may include dildos and vibrators as well as other objects such as candles and vegetables. When rougher sex is practiced, there is an increased risk for lesions and exchange of body fluids. A cardinal guideline is not to make assumptions about sexual practices without obtaining confirmation from the client [1, 3, 4, 8].

Safer Sex Practices Safer sex practices are dependent on sexual behavior and the sexual history of the partners involved. The midwife must take a sensitive sexual history in order to assist the couple in decision making about safer sex practices. Is the couple using sex toys? Are they sharing them? Is their sex gentle, rough, or somewhere in between? So little research has been done on actual rates of transmission of infection from woman to woman that a lesbian couple needs extra encouragement to assess their risk factors in order to make sound decisions about safer sex practices. Safer sex practices will decrease the likelihood of the exchange of body fluids including vaginal secretions, anal secretions, saliva, and blood. Safer sex practices for lesbians include careful handwashing before and after sexual activity, keeping fingernails short and clean, good oral hygiene, and awareness of any lesions of the mouth and tongue. Bleeding of the gums and periodontal disease should be attended to. Caution is important during menses; it may be best to avoid oral sex during menstruation, although the level of HIV in menstrual blood is unknown [3, 4, 8, 9, 13, 27, 29, 36]. Awareness and care of any known lesion(s) or cuts on the mouth, hands, fingers, genital, and anal areas are important to decrease the risk of transmission of infections. Tissue in the anus is more friable than tissue in the vagina.

Water-soluble lubricants such as Astroglide will decrease the likelihood of lesions. Latex barriers may be used and they include dental dams or latex sheets for oral sex; gloves or finger cots for vaginal or anal entry. Awareness of latex allergy or sensitivity must be considered. Vegetable oils and massage oils will break down latex; they should not be used together.

Sex toys should be washed with warm water and soap in between use; water soluble lubricants can be used on sex toys. Ideally each partner should have her own sex toys and they should not be shared. A dildo should not enter the vagina after going into the anus or vice versa unless it has been carefully washed or covered with a condom. Creative sex toys such as candles, fruits, and vegetables should also be carefully washed.

Cancer Screening

Cervical There is considerable room for improvement in knowledge, perceptions, and practices of all women regarding cervical cancer. Many lesbians are unaware of the cofactors which when combined with human papillomavirus (HPV) makes a woman at high risk for cervical cancer: cigarette smoking, multiple male sexual partners, sexual intercourse with a male partner before age 16, history of STDs, and history of or currently having genital warts (condylomata acuminata) [3–8, 13, 22, 23, 36–40]. The majority of lesbians report having engaged in heterosexual intercourse at some time. Further, woman to woman transmission of HPV can occur. Clients may not be aware of their risk for cervical cancer and the need to be regularly screened with Pap smears. It is important that all women are educated about cervical cancer screening and early detection because of their lifesaving potential. Educational material and community outreach that are inclusive of lesbians and women who partner with women need to be developed.

Ovarian/Endometrial Protective factors against ovarian and endometrial cancers include the use of oral contraceptives, and having been pregnant or given birth to a live infant. Lesbians, even those with a prior history of heterosexual intercourse, have used oral contraceptives less often and for a shorter period of time than their heterosexual counterparts [36–39]. They are also significantly less likely to have been pregnant or given birth. Therefore, many lesbians have a theoretical risk of ovarian cancer. If a lesbian has never used contraception, the potential benefit of even six to twelve months of use in reducing ovarian cancer risk could be considered [3, 4, 36–39].

Breast All women are at risk for breast cancer. Some factors that may increase an individual's risk are nulliparity or having her first child after the age of 35, heavy alcohol use, menarche before age 12, menopause after age 55, cigarette smoking, high body mass index, and hormone therapy [3, 4, 6, 8, 23–25, 36–38]. Lesbians and women who partner with women have lower rates of childbearing and higher rates of alcohol use [8, 26, 36–38]. While these factors may play a role in overall risk, the main concern for lesbians is lack of screening, which leads to delayed diagnosis and

treatment. There has been little research done on lesbians and breast cancer. A recent study found that lesbians report more breast biopsies than their heterosexual counterparts [25]. This finding needs further exploration. The current studies have predominantly sampled young Caucasian women. Future studies should sample women of different ages, ethnicity, economic groups, and geographic regions.

In the only study about understanding lesbians' mammography utilization, barriers were found to be consistent with barriers for women in general. Most often cited were systems barriers such as financial cost, scheduling, and geographic location. The sample of lesbians suggested that respect and outreach efforts targeted specifically to lesbians would promote utilization of mammography services [24].

STD Transmission

Vaginal secretions can readily be exchanged by a variety of sexual behaviors practiced by lesbians including hand/vagina, hand/anus, vagina/vagina, mouth/vagina, and mouth/anus contact. They can also be transmitted by sharing sex toys (dildos, vibrators, etc.). Because it is likely that sexually transmitted diseases can be transmitted from woman to woman, routine screening for STDs should be offered to all lesbians.

Bacterial vaginosis (BV) and candidiasis can occur when the vaginal environment becomes unbalanced. They can occur with new sexual partner(s) as different vaginal flora are introduced. It is possible for BV and vaginal candidiasis to be sexually transmitted between women [1, 3, 4, 27, 28, 36–40]. BV may be associated with pelvic inflammatory disease (PID), adverse pregnancy outcomes, and enhanced HIV transmission. These infections can also arise in women who are virginal or not currently sexually active. Lesbian partners should always be offered testing and treatment.

Risk factors for specific STDs such as chlamydia, syphilis, gonorrhea, HPV, and herpes simplex virus (HSV) include the sexual history of the female partner as well as sexual partnering with a man in the past or present. Although rates of chlamydia and gonorrhea infection are reported as low among lesbian populations, this may be due to lack of screening. HPV and HSV can be easily transmitted [36–39]. HPV is often diagnosed by cytological findings on a Pap smear; thus lesbians who delay preventive health care screening may be underdiagnosed [40].

HIV

Lesbians are a hidden population in human immunodeficiency virus (HIV) transmission statistics. Although HIV-related research on women who have sex with women, regardless of their sexual orientation, has been scarce, there have been some notable findings [8, 39]:

1. Higher HIV seroprevalence rates among women who have sex with both women and men compared to exclusively lesbian or heterosexual counterparts
2. High levels of risk for HIV infection through unprotected sex with men who inject drugs
3. Risk for HIV infection of unknown magnitude owing to artificial insemination with unscreened semen

A lesbian or bisexual woman is at risk for HIV if she or her partner has a history of a male sexual partner within the last ten years or a history of intravenous drug use. According to recent studies, from 10 to 40 percent of the lesbian and bisexual population fall into these risk behavior categories. Lesbians who perceive low-risk identity may be practicing high-risk sexual behavior [29, 39]. Sensitive education about risks and an assessment of risk behaviors are key factors. Midwives gain necessary knowledge about the range of sexual behavior of individual clients by obtaining a complete sexual history including past and present sexual behavior and intravenous drug use.

Childbearing and Parenting

Family Configurations

There are an estimated 6 million to 14 million children raised by lesbian and gay individuals in the United States [36]. Lesbian mothers cross all class, racial, ethnic, nationality, and physical ability lines. They live in heterosexual marriages or alternative family structures. Prior to the 1970s and 1980s and the lesbian feminist movement, most lesbian mothers became parents via heterosexual intercourse. The women's, civil rights, and lesbian/gay movements of the 1960s and 1970s gave confidence to lesbians to parent children. Sperm banks and adoption agencies became accessible to single parents, giving lesbians more options for having children [19].

Lesbian mothers are pioneer developers of new family forms (see Figure 11-1). Lesbian parent configurations may include any of the following:

1. A single woman with one or more children
2. Two female lovers with one or more children
3. Two or more friends with one or more children
4. A combined family consisting of two or more families coparenting each other's children
5. An extended lesbian family consisting of a single lesbian or a lesbian couple with children and other friends or ex-lovers actively involved in childrearing
6. Extended biological families of origin [19]

There is an increase in interracial lesbian families that present new opportunities and challenges within a heterosexist and racist society. The midwife needs to remember that lesbian family configurations defy traditional definitions and may take a variety of creative forms. Many studies have examined the psychosocial development of children raised by lesbians and have found no differences in sexual or gender identity compared with children of heterosexual parents [20].

FIGURE 11-1 Family rejoicing.
Source: Photo courtesy of Debbie Parker.

Although in some communities, particularly in large urban settings, well-developed resources and support groups are available for lesbian parents, in more rural settings lesbian parents and their children may be much more isolated [3, 4, 8, 36].

Options for Parenthood

The birth mother has many considerations, beginning with method of conception. A thorough preconception visit is a wonderful opportunity to explore methods of alternative insemination. Homophobic stigmatization of lesbians as inappropriate parents include potential rejection by family of origin, lack of access to and availability of resources such as sperm banks, and denial of insurance coverage. Most health insurers refuse to cover the costs of semen and office inseminations for lesbians or single women who want to become pregnant until there have been 12 cycles of insemination without conception, at which point they may qualify for infertility services [3, 4, 8]. The birth mother needs information about fertility, basal body temperature charting, ovulation prediction kits, donor selection from sperm banks, laboratory testing, insemination methods, and sensitive prenatal care.

Alternative fertilization (donor insemination), as a form of woman-controlled conception, is the process of introducing a donor specimen of sperm, either fresh or frozen, into the woman's vagina at or near the time of ovulation with the intention of fertilizing the ovum (ova). The woman herself, her partner, or a health care provider can insert the sperm. Both partners should be included in all preconception counseling and decision making as well as in prenatal, intrapartal and postpartum care. Midwives can be an excellent resource for a lesbian or lesbian couple in advocating and facilitating this process.

Whether to use a known or unknown donor has important repercussions. Issues to explore with a known donor include: Will the donor be involved in parenting? How will the lesbian mother(s) protect herself (themselves) if the donor desires custody of the child(ren)? With an unknown donor, the central issue is how much information will be available to the children. The AIDS pandemic has changed donor options. It is imperative to take thorough sexual histories and to screen for HIV and STDs in donor semen. Frozen semen should be quarantined until it is tested two times, six months apart, with negative results.

Adoption is also an option for lesbians who desire children. The issue of second parent adoption

has been fiercely contested in many states. Second parent adoption provides legal adoptive parental rights to the social/nonbiological mother. This allows both the biological and nonbiological mothers to have equal legal status as parents. Three states (Utah, Mississippi, and Florida) effectively ban second parent adoptions; Washington, D.C., and seven states (Vermont, Connecticut, California, Illinois, New York, New Jersey, and Massachusetts) permit them by law or court ruling, and otherwise the legal status varies widely. In a number of states, lesbians cannot adopt openly as a family but must apply as a single parent if two women plan to coparent. In early 2002, the American Academy of Pediatrics announced its support for the right of gay men and lesbians to adopt their partners' biological or adopted children [41]. A growing body of scientific literature demonstrates that children who grow up with one or two lesbian parents fare as well in emotional, cognitive, social, and sexual functioning as do children whose parents are heterosexual [42]. Midwives need to be familiar with local adoption regulations in order to counsel lesbians seeking to adopt children [2, 3, 8, 19].

Birth Mother

Once pregnant, the birth mother is vulnerable in unique ways and may find herself "coming out" all over again, as a pregnant lesbian, then again later as a lesbian mother. Once pregnant, her physical status becomes public. Public assumption of heterosexuality becomes pervasive. A pregnant lesbian may endure a range of questions from family of origin members, coworkers, and neighbors as well as shopkeepers and passersby. Questioning may be as benign as curiosity or as dangerous as open hostility. Women who choose to give birth as open lesbians challenge societal notions of family. A pregnant lesbian may have to come out to people whose response is not predictable—i.e., hospital administrators, pediatricians, sonographers, and third-party payors.

The birth mother and her partner face unique stressors that include the constant invention of their role(s) as mother(s) in a patriarchal society. She (they) must decide what level of disclosure about their identities and choices are optimum in each new situation in the hopes of gaining respect and attaining basic needs. Even if the midwife is respectful, the birth mother often faces homophobic attitudes and policies throughout her pregnancy and birth. Hospital staff may demonstrate a range of behaviors from ignorance about lesbian coparenting to open hostility toward the parental couple. The couple may be made to feel invisible as a parental team through lack of validation of their relationship. During labor and the birth, this can be especially stressful for an emerging family. The couple may have to endure overheard homophobic remarks. During the vulnerable postpartum period, the birth mother may face policies that deny parental visitation rights to the social mother. A knowledgeable and supportive network of caregivers is vital.

Coparenting

"Nonbiological mother" is the most common term used to describe the coparent, although this gives a sense of negation. More inclusive terms include "coparent," "comother," "social mother," "other mother," and "second female parent." Some families invent their own terms in this rapidly evolving kinship role. Lesbian families are creating a new female parent; the stress and isolation of the new female parent are due to lack of social and legal recognition. Generally, the second female parent's lesbianism is visible, while her motherhood is invisible. She may experience tremendous pain when her parenting role is not recognized by colleagues, family of origin, neighbors, and friends [19].

Children growing up with same-sex parents also must struggle with homophobic attitudes of friends, teachers, camp counselors, and societal institutions. Children do best with open and honest discussion as well as a supportive environment that values their family configuration. Children need to be educated that love is the most important family ingredient. Midwives who are educated to empower families are in a position to promote social recognition by including the second female parent as an equal family member as well as providing public support for the lesbian family configuration.

Legal Issues

Legal concerns of lesbian parents include the custody rights a donor may have to the child and custody rights of the social mother in lesbian "divorce" cases or in the event of the death of the biological mother. Individual state laws concerning parent-child relationships should be understood before using donor fertilization. Some states recognize the rights of the social mother through a second parent adoption [8]. This recognition gives the social mother equal parental rights under the law includ-

ing the rights and responsibilities of all legally recognized parents. Several documents may protect lesbian parental relationships in the event that second parent adoption is not a legal option: a will nominating the social mother as guardian in the event of the biological mother's death; a nomination of guardianship; a parental agreement between the birth mother and the social mother that recognizes the social mother's parental role and responsibility in the event of separation; and a medical consent form giving the comother medical authority. Midwives can guide their lesbian clients toward the need for legal resources and preparations during the pregnancy.

Special Health Concerns

Certain health areas of special concern have unique meaning for lesbian clients who may live in secrecy and certainly are influenced by homophobia in daily living. Midwives and other clinical providers may be the first person to whom a lesbian client reveals her vulnerability.

Mental Health Concerns

Lesbians suffer from the stress of living in a homophobic society and often need to be secretive about their lives with families, coworkers, and friends. Fears of loss of job, loss of benefits, poverty, and loss of custody if one's lesbian identity is revealed increase the risk of various mental health disorders. The process of coming out of this secrecy can lead to anxiety, rejection, loss of loved ones, and depression. In some studies adolescent gays and lesbians were more than twice as likely to attempt suicide as heterosexual young women [8, 21]. The number of hate or bias crimes against lesbians, including verbal abuse, threats of violence, property damage, physical violence, and murder is increasing each year [8, 10, 12].

All of these issues create unusual stresses on lesbian couples. Disruptions and breakups in lesbian couples, with or without children, can also be particularly difficult because of the lack of the usual societal structures and supports. The lack of traditional sanctions such as marriage and divorce create an invisibility of these breakups and losses to the world.

The midwife may be one of the few persons in whom lesbians can confide. Inquiry about the couple and family life of lesbians is usually most welcome and helpful in determining the need for assistance, intervention, or referral. Screening for social, as well as domestic violence, life stressors and coping mechanisms are part of a comprehensive health assessment.

Substance Use: Cigarettes, Alcohol, and Drug Use

Higher than typical rates of alcohol use by lesbians have been suggested. Some sources suggest that alcoholism affects as much as 30 percent of the lesbian population, compared with 10 percent of the general female population. Alcohol abuse is often correlated with other substance abuse. Lesbians who are heavy alcohol users have high rates of cirrhosis, accidents, suicide, depression, hypertension, menstrual and reproductive problems, malnutrition, colon and stomach cancer, and gastrointestinal hemorrhage [8, 11, 13].

In various surveys, 27 to 31 percent of lesbians reported currently smoking cigarettes. The rate of current smokers increases in each age group whereas in the female population in general smoking rates decrease as the age increases. Very few data are available to document the use of illegal drugs by lesbians [8].

Domestic Violence

Violence in lesbian relationships, as in heterosexual relationships, has existed behind closed doors for a long time. Abuse in lesbian relationships more often takes a nonphysical than a physical form. However, physical abuse is also used as a mechanism for resolving conflicts [8, 30–32]. Because lesbians often live in secrecy and isolation, issues of domestic violence become even more taboo and frightening.

It is crucial for midwives to be aware of the possibility of same-sex partner abuse in order to help the victims of intimate violence. Methods of conflict resolution in the lesbian couple relationship need exploration. The belief that there is a high level of emotional merging in a lesbian relationship, possibly coupled with blurred personal and role boundaries, may enhance abusive behaviors [30]. Further research is needed on the incidence and correlates of violence in all forms of intimate adult relationships in order to provide better counseling services to lesbian batterers and their victims.

Racial and Ethnic Minority Groups

Views of sexual identity and sexual behavior can vary significantly across cultures, so it should not be assumed that a lesbian sexual identity is the same

for lesbians of different racial, ethnic, or cultural backgrounds. Nor should the midwife assume that racial and ethnic minority cultures share views of lesbian sexual orientation identical with the dominant culture. It can certainly be hypothesized that the stress effects of homophobic attitudes may be greatest for lesbians who are subject to multiple forms of discrimination, such as lesbians who are also members of racial and ethnic minority groups. Lesbians of color may also experience racism within the lesbian community. The combination of homophobia, racism, and sex-based discrimination has been referred to as being in "triple jeopardy" [8]. Stress-related illnesses such as elevated blood pressure and depression are likely to be exacerbated by racism.

Transgender Lesbians (Male to Female)

Transgender lesbians are individuals who through medical and/or surgical procedures have transformed their gender and identity from male to female and then self-identified as lesbian. Society continues to view transgender people as abnormal. For many transgender people, this results in secrecy, shame, depression, and fear. This leads to isolation and delayed utilization of preventive health care. A transgender lesbian needs sensitive and knowledgeable care. A transgender male to female (MTF) lesbian does not need gynecological care although she does need breast care. She may need a referral to a urologist for specialized care. A transgender female to male (FTM) person will continue to need pap smears unless he has had a hysterectomy and closure of the vagina. An FTM individual will also continue to need breast exams. Almost no research has been done to ascertain the unique health care needs of transgender people. Midwives who are educated to provide respectful care that honors the full range of human experience can provide sensitive care to this misunderstood minority [33, 34].

Youth and Elder Needs

There are unique needs of both young and elder lesbians. The adolescent lesbian is especially vulnerable to the emotional distress of coming out and is at increased risk of attempting suicide. Parental acceptance during this process may be a primary determinant of the development of healthy self-esteem. It is important for midwives to screen adolescents for these signs and to consider confusion about sexual orientation in the differential diagnosis of depression and substance abuse [3, 4, 8, 21].

At the other end of the spectrum, lesbians who are menopausal and postmenopausal may encounter special situations associated with their sexual orientation, such as adverse societal attitudes, family rejection, and internalized homophobia. For many lesbians, the health concerns of aging may be their first entry into the health care system. Since many lesbians have not had children and have not had routine preventive screening, they are at higher risk for reproductive cancers. Societal supports such as next-of-kin benefits are not often available due to the lack of recognition of long-term lesbian relationships. Social support is lacking for elder lesbians who experience being with a partner through illness, hospitalization, hospice, funeral arrangements, and other stressful developmental events of getting older. They may not receive the same societal recognition of grief at the death of a long-term partner. Older lesbians may also be more isolated and at higher risk for stress-related illnesses. Regardless of whether they are sexually active, elder lesbians who still identify themselves as lesbian may not feel accepted in the dominant heterosexual environment of many assisted living communities [3, 4, 8, 12, 36].

Summary

Protective factors such as strong social support systems, religious institutions, schools, and community groups can promote optimum health for lesbians. Strong ties with friends and family may also decrease the stressors of homophobia. As midwives gain basic skills about the special health care needs of lesbians and how to enhance a sense of safety and assertion within the health care system, there will no doubt be an increase in utilization by lesbians of midwifery's unique offerings.

Substance Abuse

NANCY JO REEDY, CNM, MPH
MARY C. BRUCKER, CNM, DNSC, FACNM

Introduction

Substance abuse is defined as "a pattern of psychoactive substance use that involves hazards to health" [1]. Substances that are of concern include caffeine, tobacco, and alcohol as well as licit and illicit drugs. Abuse may take various forms, including occasional experimentation, misuse of prescription medication, or addiction. Addiction indicates a physical and/or psychological dependence on the substance(s) of abuse. Substance abuse, whether occasional use or addiction, has implications for the health of a woman and her fetus or newborn. A glossary of commonly used terms is presented in Table 12-1.

Women who abuse alcohol and drugs frequently suffer from serious psychological problems, are at risk for nutritional deficiencies, report late for prenatal care, and may have frequent interactions with the legal system as well as difficulty complying with recommended visit and treatment schedules. In addition, their personal and social lives are often difficult and place them at high risk for physical abuse and sexually transmitted infections.

Women and Substance Abuse

According to the National Household Survey on Drug Abuse issued in 2002, men are more likely to be users of illicit drugs than women (7.7 percent compared to 5.0 percent) [2]. However, the nonmedical use of psychotherapeutic agents (e.g., analgesics, tranquilizers, and sedatives) was slightly less than 2 percent, essentially the same for both women and men. Thus, there are both similarities and differences between genders. Reyes suggested dividing gender differences in substance disorders into four categories: (1) social issues, (2) biological variations, (3) psychiatric comorbidity, and (4) medical sequelae [3].

Social Issues

Compared to men, women experience more social stigma when they engage in substance abuse. Therefore, it is not unanticipated that, when compared to men, women who are substance abusers tend to be secretive and hide their addictions [4]. Women are more likely to live with other substance-abusing individuals. These women are more likely than men or nonabusing women to have had spouses or other nuclear family with drug addiction patterns and to be currently separated or divorced. Unlike men, who tend to have more problems at work, women tend to have more disruptive patterns in their families. Alcoholic women are more likely to have experienced childhood victimization than nonalcoholic women.

Biological Variations

Biological variations are also apparent between men and women substance abusers, especially in relationship to various types of abuse. Men metabolize nicotine more rapidly than women, resulting in a longer half-life for nicotine in smoking women. This potentially makes it easier for women to become addicted to cigarettes. Since women have less gastric alcohol dehydrogenase, they experience higher levels of intoxication after ingesting less alcohol than men. In addition, estrogen may make

TABLE 12-1 Glossary of Terms Used in Substance Abuse

Term	Definition
Designer drugs	A term that has different connotations. In the context of licit drugs, indicates new drugs intentionally created to minimize certain adverse effects (e.g., selective estrogen receptor modulators designed to decrease the risk of breast cancer). In the context of substance abuse, indicates new categories of hybrid drugs created usually by underground chemists to enhance such effects as euphoria.
Drug abuse	Also known as chemical or substance abuse. Intentional misuse of either licit or illicit drugs for recreation, perceived necessity, or convenience. Drug abuse is a more intense misuse of drugs than connoted by the term *drug use*.
Drug addiction	According to the World Health Organization, "a state of periodic or chronic intoxication detrimental to the individual and society, which is characterized by an overwhelming desire to continue taking the drug and to obtain it by any means."
Drug misuse	Inappropriate use of prescribed or OTC drugs. Examples include taking more prescribed or OTC drugs than indicated, for a longer period than indicated, mixing drugs to potentiate euphoria, sharing drugs with others, or discontinuing drugs early.
Gateway drug	An agent that leads to another drug. Alcohol, tobacco, and marijuana are the most commonly used first drugs.
Illicit drug	Illegal drugs, such as marijuana, cocaine, and LSD.
Licit drug	Legal drugs, such as caffeine-containing agents, alcohol, and tobacco.
Over-the-counter drugs (OTC)	OTC drugs account for approximately $19 billion dollars in sales per year, based on 2002 statistics. Some of these agents are misused or abused, including laxatives, diet pills, and cough suppressants.
Polypharmacy	The use of multiple agents simultaneously, risking additive, antagonistic, or synergistic effects. Also called *polydrug use*.
Prescribed drugs	Licit drugs that may be used, especially analgesics. In 2001, 3.1 billion prescriptions were written, and analgesics like oxycodone (Vicodin) were among the top 200 drugs in the United States.
Psychoactive drugs	Substances that affect the central nervous system. They alter consciousness and/or perceptions.
Recreational drug use	Use of drugs to achieve a certain mental or psychic state.
Substance abuse	See Drug abuse.

Sources: Goode, E. *Drugs in American Society*, 5th ed. Boston, MA: McGraw-Hill, 1999; Hanson, G. R., Venturelli, P. J., and Fleckenstein, A. E. *Drugs and Society*, 7th ed. Sudbury, MA: Jones and Bartlett Publishers, Inc., 2002.

liver damage with alcohol worse for women. Women alcoholics are more likely to die from cirrhosis. Some research exists indicating that in addition to alcohol and tobacco, addiction to cocaine and opiates may progress faster among women than men. This phenomenon has been termed telescoping [4]. For women, chronic use of alcohol and cocaine may result in amenorrhea or other menstrual disorders. Menstrual irregularities may be perceived by the woman as evidence of infertility, and may lead a woman not to seek contraception or recognize early pregnancy when it occurs.

Psychiatric Comorbidity

Women usually first have psychiatric problems, followed by substance use disorders. This sequence is the opposite with men. Women who abuse alcohol are more likely to have higher rates of depression, panic disorders, and phobias than their male counterparts. Male substance abusers are more likely to have conduct disorders and antisocial personality disorders than female substance abusers. Among women, depression often accompanies treatment relapse. Depressed women are less successful than depressed men in attempting smoking cessation. No significant differences appear to exist between alcoholic men and women in relation to rates of concomitant illicit drug use [3].

Medical Sequelae

In addition to risks of cirrhosis and the increased incidence of amenorrhea for some subgroups of

women substance abusers, other medical sequelae exist. Diseases of the liver, heart, and gastrointestinal system proceed more rapidly among women substance abusers than men. Higher rates of osteoporosis and breast cancer have been reported for some subgroups. In general, mortality rates among women who abuse substances are higher than among men with similar abusing patterns. When compared to nonabusing women, females who engage in substance abuse are more likely to have sexually transmitted infections, including HIV and hepatitis [4].

Attraction of Substance Abuse

Recreational drug use has been documented for more than four millennia. Attempts at drug regulation were made as early as 2240 BC [5]. Historical drug use includes opiate lozenges for the Assyrians, hashish candies for the Romans, and cocaine found in Coca Cola's original recipe for Americans. However, less is known about why certain individuals become addicted to substances, others are occasional users, and yet others are never substance abusers. Some substance abusers say that they become users because they are bored, frustrated, or alienated. For them, drugs may provide pleasurable feelings or heighten pleasure. Some drugs may temporarily relieve stress or tension or even help the individuals dissociate themselves from daily issues. For adolescents in particular, peer use of drugs may promote drug use. Some individuals begin to use analgesics and other drugs because of an acute or chronic disease and find themselves psychologically and/or physically dependent upon the agents.

The absolute etiology of substance abuse remains elusive, especially since it may vary among different individuals. Without a single etiology, or even several specific etiologies, assessment and treatment of substance abuse remain a major challenge, not only for midwives, but also for society in general.

Additionally, most substance abusers use a wide repertoire of drugs. Many individuals begin drug use with a gateway drug but then continue to mix drugs and may escalate to illicit drugs. For example, a woman may both smoke and drink a cup of coffee. That could be called a caffeine/nicotine mix. Alcohol and sedatives or opiates have proved to be deadly combinations, as illustrated by several well-publicized celebrity deaths. This polypharmacy, or polydrug, approach makes research and clinical management in the area even more difficult. Table 12-2 illustrates some examples of polypharmacy and the common interactions of agents with substances of abuse.

TABLE 12-2 Examples of Polypharmacy: Common Interactions of Agents and Substances of Abuse

Agent	Combined With	Result
Sedatives		
Diazepam (Valium) or Triazolam (Halcion)	Alcohol Barbiturates	Increased sedative effects
Stimulants		
Amphetamines or Cocaine	Insulin Antidepressants	Decreased hypoglycemic effects Increased hypertensive effects
Opiates		
Heroin or Morphine	Barbiturates, diazepam Anticoagulants Antidepressants Amphetamines	Increased sedative effects Increased bleeding Increased sedative effects Increased euphoria
Tobacco		
Nicotine	Antihypertensives Amphetamines, cocaine	Increased blood pressure Increased cardiovascular effects
Alcohol	Cocaine	Production of cocaethylene, which enhances euphoria and toxicity

Assessment of Drug Use

There is no single assessment technique for evaluating substance abuse. The complexity of individual motivations and the various physical reactions to drugs and their interactions, as well as the widespread tendency toward polypharmacy, all contribute to this problem.

However, the best available method of evaluation is a good general history. When seeking an initial or annual history for a woman, use of alcohol, tobacco, caffeine, and all drugs should be explored. Since individuals who are substance abusers also tend to have a higher incidence of sexually transmitted infections or domestic violence, it is useful to discuss substance abuse if those conditions occur. Signs or symptoms of depression, family dysfunction, sleep disorders, and gastrointestinal problems may all indicate comorbidity with substance abuse and should alert the midwife to the possibility of drug abuse. Whenever one substance of abuse, such as cigarettes, is found, there should be a concerted effort to ascertain whether or not others are also being abused.

In regard to pregnancy, the optimal time to assess for substance abuse is during a preconceptional visit. If substance abuse is identified then, there is time to implement management and treatment regimens before the woman becomes pregnant. Unfortunately, many women who abuse drugs are reluctant to interact with the health care system and may seek care later in pregnancy, if at all, especially when illicit drugs are involved, causing fear of legal implications.

Some assessment instruments are substance specific. If a woman uses alcohol, a short questionnaire may be of value. Many clinicians are familiar with the CAGE questionnaire that consists of four questions. However, the CAGE has been found to be less accurate among women, particularly Whites. Recently, the TWEAK questionnaire has been advocated [6]. Table 12-3 presents the components of the TWEAK questionnaire, including the weighting of each question. If a woman scores two to three points on the TWEAK scale, whether she is pregnant or not, it is considered a positive result. Some clinicians recommend that TWEAK scales be administered annually for all women in outpatient facilities [4]. It should be noted that this questionnaire has been studied with alcohol, but there is no strong recommendation for its use if adapted to other substances of abuse.

If the midwife is caring for a woman whom she believes to be under the influence of drugs that will impact her life or that of her fetus or child, immediate drug testing may be indicated. Drug testing may be done on urine, blood, or hair. In the case of a newborn, positive drug testing of meconium provides indication that drugs have been used within the last two to three days. The most common source for drug testing for adults and adolescents is urine, but midwives should be aware that confounding factors can interfere with the accuracy of the results. For example, poppy seeds found in pastries may cause a urine test to be positive for narcotics. Sodium bicarbonate antacids alkalizes urine and increases excretion of some drugs such as methamphetamines. Use of diuretics may dilute the volume of drugs in the urine, making it more difficult to find them via urine tests.

Legal and institutional policies and regulations may influence the situations wherein a midwife can

TABLE 12-3 The TWEAK Questionnaire for Alcohol Use

T	Tolerance (2 points)	How many drinks can you hold? (Cutoff: Four or more is a conservative cutoff for use with women compared to six or more for men)
W	Worried (2 points)	Have close friends or relatives worried or complained about your drinking in the past year?
E	Eye Openers (1 point)	Do you sometimes take a drink in the morning when you first get up?
A	Amnesia (1 point)	Has a friend or family member ever told you about things you said or did while you were drinking that you could not remember?
K	Cut down (1 point)	Do you sometimes feel the need to cut down on your drinking?

Note: A total of 2 to 3 points may indicate an alcohol abuse problem.

Source: Chan, A. K., Pristach, E. A., Welte, J. W., et al. The TWEAK test in screening for alcoholism/heavy drinking in three populations. *Alcoholism: Clinical and Experimental Research* 6:1188–1192, 1993.

order drug testing. A midwife should know the appropriate policies and recognize that when such testing is performed the collection and results should be confidential.

General Treatment Issues

The care of a woman struggling with substance abuse requires the collaboration of her midwife and professionals in multidisciplinary programs who have skills in treating chemical abuse and addictions. The professionals may include social workers, chemical abuse counselors, psychologists, psychiatrists, nutritionists, pharmacologists, and physicians with knowledge and experience in managing withdrawal, detoxification, and long-term treatment. The midwife must coordinate care for the woman with the professionals in substance abuse treatment. It is essential that the woman in treatment receive consistent information and that all team members hold the same expectations for her behavior. The course of treatment and recovery is often long, marked by periods of success and times of relapse. The cycle of recovery includes a period when the woman does not recognize the need to change behavior, a period of contemplation when the problem is recognized but no action is taken, a period when the woman plans action, a period of action, and a period of maintenance [7]. Relapses are to be expected, and recovery after relapse means repeating the cycle of recovery.

The factors that motivate recovery in a woman who has been abusing drugs or alcohol are varied and unpredictable. Sometimes concern about a baby during pregnancy may be the catalyst to begin the cycle of recovery. For a woman with an addiction who has not moved into a recovery cycle, any concern for a baby may be overridden by her concern for acquiring drugs. The woman alone has the power to change her addictive behavior. The midwife must provide continuous support to the woman while recognizing the recovery and relapse pattern of addiction. By providing ongoing care, the midwife can work to minimize maternal and fetal complications, encourage decreased substance usage, and support the cycle of recovery.

Many methods of drug treatment have evolved over the last several decades. These methods include self-help groups, institutional rehabilitation, therapeutic counseling, and use of various pharmaceuticals, or any combination thereof. In general, it is difficult to ascertain the effectiveness of the methods since few randomized controlled trials have been conducted. Perhaps the most famous of the self-help groups is Alcoholics Anonymous. Detoxification, or detox, units were common at one time in order to provide a facility for people undergoing withdrawal symptoms, but such units are no longer as common since the emergence of inpatient institutional care.

Institutional rehabilitation was made popular by the introduction of the Minnesota Model, an inpatient facility where a person could go for approximately one month during which time individual and group work would address some of the issues of desire and craving. The original 28-day time frame was determined by insurance reimbursement in Minnesota at the time but has since become a general standard. In addition to the original Minnesota facility, other institutions such as California's Betty Ford Clinic made institutional treatment in style. Therapeutic counseling and behavioral modification have become the cornerstone of many programs. A wide variety of pharmaceutical agents including antidepressants and narcotic antagonists have been used in the quest for addiction treatment. However, the unique relationship of an individual with her addiction, the polypharmacy aspects, and the lack of quality research make it difficult to implement management with a known degree of success.

General Management of Substance Abuse During Pregnancy

Obtaining a thorough patient history with questions specifically directed to detect substance abuse is essential. Midwives should recognize that women often use more than one substance. For example, use of caffeine and cigarettes is highly correlated; women who abuse sedatives may also abuse stimulants. Polydrug use is common in women using illicit drugs such as cocaine, heroin, or marijuana. The midwife must ask for information on all substances used, including over-the-counter medications, prescription drugs, illicit drugs, tobacco, and alcohol. It is important to know the method of consumption, amount, and combinations of drugs that

the woman uses. Combining drugs may potentiate the effect of the individual substances.

After identification, management is directed at reducing or eliminating the substances and the concomitant risks. Specific strategies for intervening in substance abuse situations depend on the substance and pattern of usage.

When substance abuse occurs during pregnancy, management must take into account the maternal, fetal, and neonatal risks associated with the substance(s) used. In prescribing medications or recommending over-the-counter medications, care must be taken to avoid preparations with high alcohol content. For the woman abusing alcohol and/or drugs, products containing alcohol can potentiate the effects of other drugs she is using. Prescribing medications containing alcohol sabotages the woman who is working toward abstinence.

When a woman is suspected of actively abusing alcohol or drugs or is known to do so, care must be taken in managing acute pain such as that experienced during labor and delivery. Women need the full support of analgesics and anesthetics. A careful history and monitoring of the woman's reaction to medication will enable appropriate pain relief without risk of overmedication. Withholding medication because of past or current substance abuse is cruel and unnecessary. Appropriate pain management will not precipitate a relapse or reinforce a drug habit. More information about pregnancy is contained in the discussion about common substances of abuse. Table 12-4 provides an overview of substances of abuse, maternal overdose, and neonatal effects.

Substance Abuse and Lactation

Substances used by lactating women can be passed to the infant during breastfeeding. The benefits of breastfeeding must be weighed against the risks of the infant's ingesting the abused substance. The infant, with an immature liver, may have diminished ability to metabolize and excrete the drug. In addition, the effect of the drug on the infant (for example, irritability) may compound the mother's problems in caring for the infant. Women who abuse substances often have decreased ability and resources to cope with difficult infants. Women actively abusing drugs are at increased risk of behaviors that predispose them to sexually transmitted infections, including HIV, which can be transmitted to the baby in breast milk. The midwife must help the mother make a decision about whether to breastfeed after reviewing her history, current drug usage, social situation, and the risk to the infant posed by the drug used by the mother. Alternatively, midwives should not assume that a woman who abuses substances should automatically not breastfeed since this vulnerable dyad may benefit best by the nutritional and psychological advantages of breastfeeding. In the following discussion of specific substances, lactation is discussed in relationship to each of the common substances of abuse.

Neonatal Implications

Some states require reporting of substance abuse in pregnancy, and some require universal screening of newborns for evidence of maternal drug usage during pregnancy. The ethics of screening are the subject of active debate. It is important for the midwife to know and to comply with state laws governing screening and/or reporting. In some jurisdictions, a positive test for maternal drug use mandates social services referrals and may result in the newborn being removed from maternal care. Therefore, such interventions must not be capricious for the sake of all involved. The midwife must be supportive of the family's needs and concerns, while intervening in the child's best interest.

Occasionally, the first time that substance abuse is noticed is when neonatal signs are observed. The classic withdrawal signs of a newborn, especially associated with maternal opiate use, include CNS irritability (e.g., tremors, jitteriness), respiratory distress (e.g., increased rate of sneezing, increase in respiratory rate), fever, sweating, excessive sucking, and poor feeding. Nonpharmacological interventions such as swaddling and other calming behaviors are often implemented. As with maternal treatments, neonatal treatments have rarely been assessed with great scientific rigor and much remains to be understood about substance abuse and the newborn, including the best methods of care. Table 12-5 uses the algorithm of "withdrawals" to summarize symptoms of neonatal withdrawal and associated physical problems.

TABLE 12-4 Substances of Abuse, Maternal Overdose, and Fetal/Neonatal Effects

Substance of Abuse	Maternal Overdose/Withdrawal	Fetal/Neonatal Effects
Alcohol	*Overdose:* Unusual behavior, depression, amnesia, hypotension *Withdrawal:* Agitation, tremors	Microcephaly, growth retardation, mental retardation, craniofacial abnormalities, abortion Growth restriction occurs both before and after birth Nutritional deficiencies, smoking and polypharmacy confound data The fetus of a woman who ingests six drinks per day is at a 40% risk of developing some features of FAS, but the threshold is still unknown
Anticholinergics Atropine Belladonna Scopolamine	*Overdose:* Pupils dilated and fixed, increased heart rate and temperature, amnesia, vagueness *Withdrawal:* None	None noted
Cannabis Marijuana THC Hashish	*Overdose:* Infected conjunctiva with normal pupils, decreased blood pressure when standing, increased heart rate, time and space disoriented *Withdrawal:* None	Some subtle behavioral alterations noted but no anomalies or growth delay
CNS sedatives Barbiturates Chlordiazepoxide Diazepam Flurazepam Glutethimide Meprobamate	*Overdose:* Normal pupils, decreased, shocky blood pressure, depressed respiration, depressed tendon reflexes, coma, ataxia, slurring, convulsions *Withdrawal:* Tremulousness, insomnia, chronic blink reflex, agitation, toxic psychosis	No anomalies Limp baby
CNS stimulants Antiobesity Amphetamines Cocaine Methylphenidate Phenmetrazine Methaqualone	*Overdose:* Dilated and reactive pupils, shallow respirations, increased blood pressure, hyperactive reflexes, cardiac arrhythmias, dry mouth, tremors, sensorium hyperacute *Withdrawal:* muscle aches, abdominal pain, hunger, prolonged sleep, possibly suicidal	Questionable increased rate of abortion, hyperactivity in utero, depression of interactive behavior, controversy about anomalies Cocaine has been linked with some bowel atresias and possible congenital malformations of heart, limbs, face, and GU tract as well as growth restriction. Maternal and fetal complications include sudden death and placental abruption (sixfold increase in obstetrical complications)
Hallucinogens LSD Ketamine Mescaline Dimethyltryptamine Phencyclidine (PCP)	*Overdose:* Dilated pupils, increased blood pressure, heart rate and tendon reflexes, flush face, euphoria, anxiety, illusions, hallucinations *Withdrawal:* None	Dysmorphic face Behavioral problems
Opiates Codeine Heroin Hydromorphone Meperidine Morphine Opium Pentazocine Tripelennamine	*Overdose:* Constricted pupils, decreased blood pressure, heart rate and reflexes, hypoactive sensorium *Withdrawal:* Agitation, flu like symptoms, dilated pupils, abdominal pain	Intrauterine withdrawal with increased fetal activity Neonatal withdrawal Depressed breathing movements Methadone usually treatment of choice

TABLE 12-5 Signs and Symptoms of Neonatal Withdrawal and Associated Physical Problems

Signs and Symptoms	
W	Wakefulness
I	Irritability, insomnia
T	Tremors, temperature variations, tachypnea, twitching (jitteriness)
H	Hyperactivity, high-pitched cry, hiccups, hyperreflexia, hypertonus
D	Diarrhea (explosive), diaphoresis, disorganized suck
R	Rub marks, respiratory distress, rhinorrhea, regurgitation
A	Apnea, autonomic dysfunction
W	Weight loss (failure to gain weight)
A	Alkalosis (respiratory)
L	Lacrimation (photophobia), lethargy
S	"Stuffy" nose, sweating, sucking (nonproductive), sneezing, seizures
Physical Problems	
P	Prematurity
H	High incidence of intestinal, genital, and urinary tract abnormalities, hypertension
Y	"Yellow" (jaundice)
S	SGA, small head, SIDS (8–10 times increase in risk), stroke
I	Immune system suppression (infection)
C	Cranial abnormalities (abnormal EEG, seizures)
A	Asphyxia, aspiration pneumonia, "abnormalities" aspiration (meconium), abruptio placenta
L	Low birth weight
	Others: Vomiting, yawning, coughing, shock

Common Substances of Abuse

The following sections address the most common substances that are abused. Common treatments and implications for pregnancy and lactation are described. It should be noted that with the advent of designer drugs, new combinations frequently emerge and midwives need to continue to be aware of such complications. Public health and law enforcement agencies often provide updates on "street" drugs in a given locality.

Caffeine

Caffeine is the most common substance of abuse in the United States. It is estimated that the average daily intake is more than 200 milligrams and approximately one-third of the population consumes more than 500 milligrams. Caffeine is a methylxanthine or xanthine and is known as a mild central nervous system stimulant. Although coffee and tea are the best-known sources of caffeine, soft drinks, chocolate, cocoa, over-the-counter drugs, and prescription drugs can also contain caffeine. Table 12-6 lists caffeine content of common foods and beverages.

Many women drink a cup of coffee every morning because it tends to enhance alertness and diminish fatigue [8]. However, caffeine can cause heart rate and rhythm changes as well as the more common effects of sleeplessness, irritability, nervousness, and anxiety. More minor effects include an increase in gastric secretions, potentially increasing hunger symptoms, as well as mild diuretic effects. Adults who consume more than 500 milligrams of caffeine daily may experience symptoms such as headache, nausea, and lethargy when caffeine is stopped or withdrawn. Many individuals consume caffeine regularly, but when they note some of the above symptoms, they will decrease their consumption until they are asymptomatic. Individuals suffering from caffeinism—severe symptoms caused by chronic consumption of high doses of caffeine—may be treated by slow or abrupt withdrawal. It should be noted that caffeine dependence is usually very difficult to cure. More than two-thirds of people who are treated for caffeinism relapse [5].

Caffeine dependence often is viewed as a minor issue, if one at all, in the field of substance abuse. However, it has been a major area of controversy among health care providers of pregnant women.

TABLE 12-6 Caffeine Content of Common Foods and Beverages

Food	Estimated Caffeine (mg)	Serving Size
Brewed coffee	180–250	10 oz
Instant coffee	70–320	10 oz
Decaffeinated coffee	2–12	10 oz
Tea	50–250	10 oz
Coca Cola (caffeinated)	46	12 oz (1 can)
Mountain Dew soft drink	54	12 oz (1 can)
Red Bull energy drink	80	8.3 oz
Chocolate bar	1–35	1 oz

Source: Hanson, G.R., Venturelli, P.J., and Fleckenstein, A.E. *Drugs and Society*, 7th ed. Sudbury, MA: Jones and Bartlett Publishers, Inc., 2002.

During pregnancy, the half-life of caffeine increases twofold to fourfold [9]. Thus a woman who experiences the caffeine "buzz" when she drinks six cups of coffee may find herself irritable, anxious, and tachycardic after only two cups when she is pregnant. Therefore, she may self-discontinue or decrease her intake. Not only is maternal tachycardia possible, but fetal tachycardia is also common after ingestion of high doses of caffeine. A woman should not imbibe a beverage containing caffeine for a few hours prior to fetal monitoring or a nonstress test.

In the past, there were several observational studies that suggested caffeine intake was associated with low birth weight infants. However, these early studies did not account for the factor of smoking. Subsequent studies were less clear about any association. Currently, the recommendation is that moderate use of caffeine poses no major issue to the birth weight of the newborn.

Studies about caffeine and spontaneous abortion have been inconsistent. In 1996, Dlugosz and colleagues suggested that caffeine might result in a higher risk of first trimester abortion [10]. Klebanoff and colleagues provided reassurance that if such a link existed, it was unlikely for women drinking six cups or less of coffee daily. They also found that caffeine metabolites are higher with women who smoke [11]. Cnattingius and colleagues may have provided more insight into the issue when they noted that many women who have nausea during pregnancy self-discontinue or decrease caffeine as a comfort measure. Considering that there is some research suggestion that gestational nausea tends to be associated with healthy pregnancies, women who are destined to abort may be the ones who continue to consume caffeine [12]. Additional studies are ongoing regarding caffeine and pregnancy. Caffeine is not contraindicated for breastfeeding women, but if sleeplessness and irritability are seen in the breastfed infant, the mother should decrease her intake.

Tobacco

More people die annually in the United States from tobacco-related illnesses than all deaths due to alcohol, cocaine, heroin, AIDS, suicides, homicides, fires, airplane and car crashes, fires, drowning, and the death penalty combined [3]. Smoking and passive, or secondary, smoking (inhaling the smoke of others) have received significant attention from public health agencies, with a resulting overall decrease in smoking nationwide. Figure 12-1 illustrates the general decrease in smoking juxtaposed with major public health and other historical events.

However, smoking remains a major health concern, especially for women and girls. In 1997 and 1998, 34.5 percent of American Indian or Alaskan Native, 23.5 percent of White, 21.9 percent of African American, 13.8 percent of Hispanic, and 11.2 percent Asian/Pacific Islander women were current smokers. Among high school seniors, past-month current smoking rates for girls decreased from 39.9 percent in 1977 to 25.8 percent in 1992, but again increased to 35.3 percent during 1997. In 2000, smoking prevalence declined again to 29.7 percent. However, that percentage is essentially the same as in 1988, eradicating any success of the 1990s in decreasing smoking among the group [13].

Nicotine is a powerful vasoconstrictor, and it increases blood pressure, heart rate, and blood levels of epinephrine and norepinephrine. Prolonged tobacco use is associated with cancers, particularly lung cancer in smokers but also cancer of the oropharynx and even the bladder. Women who smoke are at increased risk of cardiovascular and respiratory disease as well as experiencing menopause at an earlier age [14]. Few women smoked in the early twentieth century, but as more adopted the habit, lung cancer overtook breast cancer in relation to mortality, as illustrated in Figure 12-2. Today lung cancer is the most common cause of cancer death among females.

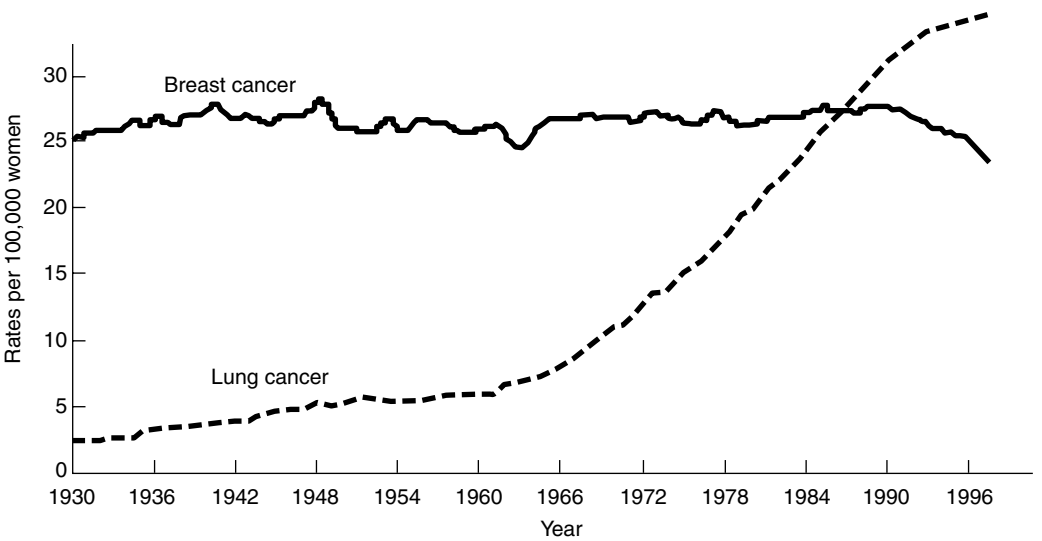

FIGURE 12-2 Age-adjusted death rates for lung cancer and breast cancer among women, from 1930–1997 in the United States.

Source: U.S. Surgeon General. *Women and Smoking*. Washington, DC: Government Printing Office, 2001.

Preventive health care for all women, especially adolescents, must include avoidance of tobacco and tobacco smoke (passive smoking). The woman who smokes a cigarette once or twice a month may be able to stop smoking when given information on the impact of smoking on her health and/or the health of her children. Information alone may not be enough for the pregnant woman with a history of years of heavy smoking.

Tobacco cessation is a major problem for most smokers. The majority of men and women who stop smoking, do so by the "cold turkey" method, without the aid of any drug or agent. However, individuals who are unable to self-discontinue smok-

ing may benefit from nicotine replacement therapy (NRT). No one method is best for all individuals, but any NRT appears to be better than placebos for recalcitrant smokers [15]. Combining NRT with buproprion (Zyban), a pharmaceutical that reduces nicotine craving, produces a higher cessation rate than either method alone [16]. A handout from the American Lung Association in regard to NRT and smoking cessation is found in the appendix at the end of this chapter. Table 12-7 provides a summary of evidence-based systematic reviews on various tobacco cessation methods [17–32].

The use of NRT during pregnancy is controversial. One study explored nicotine patches for six pregnant women in late pregnancy and found no adverse maternal or fetal effects. It was well received by the women, but the small sample size limits any conclusions [33]. According to evidence-based systematic review, smoking cessation programs in general during pregnancy appear to reduce smoking, which in turn lowers the incidence of low birthweight and preterm birth, but no effect was detected for very low birthweight or perinatal mortality [34].

Despite the adverse implications, smoking continues to be a relatively common activity in pregnancy, with an estimated 10 to 20 percent of pregnant women smoking. Of the various ethnic/racial groups, almost a quarter of Native American women smoke during pregnancy, as shown in Figure 12-3 [35].

Smoking prior to or early in pregnancy increases the risk of spontaneous abortion and abnormal placentation (including abruptio and placenta previa). During pregnancy, nicotine, carbon monoxide, and the various other components of cigarettes affect maternal circulation and cause constriction of uterine and placental vessels. In particular, carbon monoxide diminishes the oxygen carried to the fetus, culminating in growth restriction [36]. Studies of the placentas of smokers are able to isolate some metabolites from cigarettes, including nitrosaminioketone (NNK), a known carcinogen. It has been suggested that these biological components may make the intrauterine fetus more likely to engage in smoking as an adult and may explain in part why daughters whose mothers smoked during pregnancy seem to be more likely to smoke, even when their mothers stopped smoking shortly after their births [37].

Smoking during pregnancy is closely associated with low birth weight, decreased birth length, and preterm delivery. These fetal effects seem to be more pronounced if the woman combines cocaine with

TABLE 12-7 Results of Evidence-Based Systematic Reviews of Various Methods Used for Tobacco Cessation

Evidence of Effectiveness*
Antidepressants: bupropion (Zyban, Wellbutrin), nortriptyline (Sensaval)
Clonidine: Catapres
Community interventions for youth
Group therapy
Individual counseling
Nicotine replacement therapy (NRT)
Self-help groups
Insufficient Evidence of Effectiveness†
Aversion therapy
Anxiolytics: diazepam or Valium; meprobamate or Equanil, Meprospan and Miltown; metoprolol or Toprol; and oxpreonol or Trasicor
Exercise
Mecamylamine or Inversine (nicotine antagonist/antihypertensive)
Opiate antagonist: naloxone or Narcan
Telephone counseling
No Evidence of effectiveness
Acupuncture
Hypnosis
Lobeline (partial nicotine agonist)

* Degree of effectiveness is not the same for each intervention, but all demonstrate some effectiveness.

† Usually too few studies available.

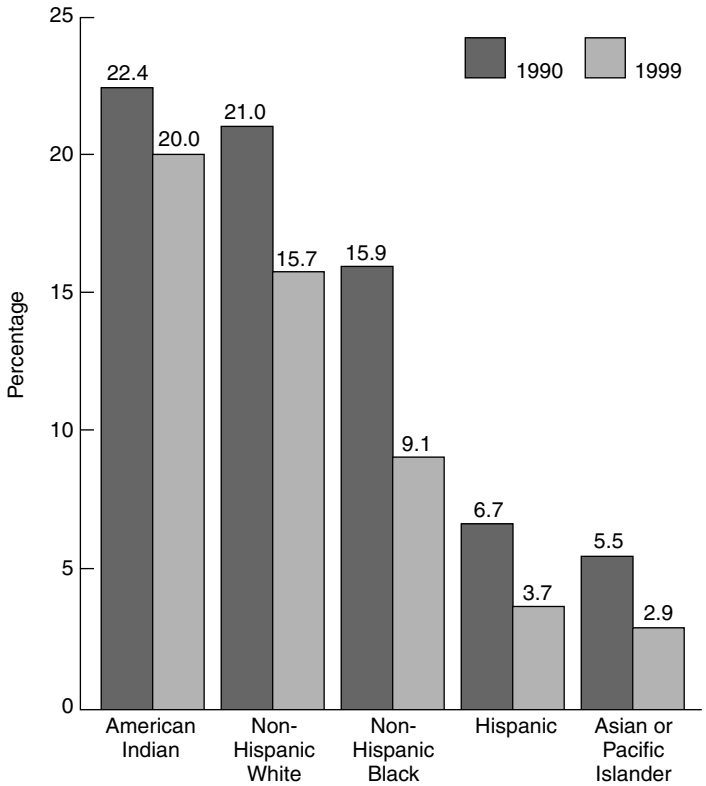

FIGURE 12-3 Percentage of mothers who smoked during pregnancy, by race and Hispanic origin: Selected reporting areas, 1990 and 1999.

Note: Excludes California, Indiana, New York State and South Dakota for 1999 and California, Indiana, New York, Oklahoma, and South Dakota for 1990.

Source: Matthews, T. J. Smoking during pregnancy in the 1990s. *Natl. Vital Statistics Rep*. 49(7):1–15 (November 19) 2001.

cigarettes [38]. Infants of women who smoke have a higher incidence of apnea and sudden infant death syndrome. The newborn effects may be a combination of intrauterine effects of smoking and the passive smoking during the newborn period.

Women should be helped to stop smoking not only during pregnancy but also during breastfeeding. The infant is at risk from ingestion of nicotine through breast milk and also from the effect of passive smoking. However, for women who are unable to completely stop smoking, breastfeeding should not be contraindicated. The myriad of benefits of breastfeeding should be available to children of smokers.

Marijuana

Of all the drugs involved in substance abuse, perhaps the most controversial is marijuana. Derived from the hemp plant, *Cannabis sativa*, it has a long history of use as a drug in Asia and Europe. In the United States, hemp was used in colonial times for making rope and apparel, and also for folk medicine. By the 1930s, marijuana began to be perceived as a narcotic, and a link was assumed with violent criminal acts. Its use rose with the counterculture movement in the 1960s and then it began to decline. By the 1990s, however, marijuana use unexpectedly rose. Two percent of women aged 26 and older reported using marijuana in 2000, which although relatively small, reflects an increase of more than 40 percent from the previous year [39].

Marijuana remains controversial today: Proponents for its use and legalization are engaged in ongoing battles with those who strongly disapprove of the drug. Advocates point out that there are no reports that anyone has ever died of a marijuana overdose and characterize the agent as a mild lifestyle drug, similar to if not less problematic than alcohol. Furthermore, they point to the use of medical marijuana for such therapy as reduction of nausea and vomiting. Opponents emphasize the hallucinogenic properties of the drug and even suggest that centuries ago assassins emerged from hashish cults. As usual, it is likely that the truth lies between.

Marijuana is classified as a hallucinogen, although the psychoactive ingredient tetrahydrocannabinol (THC) specifically has been found to have characteristics of stimulants, depressants, and psychedelic agents. The action of marijuana is similar to that of alcohol, with an initial stimulation followed by a sense of well-being or mild euphoria, called a "high." Marijuana causes tachycardia and decreased blood pressure, resulting in orthostatic hypotension. Marijuana smoke has effects on the lungs that are similar to those caused by tobacco smoke. Marijuana smoking increases respiratory diseases and produces more residue in the lungs than tobacco, particularly because the smoker tends to inhale more deeply. Smoking marijuana carries the same or an even greater risk for cancer as smoking tobacco.

Marijuana is considered a gateway drug, although most users do not go beyond marijuana, cigarettes, and/or alcohol. For most people, the high experienced with marijuana is mild, but it is associated with impaired memory, coordination, and critical thinking. Thus, it is dangerous for a pregnant woman or new mother to attempt to perform tasks requiring complex mental components. Although the high lasts a few hours, THC and the other metabolites are fat-soluble and may remain stored in adiposity for prolonged periods. Even THC in plasma can be found for several days after a single use [40].

Some research has linked a condition known as the amotivational syndrome with marijuana users. The syndrome involves poor productivity and lack of motivation and is seen in some heavy marijuana users. However, it is difficult to ascertain any cause and effect between the drug use and the syndrome since it has been argued that the syndrome may preexist use of the drug. The symptoms even may cause the individual to seek solace in marijuana use.

Over the last decade, controversy has swelled around the use of medicinal marijuana, which has been found to have some therapeutic effects against nausea, glaucoma, asthma, and muscle spasms as well as positive effects as an appetite stimulant, antidepressant, and antiseizure agent [41]. Although marijuana is an illicit drug, some locales have legalized the use for medical purposes and discussion is under way in many others.

Few programs exist specifically to help individuals discontinue marijuana. Research has not focused on various treatment modalities. Most reports of discontinuation are based on anecdotes or personal stories involving cold turkey or self-help groups.

During childbearing, no adverse effects of marijuana have been confirmed, although debate continues. Theoretically it may be surmised that smoking marijuana, like smoking cigarettes, would produce low birth weight infants. However, either due to secrecy about the drug habit, or consumption of less marijuana than tobacco, no link between the drug and small infants has been found. What is known is that marijuana commonly is used with other substances and the combination may alter the effects of the individual drugs. Marijuana potentiates the adverse effects of alcohol during pregnancy and may increase the risk of fetal alcohol syndrome.

According to the American Academy of Pediatrics (AAP), marijuana is a substance of abuse that should not be used by the lactating woman. Among the almost 400 research-based references on which their policy statement was based, the AAP Committee on Drugs noted only one study of marijuana during breastfeeding. No untoward effect was found, although it was noted that there possibly was a longer half-life for the psychoactive ingredients [42].

Alcohol

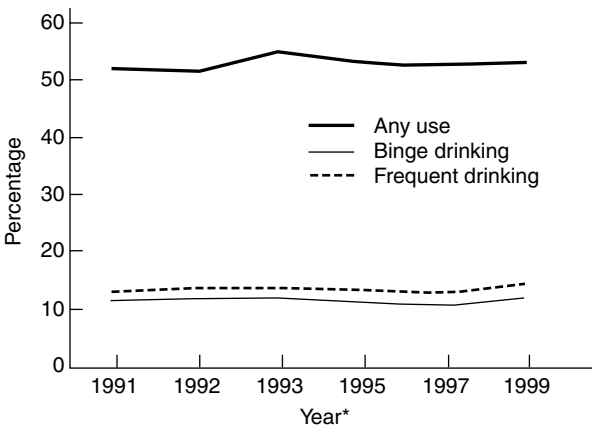
Alcohol consumption in the United States has a long and paradoxical history. In colonial times, alcohol use was viewed favorably. The slave trade involved the procurement of molasses, which was transported to New England where the manufacturing of rum became the area's largest and most profitable industry. Patent medicines liberally laced their concoctions with alcohol. By the mid-nineteenth century, the availability of alcohol and the number of alcoholics caused the temperance movement to gain momentum so that by the early twentieth century many locales had abstinence acts. In 1919 the Eighteenth Amendment to the U.S. Constitution abolished alcohol, but within the next decade criminally supported illegal trade in alcohol flourished. In 1933, the amendment was repealed. In the latter half of the twentieth century risks associated with alcohol again gained center stage when groups coalesced around drug and alcohol issues. For example, MADD (Mothers Against Drunk Drivers) emerged in 1980 as a powerful societal force in America.

Alcohol is a central nervous system depressant. After caffeine, it is the most widely used drug in the United States. Alcohol is a common ingredient in over-the-counter medications, especially liquid cough and cold preparations. Although men are

more likely than women to drink, according to the 2000 National Household Survey of Drug Abuse, more than 40 percent of women were current drinkers [43]. In contrast to men, women are more likely to start drinking heavily later in life. Working women tend to drink at the end of the work day, while women who do not work outside the home are more likely to drink throughout the day.

A basic problem with alcohol as a substance of abuse concerns how to define alcoholism. Some individuals drink essentially all the time, others binge drink or drink to excess only at certain times, and yet others are frequent drinkers but never to the degree of intoxication. The percentage of women who drink, binge drink, or frequently drink has remained relatively constant in the last decade, as illustrated in Figure 12-4 [44]. Alcoholism is described by the National Institute on Alcohol Abuse and Alcoholism as being composed of craving, tolerance, physical dependency, and loss of control [45]. The average alcoholic is not a skid row bum, but rather the typical working person.

As a chemical agent, alcohol is readily absorbed in the stomach and gastrointestinal system. In the healthy adult, more than 90 percent of ingested alcohol is metabolized in the liver. Intoxication occurs when more alcohol is ingested than can be metabolized. Tolerance develops when the metabolism has accommodated the chronic presence of alcohol and more alcohol is required to produce the same effects. Of particular concern is the cross-tolerance that can develop between alcohol and other central nervous system depressants. Individuals who develop a tolerance for alcohol may have a similar tolerance for sedatives and hypnotics, thereby requiring more drug to achieve an effect. Even when they have developed tolerance, women who abuse both alcohol and sedatives or hypnotics will show the additive effect of two central nervous system depressants.



*Data were not collected in 1994, 1996, and 1998.

FIGURE 12-4 Weighted percentage of nonpregnant women aged 18 to 44 years who reported alcohol use, from 1991 to 1999 in the United States.

Source: Centers for Disease Control and Prevention. Alcohol use among women of childbearing age: United States, 1991–1999. *MMWR* 51(13):273–276 (April 5) 2002.

Like other substances of abuse, there is no single effective treatment for alcoholism. Relapse is a constant issue for an alcoholic, especially since, unlike other addictive substances, alcohol is socially sanctioned. Withdrawal from alcohol is associated with severe withdrawal symptoms. Of the many treatment options for alcoholics, one of the oldest is the self-help group Alcoholics Anonymous (AA). This organization was founded approximately 75 years ago and sponsors meetings around the world. Offshoots of AA include groups for families and friends such as Al-Anon and Alateen. Local meeting locations can be found on the Web site for AA (www.alcoholics-anonymous.com). Research about the effectiveness of AA has been scant since the program is committed to the anonymity of its members. Membership is voluntary, and members tend to be homogeneous in terms of socioeconomic level, education, etc.

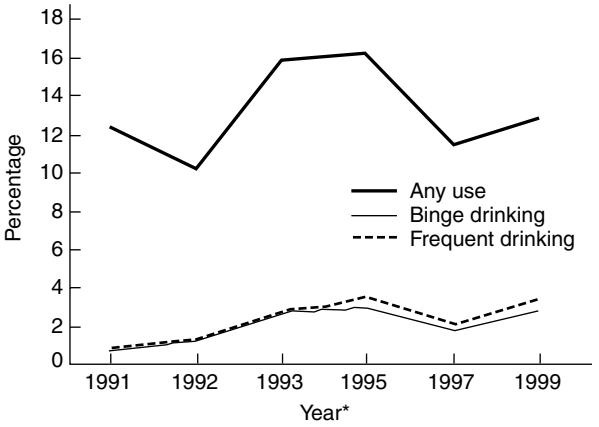
Detoxification units once were very popular but have been replaced largely by institutional rehabilitation settings where withdrawal can be medically supervised and therapeutic counseling begun. Opiate antagonists such as naloxone (Narcan) are sometimes used to augment therapy, and they have demonstrated some effectiveness, although recent evidence-based scientific review found the research insufficient to draw the conclusion that the pharmaceuticals should be part of management [46]. Disulfiram (Antabuse) is a deterrent drug that, when combined with alcohol, results in profound nausea and vomiting. It must be ingested by the alcoholic and may be of greatest value in deterring impulsive drinking.

During pregnancy, it is unclear how much alcohol intake, or what threshold, will result in abnormalities and features of fetal alcohol syndrome (FAS). The fetus seems to be the most vulnerable to alcohol during the first few weeks of pregnancy, usually before the woman suspects she is pregnant. Regular moderate (more than two mixed drinks, two glasses of wine, or two beers a day) to heavy alcohol consumption during any stage in pregnancy has been associated with central nervous system ab-

normalities, behavioral abnormalities, and features of fetal alcohol syndrome.

Because there is no known threshold, public health officials in the United States advocate total abstinence during pregnancy. In other countries, moderation or restriction of alcohol are the public politics. In spite of widespread public health campaigns to stop drinking in pregnancy, between 10 and 20 percent of American women continue to drink during pregnancy, with 2 to 4 percent frequently drinking or binge drinking, as illustrated in Figure 12-5 [47].

Alcohol consumption during pregnancy is associated with increased risk of second trimester spontaneous abortion and nutritional deficiency. Alcohol is teratogenic to the fetus; the degree of effect depends on the amount of alcohol consumed and the point in the pregnancy when it is consumed. Fetal alcohol syndrome manifests itself as prenatal and postnatal growth retardation, central nervous system abnormalities in the fetus and child, and abnormal facies. Classic fetal alcohol syndrome includes at least two of the following: microcephaly, micropthalmia, short palpebral fissure, and poorly developed philtrum. Figure 12-6 illustrates the facial features of a baby with FAS. Software programs have been developed to help health care professionals assess neonatal facies for the characteristics of FAS. Additional abnormalities associated with alcohol include cardiac septal defects, hemangiomas, abnormal oral cavities, and hypospadias.



*Data were not collected in 1994, 1996, and 1998.

FIGURE 12-5 Weighted percentage of pregnant women aged 18 to 44 years who reported alcohol use, from 1991 to 1999 in the United States.

Source: Centers for Disease Control and Prevention. Alcohol use among women of childbearing age: United States, 1991–1999. *MMWR* 51(13):273–276 (April 5) 2002.

The prevalence of FAS is unknown. According to the U.S. National Center for Birth Defects and Disabilities, prevalence rates for the United States range from 0.3 to 2.2 cases per 1000 births. Therefore, every year, between 1200 and 8800 babies are born with FAS. Babies may have some, but not all of the manifestations of FAS. These children are said to have alcohol-related neurodevelopmental disorder (ARND), which shares some but not all of the characteristics of FAS [48].

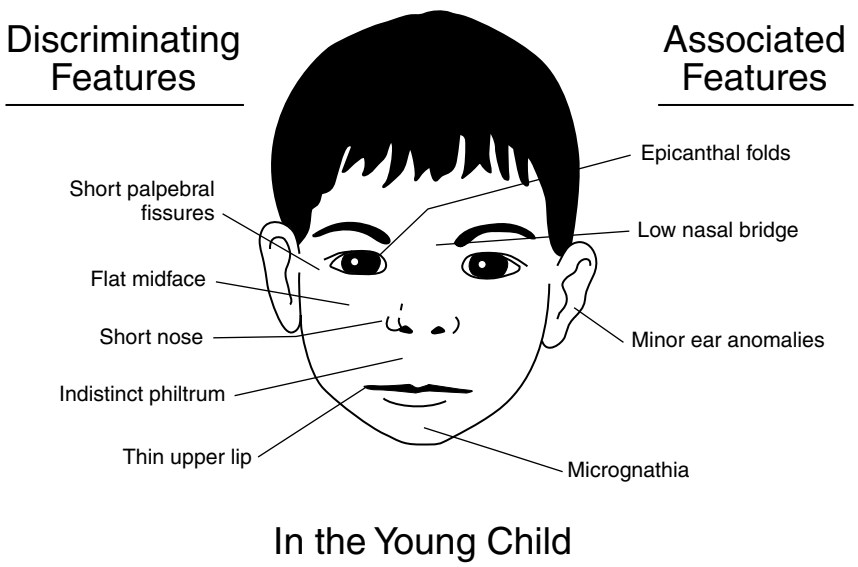


FIGURE 12-6 Facial characteristics of a child with fetal alcohol syndrome.

Women should be counseled before pregnancy to avoid alcohol if they are planning a pregnancy or if pregnancy is suspected. During pregnancy, the woman abusing or addicted to alcohol should be encouraged to reduce her consumption with the goal of total abstinence. A safe level of alcohol consumption during pregnancy is unknown.

According to the Academy of Pediatrics Committee on Drugs, alcohol is compatible with breastfeeding. However, neonatal drowsiness, diaphoresis, deep sleep, weakness, decrease in linear growth, and abnormal weight gain have been reported when mothers drink large amounts of alcohol. Maternal use may also decrease the milk ejection reflex. Contrary to popular thought, alcohol tends to change the scent/taste of the milk, causing babies to consume less [49].

Cocaine

Until recently, it was believed that cocaine did not cause dependency because withdrawal symptoms were so minor, especially compared to alcohol. Yet the popularity of cocaine, particularly since the 1980s, has resulted in a new respect for the serious nature of cocaine addiction. Cocaine has been available for centuries in the form of coca leaves. However, cocaine derived directly from the leaves tends to be mild. In the late nineteenth century, chemists were able to remove the active ingredient from the leaf, purify it, and obtain a far more potent version. Cocaine became a common ingredient in patent medicines, and even Sigmund Freud characterized it as a magical cure-all. Within the next several decades, the addictive properties of cocaine were recognized and it fell into disuse. With the advent of the 1980s, cocaine developed a cachet among prominent actors, athletes, and other celebrities. Within the decade, individuals at all socioeconomic levels were using it.

A sophisticated infrastructure exists to move cocaine throughout the world, and especially into America. The U.S./Mexico border is the primary point of entry for cocaine shipments into the United States. The price of a kilogram of cocaine in a major metropolitan area can be as high as $25,000. However, crack cocaine, or "rock," is relatively inexpensive with small amounts available from $5 to $25, making it within the reach of most people [50].

A central nervous system stimulant, cocaine can be taken in virtually every form—orally, intravenously, subcutaneously, and inhaled through the nose—and it can also be smoked, a method known as "freebasing." A particularly powerful and pure form of cocaine is "crack," which is inhaled and/or smoked. The euphoria brought on by crack is rapid and profound. The danger is that cocaine consumed by freebasing or in crack form is purer than other forms, and the abuser may inadvertently overdose.

Effects of cocaine ingestion include tachycardia and cardiac dysrhythmia, vasoconstriction, hypertension, hyperthermia, and seizures. Complications as a result of the vascular effects of cocaine include myocardial infarction, cerebrovascular accidents, and death. A woman who has recently used cocaine may be misdiagnosed as preeclamptic or eclamptic during pregnancy [51].

Cocaine withdrawal does exist, and the symptoms are related to the duration and intensity of use. Symptoms of withdrawal include depression, sleep disorders, and agitation. Three phases have been identified during recovery from cocaine dependence: (1) crash, (2) withdrawal, and (3) extinction. A variety of drugs have been suggested to aid in therapy during this time. None of the three major pharmaceuticals tried—antidepressants, dopamine agonists, and the antiseizure drug carbamazepine (e.g., Tegretol)—demonstrated effectiveness in randomized clinical trials [52–54].

During pregnancy, cocaine use is associated with spontaneous abortion, preterm labor and delivery, abruptio placentae, rapid labor and delivery, fetal intolerance to labor, low birth weight, and fetal death. Cocaine has been linked with fetal bowel atresias and possible congenital malformations of heart, limbs, face, and GU tract as well as growth restriction, although no clear teratogenic link has been established. Women who abuse cocaine need the full services of a drug treatment program and a health care facility prepared to manage the complications of labor, delivery, and the newborn.

Newborns exposed to cocaine have a higher incidence of congenital malformations in general, although unlike alcohol no particular facies have been identified. Behavioral abnormalities, especially short sleep cycles and irritability, have been noted. Babies exposed to cocaine in utero have a higher risk of sudden infant death syndrome. Intrauterine exposure to cocaine has been linked to cognitive delays, although not necessarily mental retardation [55]. Long-term effects are unknown. Withdrawal in the newborns of cocaine-addicted mothers is milder than in babies born addicted to opiates, but it still exists. Symptoms of withdrawal in the newborn include irritability, gastrointestinal problems, and respiratory problems.

Breastfed neonates are at risk if their mothers use cocaine. Cocaine intoxication manifesting itself by neonatal irritability, vomiting, diarrhea, tremulousness, and seizures has been reported. Thus it is important that the breastfeeding mother refrain from cocaine.

Amphetamines

Amphetamines are potent synthetic central nervous system stimulants that are essentially a chemical product of the twentieth century. Originally they were used therapeutically as decongestants, although they no longer are indicated for that use. Today, they are FDA approved for treatment of narcolepsy, attention deficit hyperactivity disorder, and weight reduction.

Amphetamines can be synthesized in kitchen laboratories, and in some parts of the country they are more popular than cocaine. One type, a methamphetamine known as speed, tends to be less expensive and longer acting than cocaine. Amphetamines can be ingested orally or intravenously or they can be smoked. A smokable form of methamphetamine commonly is called ice. In recent years, a designer amphetamine, methylenedioxymethamphetamine—also known as MDMA or Ecstasy—has developed a following among adolescents and young adults due to its availability at clubs and dance parties such as raves. It has been estimated that almost one-third of people aged 16 to 25 in England have used Ecstasy [56].

People who abuse amphetamines often do so to enhance the effects of other drugs such as cocaine. The risks of amphetamines depend upon amount and duration. These risks include the increased stress on the cardiovascular system, like cocaine, as well as psychological symptoms. For example, decreased fatigue, irritability, and talkativeness can evolve into apprehension, fearfulness, paranoia, hallucinations, and psychosis.

Treatment for amphetamine addiction is similar to other general treatments. Support groups and therapy to help modify behaviors are among the most common. Withdrawal has been estimated to occur in more than 80 percent of amphetamine users. No pharmaceutical treatment or model has been found to be effective, and supportive therapy remains the standard for withdrawal and amphetamine psychosis [57, 58]. Treatment during the recovery phase is also limited. There is some evidence that fluoxetine (Prozac) may decrease cravings to some degree and imipramine (Tofranil) may increase duration of adherence to treatment [59].

In spite of the growing popularity of amphetamines, little has been published about maternal and fetal effects. It is generally accepted that fetal and newborn effects are similar to those associated with cocaine. A breastfed baby of a mother using amphetamines will often demonstrate similar signs of irritability and sleeplessness that the woman manifests. More research is needed in this area.

Narcotics/Opiates

The term *narcotic* is from a Greek word meaning deadening or numbing. In the past the word has been applied liberally to a variety of drugs including heroin, marijuana, and cocaine. Today, many scientists advocate use of the term *opiate* instead of *narcotic* because opiates have a clearer pharmaceutical definition. Functioning as central nervous system depressants that act on opiate receptors opiates, or opioids, include heroin, morphine, codeine, meperidine (Demerol), fentanyl (Sublimaze), hydromorphone (Dilaudid), methadone (Methadose), nalbuphine (Nubain), oxycodone (OxyContin), and oxymorphone (Numorphan). A commonly abused drug is the combination of acetaminophen and hydrocodone known as Vicodin.

Natural opiates are derived from the opium poppy, *Papaver somniferum*. The addictive properties of opium have been known for centuries, and in the United States they were used for medical analgesia as well as in many folk remedies or patent medicines. Heroin was first introduced into the country in the late 1800s as a cough suppressant, and as an alternative to opium for those addicted. Since heroin enters the brain more quickly than opium, it rapidly replaced opium as the drug of choice for abuse, and it was banned from medical practice in 1924. Unlike other substances that are used only for abuse, opiates such as meperidine, morphine, and others continue to be major therapeutic agents.

Opiates are primarily taken intravenously, although a few are usually taken orally. Since the 1980s, a smokable form of heroin has been available, sometimes called Persian heroin. The risks of the intravenous forms of the drugs are compounded by the risks associated with shared needles: hepatitis, human immunodeficiency virus, endocarditis, abscess, and cellulitis. Women dependent on opiates are at high risk for sexually transmitted infections, severe nutritional deficiency, and polydrug use. The acute dangers in opiate use are overdose and withdrawal.

Symptoms of withdrawal include anxiety, yawning, perspiring, pupil dilation, insomnia, hypertension, hyperglycemia, diarrhea, and vomiting. The symptoms vary according to duration and to the purity of the drug involved. In the last several years, purity of heroin has increased, and the price has dropped. The advent of smokable and sniffable heroin introduced the drug to groups that previously had avoided it in an intravenous form.

Treatment of opiate dependency and addiction, as with other substances, is challenging. However, treatment programs for most other substances of abuse strive for total cessation. Heroin addiction in particular is refractory, and for more than a quarter of a century many heroin addicts have substituted a synthetic opiate, methadone, for heroin. Methadone is FDA approved as an opiate maintenance therapy although there is no single standard procedure for use [60]. Other similar preparations have been suggested, including LAAM (L-alpha-acetyl-methadol), which is long-lasting and requires only three weekly administrations, and buprenorphine (Buprenex, Subutex), an opiate agonist/antagonist that substitutes for the opiate but has minimal issues with dependency. Naltrexone (ReVia) has also been suggested for maintenance treatment, but studies are insufficient at this time to draw conclusions about effectiveness [61].

Systematic reviews evaluating withdrawal treatments have found that naltrexone (ReVia), buprenorphine (Buprenex, Subutex), and clonidine (Catapres) appear to ameliorate the signs and symptoms of withdrawal from opiates [62, 63]. When treatment attempts to wean people from opiates by the use of methadone or clonidine (Catapres), both seem effective, although side effects appear less with methadone and people remain in treatment longer [64].

Withdrawal from opiates during pregnancy has been associated with fetal distress and fetal death. Chronic opiate use is associated with low birth weight and small head circumference in the newborn. Withdrawal in the newborn requires supportive as well as drug therapy. Usually women who abuse opiates, such as heroin, will have a child born dependent upon the agents. Most neonates demonstrate withdrawal symptoms between six hours and eight days after birth, although the timing seems to be associated with type and dose of opiate involved. Neonatal symptoms tend to be multisystemic and usually involve prolonged neurological changes, including hyperirritability, respiratory distress, tremors, and vasomotor irritability. Treatment combines nonpharmaceutical and pharmaceutical interventions such as loose swaddling, a quite environment, and a diluted opiate like paregoric that is administered by slowly decreasing the dosage. Newborns who have been exposed to opiates are considered at risk for developmental and cognitive problems and should have early and continued developmental follow-up.

The midwife should consult with a physician regarding management and possible detoxification or conversion to methadone for the opiate-addicted woman. The woman may be offered a methadone program during pregnancy so that the drug received can be regulated and the risks of overdose and withdrawal can be avoided. The use of methadone is controversial because the newborn's withdrawal from methadone is often more severe than withdrawal from opiates and because the woman may use the methadone in addition to illicit drugs.

During labor, care must be taken to watch for signs of withdrawal, including vomiting, diarrhea, anxiety, restlessness, sweating, and abdominal cramping. Because these symptoms can also be normal findings in labor, careful evaluation is required. On her admission to labor and delivery, it is essential to question the woman carefully to ascertain when she last ingested opiates. If symptoms consistent with withdrawal begin, prompt assessment and provision of narcotic are required. Adequate drug levels need to be maintained to avoid withdrawal and the concomitant risk to the mother and fetus. When opiate use or addiction is suspected, butorphanol (Stadol) should be avoided in labor because this may precipitate withdrawal in the woman who has been using opiates.

Appendix A

Health Education Fact Sheet from the American Lung Association on Nicotine Replacement Therapy (NRT)

Nicotine replacement products help relieve some of the withdrawal symptoms people experience when they quit smoking. Three nicotine replacement products are currently available over-the-counter in the United States, including two nicotine patches and nicotine gum.

Nicotine nasal spray and a nicotine inhaler are available only by prescription. A new non-nicotine pill also is available as a smoking cessation treat-

ment option. To be most effective, nicotine replacement products should be used in conjunction with a behavior change program.

The nicotine patch releases a constant amount of nicotine in the body; the nicotine dissolves right through the skin and enters the body. The patches are similar to adhesive bandages and are available in different shapes and sizes. A larger patch delivers more nicotine through the skin.

Less nicotine is obtained through the patch than in cigarettes. The patch also does not contain all the tars and poisonous gases that are found in cigarettes.

Most of the patch products are changed once every 24 hours. One particular patch is worn only during the waking hours and is removed during sleep.

Studies have shown that it is much easier to give up the patch than it would be to give up cigarettes for two reasons. First, people usually develop cravings for things that provide immediate satisfaction, such as chocolate. With the patch, the nicotine level in the body stays relatively constant day after day. There is not immediate satisfaction, so there is little craving for a patch. Second, anything people do often, such as smoking, becomes a habit; since you apply the patch only once a day, there is no strong habit to break.

The goal in using nicotine medications is to stop smoking completely. If you plan to take nicotine medications, begin using them on the day you quit. If you continue to have strong urges to smoke or are struggling to stop smoking completely, ask your health care provider about additional help.

Some side effects from wearing the patch can include

- Headaches
- Dizziness
- Upset stomach
- Weakness
- Blurred vision
- Vivid dreams
- Mild itching and burning on the skin
- Diarrhea

Wearing the nicotine patch lessens chances of suffering from several of the major smoking withdrawal symptoms such as tenseness, irritability, drowsiness, and lack of concentration.

Nicotine gum contains enough nicotine to reduce the urge to smoke. The over-the-counter gum is available in the same strength as the original prescription product, 2 milligrams (for smokers of 24 or fewer cigarettes each day) and 4 milligrams (for smokers of 25 or more cigarettes each day).

Like nicotine patches, nicotine gum helps take the edge off cigarette cravings without providing the tars and poisonous gases found in cigarettes. It is a temporary aid that reduces symptoms of nicotine withdrawal after quitting smoking.

Nicotine gum must be used properly in order to be effective. Steps for nicotine gum users to follow include:

> Stop all smoking when beginning the nicotine gum therapy. Do not eat or drink for 15 minutes before using, or while chewing the gum (some beverages can reduce its effectiveness). Chew the gum slowly on and off for 30 minutes to release most of the nicotine. Parking the gum between the cheek and gum allows the absorption of nicotine into the lining of the cheek. Chew enough gum to reduce withdrawal symptoms (10 to 15 pieces a day but no more than 30 a day). Use the gum every day for about a month or so, then start to reduce the number of pieces you chew a day, chewing only what you need to avoid withdrawal symptoms. Discontinue use of gum after three months.

Nicotine nasal spray, dispensed from a pump bottle, relieves cravings for a cigarette. It delivers nicotine to the nasal membranes and reaches the bloodstream faster than any other NRT products. It is available by prescription.

The nicotine inhaler consists of a plastic cylinder containing a cartridge that delivers nicotine when you puff on it. Although similar in appearance to a cigarette, the inhaler delivers nicotine into the mouth, not the lung, and enters the body much more slowly than the nicotine in cigarettes. The nicotine inhaler is available only by prescription.

A non-nicotine pill, bupropion hydrochloride (Zyban) was approved in 1997 to help smokers quit. The drug, available by prescription only, is also sold as an antidepressant under the name Wellbutrin.

It is necessary with all types of nicotine replacement therapy to follow the health care provider's orders and use these products only as prescribed and/or according to labeling. These products can also be dangerous for pregnant women.

CHAPTER

13

Health Care of Midlife and Aging Women

MARY ELLEN ROUSSEAU, CNM, MS, FACNM

Menopause is a normal life event, not a disease. The Massachusetts Women's Health Study—the largest and most comprehensive prospective, longitudinal study of middle-aged women, conducted between 1981 and 1986—demonstrates that the menopause is not a negative experience for most women [1]. Midlife, though, is a time of change. Only the multiple influences of biology, psychology, and sociocultural factors can explain many of the behavioral complaints that occur. The normalcy of the process cannot be overemphasized. Changes in menstrual function are not symbols of ominous change; understanding the physiologic reasons for these changes will do much to reinforce a healthy, normal attitude toward menopause [2].

For many decades the medicalization of menopause has caused Western society to perceive the cessation of menses in a very negative light, as a time of impending decline rather than a developmental milestone that promises a positive time of life with new opportunities. Many women with questions or concerns are told simply that they may either choose hormone therapy or not. There has been little opportunity for unfettered exchange of information and alternative therapies such as lifestyle modifications to reduce the symptoms and risk factors for diseases occurring decades after menopause.

Definitions

Margaret Lock suggests that the term *menopause* should be restricted to the actual event—the end of menstruation—and that it describes, not a condition, but rather a physical and psychological change that takes place at a certain time in a woman's life [3].

Menopause is the permanent cessation of menses. The prefix *men-* is derived from the Greek word *men*, which refers to the menstrual cycle; *-pause*, a Latin word, signifies the cessation of the process. Since cessation of menstruation affects only a few days in a woman's life, it is worthwhile to think of menopause more broadly, as the period of time during which women define themselves to be in the "change." This refers to the period when social, physiological, or psychological changes are occurring—a phase that can last from a few months to more than a decade. The physiological changes include a series of hormonal and clinical alterations reflecting declining ovarian function. Gilligan suggests using the term *the change*, because "the change of life" implies women's capacity for change during this period and suggests that this is the time when women learn to care for themselves after having always taken care of others [4].

The *climacteric*, the name of the transition period as a whole, is defined as the phase of the aging process during which a woman passes from the reproductive to the nonreproductive stage. Since medieval times the term *climacteric* was used to express the idea of a transition at midlife, making no distinction between men and women. The climacteric (derived from the Greek word for rung on a ladder) is usually the seven to ten years of physiological change in the reproductive system that culminates in the last menstrual period. *Premenopause* is the part

of the climacteric before the menopause occurs—the time during which the menstrual cycle is likely to be irregular and during which time women may experience climacteric symptoms such as hot flashes. *Postmenopause* is that phase after menopause with the end point not well defined—until symptoms disappear or until the end of life. *Perimenopause* is the term applied to the several years prior to and following the cessation of menses.

Age at Menopause

In the Massachusetts Women's Health Study, women who reported irregular menstrual periods were considered to be perimenopausal [5]. The authors found the median age for the onset of this time period was 47.5 years and the premenopausal period was approximately four years' duration. The median age for menopause for this group of women was 51.3 years, with only current smoking found to be related to an earlier menopause (by 1.5 years). The range of menopause is between the ages of 48 and 55 for most women. Other authors also report the average age at which menopause occurs in the United States as 51 years [6, 7].

Approximately 1 percent of women will undergo menopause prior to age 40, when it is considered premature ovarian failure rather than menopause [8]. Women who have had an abdominal hysterectomy without oophorectomy may also be at risk for premature ovarian failure, presumably due to compromise of the ovarian vasculature [9]. Genetic inheritance is thought to play the most important role in the etiology of premature ovarian failure [10].

Adult Development, Society, and Menopause

According to Neugarten and Kraines, reflection and self-evaluation become characteristic for both sexes during the fifth decade [11]. They report that men become more affiliative and nurturant, and increasingly abstract and cognitive, while women become more comfortable with aggressive and egocentric impulses and deal with the environment in increasingly affective and expressive terms. Neugarten was one of the first investigators of psychology of the menopause and its relationship to midlife. She and her coworkers found that biological events were not necessarily the important events in understanding the psychology of adulthood.

Menopause is symbolic because it is colored by two processes: (1) the change from reproductive to postreproductive life, and (2) aging [12]. The emphasis in the literature on menopause as loss has meant that the developmental context of midlife has been undervalued and consequently, underevaluated. Benedek [13] described menopause as a time of freeing of constructive energy, which is seen in the postmenopausal energy that supports many women's activities. Menopause tends to be hardest for women who have defined themselves solely in terms of childbearing and who have been cut off from other options [14]. For those women with options, however, the menopause can be a time of renewed energy, new interests, and new definitions.

If we conceptualize menopause as a deficiency disease, related to the estrogen effects on cardiovascular and bone health, then we are left with the problem of having no way to think of women's functioning other than in reproductive terms [12]. Broadening the role of menopause and its interrelationships with such events as family development, the growth of the capacity to work, and physical and psychological changes, can lead to a deeper, and more functional view of menopause.

Medicalization of Menopause

Symptoms, Signs, or Age-Related Change?

What is normal and what is defined as disease, as well as the way individuals subjectively experience and report symptoms, vary through time and space [15]. Lifestyle transitions including birth and menopause have increasingly come under medical management and although it has sometimes resulted in the improved health and well-being of women, the focus has been mostly on pathology. While there is often room for improvement in any woman's health, most women entering midlife are healthy. At the same time, most assumptions thought to be universal about menopause were drawn from research on small nonrepresentative samples in clinical settings—findings that were then extrapolated inappropriately to the population of women at large [16]. The normal midlife changes may not be a revolutionary transition at all [15, 17–20] but rather a time of changing hormones, relationships, and roles during which most women get along quite well.

During the nineteenth century, the dominant view was that menopause was a physiological crisis leading to physical and psychological diseases such as tumors, depression, hysteria, and insanity [21]. Scientific explanations focused on women's education, past attempts at contraception or abortion, undue sexual indulgence, insufficient devotion to husband or children, or advocacy of women's suffrage [22]. In other words, a crisis occurred under certain conditions and the most important of these were social—a woman's adherence to or departure from her prescribed social role [23]. Long after that era, the definition and meaning of menopause have been negotiated and renegotiated regularly; the challenges to this definition have come from both within and outside the medical community and continue to raise questions, such as what the symptoms of menopause are.

Sociologists have begun to study the origins and consequences of defining and treating human experiences as medical problems (medicalization of menopause, pregnancy, homosexuality, alcoholism, hyperactivity etc.), drawing attention to the political and social elements of medicine [23]. In 1972, Zola warned that "medicine is becoming a major institution of social control . . . the new repository of truth, the place where absolute and often final judgments are made by supposedly morally neutral and objective experts" [24]. MacPherson [22] looks upon the medicalization of menopause as a social construct that has been adapted and changed over time and suggests that by conceptualizing menopause this way, medical researchers are in search of an intervention, hormonal or otherwise, to prevent or cure a health problem.

After synthetic estrogen was developed in 1938, physicians agreed that menopausal women should be managed by physicians and that medical intervention was a given. Medicine thereby defined menopause as a disease, rather than as a cause of disease, which the physicians of the nineteenth century had believed. In 1966, Robert A. Wilson, author of *Feminine Forever*, suggested that readers "think of menopause as a deficiency disease . . . similar to diabetes: caused by a lack of insulin or estrogen" [25].

In 1975, papers in the *New England Journal of Medicine* linked estrogen use with endometrial cancer [26–28], causing a 40 percent decline in the number of estrogen prescriptions, which had risen since the publication of *Feminine Forever*. This decline led medical researchers and pharmaceutical companies to put forth an effort to "rehabilitate" estrogen therapy by demonstrating that the benefits of use outweighed the risks [29]. During the mid-1970s progestogen, a progesterone-like substance, was added to the therapeutic regime to combat the carcinogenic effects of estrogen on the endometrium. The term *hormone replacement therapy* (HRT) replaced *estrogen replacement therapy* (ERT) to designate the added protection against the problem of unopposed estrogen stimulating growth of the uterine lining.

Since the 1980s, menopause has been investigated as a cause of chronic diseases formerly associated with aging [22]. Health researchers and physicians have rationalized use of hormone therapy as a prevention strategy for heart disease and osteoporosis. MacPherson suggests that, in contrast, nurses have maintained more distance from the medicalization of menopause as a social construct. She urges nurses to remain skeptical about the neutrality and objectivity of menopause research, which has commonly used clinical samples unrepresentative of healthy midlife women [22].

Today, medical institutions, pharmaceutical companies, and the mass media provide an abundance of information, both to health care providers and to women encountering the menopause transition. A blitz of input from scientific, technological and medical sources, however, may actually cut women off from traditional sources of information [30]. When women rely only on experts, they are left with no role models for dealing with life-stage transitions [31]. Under such conditions, women can become more vulnerable to messages from medical institutions or pharmaceutical companies whose main interest may be more in the profit margin than in women's health and well-being. New forums need to be developed to allow women a place and time for sharing their midlife experiences and for passing these on to the next generation.

The only universal "change" is the cessation of menstruation. This results from anovulation, which itself results from a depleted supply of follicles. Lock suggests that the assumption that menopause is a universal experience at *any* level should be subjected to serious questioning and that it is essential to allow women to define their own menopausal status [32]. She cautions that the definitions of climacteric symptoms are culturally determined to a great degree and generalizing from the experiences of one group of women to other groups can lead in unproductive directions and muddy understanding of the menopause transition. Until recently, it was

assumed that medical knowledge was culturally independent because of its scientific origin [3]. However, the extent to which biomedicine is a cultural product is now acknowledged [33]. Some authors define the changes accompanying menopause rather narrowly, to include only vasomotor symptoms and vaginal dryness, while others attribute many experiential, behavioral, and somatic problems as well as psychological symptoms to falling estrogen levels [3]. It has been claimed that because life expectancy has increased in the past 100 years, the existence of postmenopausal women is a recent observation. Thus the endocrine deficiency model has been developed for this new group of women who now live past menopause, leading to the prescription of hormone therapy as an immunization against heart disease and osteoporosis. In the past such diseases were ascribed to problems of aging rather than menopause. Contrary anthropologic evidence from 100,000 years ago, however, shows that many females who survived childhood and childbearing lived to well beyond menopause [34]. Menopause has not yet been subjected to the same medicalization as childbirth because most women do not seek medical help for this life change [35]. Health care providers must be wary of the attempt to define women as an expanding market for drugs, cosmetics, and plastic surgery. Care must be taken so that various populations of postmenopausal women are not considered equally at risk for heart disease, osteoporosis, or other late-onset chronic diseases. At this time recommendations for wholesale treatment of women with hormone replacement are not supported by current science.

In contrast to clinical medical research literature, the social science and epidemiology research literature emphasize that most women go through menopause with little or no disturbance and usually do not seek help at this time [15]. The discrepancies between the social science literature and the medical literature can be explained in part by the use of two different populations. Clinical trials have for the most part used clinical populations. Social scientists like McKinlay and McKinlay in the Massachusetts Women's Health Study, on the other hand, draw their samples from the whole population [5]. Lock [15] explains that these competing explanations of menopause contribute to the fragmentation of a complex and poorly understood event because the various arguments are rooted in certain unexamined assumptions and values. Symptoms must be placed in the context of a woman's culture, and the inherent biases of the researchers must be recognized.

Hormone Therapy

After 1975, standard postmenopausal treatment with hormones included the addition of progestins to offer protection against the risk of estrogen's effects upon the endometrium. Pharmaceutical companies and the medical establishment began to shift their resources to the discovery and promotion of other benefits of exogenous hormones—for example, prevention of diseases such as osteoporosis and cardiovascular disease [31]. Prior to that time, women usually decided to use hormone therapy for short-term symptom relief of menopausal discomforts such as hot flashes or vaginal dryness. With new information about the protective effects of exogenous estrogen on the skeletal system in the prevention of osteoporosis and on the cardiac system, women were advised to use hormones as a prophylaxis against diseases, osteoporosis, and heart disease, which were formerly associated with aging, not menopause. During the 1980s and 1990s, women were advised to begin hormones at the onset of menopause to obtain protection for diseases that may or may not affect them many decades in the future. In 1994, the incidence of hormone use was estimated: 16 percent African-American or Latina [36], 22 percent in premenopausal women [37], 32 percent in postmenopausal women [38], and 6 percent in women over the age of 65 [39]. The mean duration of use is less than one year [40, 41]. It is evident that women are not using HRT for the long run; women still consider short-term symptom control the main reason for hormone use [42]. Prior to results in July 2002 of the Women's Health Initiative, women had been sometimes made to feel guilty or neglectful if they did not choose hormone therapy in order to protect themselves against osteoporosis and heart disease.

This attitude is engendered by the fact that medical research and its scientific base are seen as universally correct. In fact, most research on hormone use in midlife women has been on clinical populations (i.e., women seeking care), which give biased results. Women in these studies frequently have been screened out prior to the trials if they have histories of cardiac disease or other factors that potentially confound the results. This can lead to study populations being generally healthier than control groups [43]. Women who have used HRT in the past have been found to be thinner and to have higher high-density lipoprotein (HDL), both of which can contribute to lower rates of heart disease [44]. In many cases, women who participate in clin-

ical trials tend to interface with the medical establishment more than the general population and therefore are potentially either more symptomatic or have greater access to medical care when compared to women who are not studied. Thus the two groups can be very dissimilar, and generalizing from the study groups to the general population is not only useless, it can be harmful when potential side effects from medical interventions are not considered in equal light. Risk factors such as lifestyle, poverty, and chronic disease can put women at risk for heart disease to a greater degree than menopause or hormone status [45]. Furthermore, research funding is usually greater for studies that may lead to profits from intervention; studies on options such as making lifestyle changes often have to struggle for any funding whatsoever.

The Women's Health Initiative (WHI) is a randomized controlled primary prevention trial (planned duration, 8.5 years) in which 16,608 postmenopausal women age 50 to 79 with an intact uterus at baseline were recruited by 40 U.S. clinical centers between 1993 and 1998. In May 2002 the WHI was stopped because of unacceptable increased risks for breast cancer, coronary heart disease, stroke, and pulmonary embolism. The authors suggested that clinicians stop prescribing estrogen plus progestin for long-term prevention because of the increased risks. When menopause is defined as a "deficiency disease," menopause as a disease legitimizes and condones the use of risk/benefit, usually used to assess risks versus harms in sick people, for well individuals [250]. When treating women with a disease, the risk-benefit ratio is changed because the risks become acceptable in light of the disease process. Just like the need to see pregnancy and birth as normal physiological processes, it is the role of the midwife to support women through a natural menopause without causing harm. The results from the WHI provide strong evidence that the risks do not justify use for long-term protection, even though the absolute risks are low [46].

Lifestyle changes have been undervalued by women and providers yet they can afford relief for short-term physical or psychosocial changes, provide protection against osteoporosis, and provide protection against cardiovascular disease.

Midwives need to understand their own biases and prejudices for or against hormone therapy during the menopausal years. As with midwifery care for women of other ages, its provision during the climacteric needs to be individualized by the midwife. Women bring their own biases to health care that must be acknowledged. Fears of breast cancer or of "unnatural" interventions are legitimate reasons for making health decisions. Prescriptions for menopausal hormone treatments often go unfilled at pharmacies because women's worries, concerns, or questions have not been adequately addressed. The two most common reasons found for not filling prescriptions or for discontinuance of hormone use include fear of cancer and vaginal bleeding [47], both of which should be addressed prior to initiation of HRT.

Endocrinology

From the standpoint of the ovary, menopause is not a sudden event. It is instead the cumulative result of many events, some of which begin in fetal life [48] and are followed by others that continue through adolescence, pregnancy, and menopause. The loss of follicles occurring at a steady rate until near menopause is primarily due to atresia, not ovulation, since most women start with 2 to 6 million follicles during fetal life but will ovulate only 480 times during their reproductive years [49].

When women are in their forties, anovulation becomes more characteristic [2]. Beginning six to seven years preceding this development, women often experience increasing menstrual cycle length [50]. The development of fewer follicles accompanies this phenomenon, until eventually the supply is depleted [49]. Menstrual cycle change is marked by elevated follicle-stimulating hormone (FSH) levels and decreased levels of inhibin but normal levels of estradiol and luteinizing hormone (LH) [51]. Estradiol levels do not gradually wane in the perimenopause years but remain in the normal range until follicular growth and development halt [2]. Women can have elevated FSH levels of >30 mIU/L despite continued menstrual cycles, with occasional corpus luteum formation. Consequently, the perimenopausal woman still needs to protect herself from undesired pregnancy. As cycles become irregular, vaginal bleeding occurs at the end of an inadequate luteal phase or after a peak of estradiol without ovulation or corpus luteum development [2].

During the climacteric, several changes occur: (1) in the ovary itself, (2) in the endocrine milieu, (3) in receptor tissues throughout the body (for example, in the cardiovascular system or the skeletal system), and (4) in what the woman herself perceives,

both physically, such as hot flashes, or psychologically, such as new perspectives on her life. The ovaries and the endocrine system change over time. The number of follicles diminishes and the ovaries become more resistant to the action of FSH. The ovaries also produce decreased quantities of estrogen, androgen, and progesterone. Loss of the negative feedback from ovarian estrogen production means that gonadotropin production is no longer inhibited; hence FSH and LH rise markedly, with FSH higher than LH. Secretion of the ovarian glycoprotein inhibin (which selectively inhibits FSH) also decreases; the decrease eventually results in sustained elevation of FSH. Elevated levels stabilize at about 12 months for FSH and 6 months for LH.

Although the ovary is considerably changed both in physical appearance and function after the menopause, functional cysts can occur up to ten years postmenopause. Perhaps more important is that despite the absence of functional follicles, both the remaining corticostromal cells and the hilar cells are steroidogenic—that is, they contribute to androgen production [52]. Thus the ovaries are far from inert and continue to provide significant amounts of androstenedione and testosterone for several years [53]. These hormones contribute to a woman's muscle strength and sexual drive, making them important to the quality of life for postmenopausal women.

There are three main human estrogens: (1) estriol, (2) estrone, and (3) estradiol. Estriol, a weak estrogen is secreted from the placenta and is also metabolized from estrone. Estradiol, the most potent of the three, makes up 95 percent of the circulatory estrogen in premenopausal women [54, 55]. It is excreted by the dominant follicle and the corpus luteum. Estrone, the estrogen associated with the postmenopause, is derived principally from the metabolism of estradiol and from the conversion of androstenedione in adipose tissue. It accounts for most of the circulating estrogen after menopause, and is derived with increasing efficiency with advancing years from the adrenal glands and fat cells.

Postmenopausal women have serum estradiol levels below 15 pg/mL (pica grams/milliliter) and mean estrone levels between 30 and 70 pg/mL [56, 59]. Most of the estradiol and estrone in postmenopausal women is produced by the peripheral conversion of androstenedione to estrone rather than by direct secretion of estrone by the ovary or adrenal glands [60, 61]. Ninety-five percent of postmenopausal androstenedione production occurs in the adrenal gland and 5 percent in the ovaries. Yet the ovarian stroma continue to produce androstenedione and testosterone under the influence of LH. These hormones along with androstenedione produced by the adrenal glands are converted to estrone in peripheral adipose tissue. Thus the body weight of the postmenopausal woman contributes to her postmenopausal estrogen level and increased conversion occurs with increasing weight [58, 62].

After menopause the circulating levels of androstenedione are about one-half that seen before menopause [58]. In contrast, testosterone levels do not fall, and furthermore, with the disappearance of follicles and estrogen production, the elevated gonadotropins, FSH and LH, drive the remaining stromal tissue in the ovary to a level of increased testosterone secretion [2]. However, the total amount of androgens produced is lower in the postmenopausal woman because of decreased conversion from androstenedione in adipose tissue.

Despite the discontinuation of estrogen production by the ovaries, postmenopausal women can have significant estrogen levels as a result of conversion of androstenedione and testosterone to estrogen [2]. This correlates with body weight, probably due to the ability of fat to aromatize androgens. At the same time there is a decrease in the levels of sex hormone binding globulin (SHBG), which results in increased free estrogen concentrations. However, the marked change in the androgen/estrogen ratio secondary to the decline in estrogen productions causes mild hirsutism in some women.

Changes of Perimenopause and Aging

Bleeding Pattern Changes

Since the change in women from reproductive to postreproductive life is a gradual process spanning many years, changes in menstrual function change gradually as well. The most common pattern is a gradual decrease in both amount and duration of the menstrual flow, leading to spotting and then to cessation [63]. A few women will experience more frequent or heavier periods; this is usually a reflection of continued follicular estrogen production with or without ovulation. However, it may also be indicative of organic disease, such as atypical endometrial hyperplasia or endometrial carcinoma. Only 10 percent of women will have sudden amenorrhea [5]; 70 percent experience oligomenorrhea

(intervals of 36 to 90 days) or hypomenorrhea (regular menses but decreased amounts); 18 percent report menorrhagia (bleeding irregularly between cycles), and hypermenorrhea (excessive bleeding) [64]. Consequently, women have little idea of what to expect as they approach the climacteric.

Although midwives need to consider pathological conditions in their differential diagnoses, normal physiological changes must be considered with equal emphasis, since for most women menstrual changes are normal. However, only rarely will vaginal bleeding, reflecting ovarian follicular activity, recur after one year of amenorrhea. Uterine bleeding after prolonged amenorrhea (more than 12 months) is suggestive of organic disease and investigation of its cause is necessary.

Hot Flashes

In most Western countries, as well as the United States, the most common physical change that women describe is the "hot flash," which is reported to occur in anywhere from 25 to 85 percent of the women passing through the climacteric [65]. Kronenberg defines hot flashes subjectively as recurrent, transient periods of flushing, sweating, and a sensation of heat, often accompanied by palpitations and a feeling of anxiety, and sometimes followed by chills. These symptoms are also variously called *hot flushes*, *night sweats*, and *vasomotor symptoms*. Women may experience hot flashes for short periods of time to many years. The highest prevalence is in the first two years post menopause. For some women, these occurrences can be persistent and disruptive problems. Women who have undergone surgically induced menopause have a higher incidence of hot flashes, at least for the first year, than do women having naturally occurring menopause [66, 67]. The frequency of hot flashes may vary from several per year to many a day although as many as 70 percent may experience daily hot flashes for some period of time [68].

In the Massachusetts Women's Health Study, the incidence of hot flashes varied from 10 percent during the perimenopausal period to about 50 percent just after the menopause, waning to about 20 percent by four years after the end of menses [69]. The hot flash is not always related to changes in estrogen levels and can be associated with psychosomatic or other organic causes [2].

Suggestions for living with hot flashes include many common-sense means. Women who recognize precipitating factors—such as hot drinks or meals, alcohol, emotional upset, hot weather, or a hot room—can more effectively manage the incidence or severity of hot flashes. Changes in lifestyle, including daily exercise and self-calming techniques such as yoga, meditation, or prayer, can also be helpful, as can maintaining ideal weight. Underweight women can suffer because of the association between low body mass and decreased endogenous estrogen production. Obese women can suffer heat intolerance due to extra layers of adipose tissue. Dressing in layers in breathable clothing such as cottons and keeping the thermostat down are also helpful coping options.

Drugs including estrogen and progestin preparations are often prescribed for relief of hot flashes. For many women who choose not to use hormones or for whom they are contraindicated, other pharmaceutical preparations are available. Bellergal (a combination of phenobarbital, ergotamine, and belladonna) can cause side effects such as dry mouth, constipation, rapid pulse, and hypertension, and can be habit forming. Another preparation is Clonidine (Catapres), which is primarily used to treat hypertension. Side effects include dry mouth, hypotension, and sleepiness. Other products used to treat hot flashes include vitamin E (400 IU once or twice a day), ginseng tea, black cohosh, dong quai, and chaste tree [70]. Evidence from several human studies demonstrate that dietary phytoestrogens can produce mild estrogenic effects in postmenopausal women, including reduction in hot flashes and other signs of menopause. Over the past decade, however, it has become apparent that no single action can explain the many effects of phytoestrogens [71]. Dietary phytoestrogen supplementation may benefit some women in alleviating menopausal discomforts, but it is difficult to make recommendations to patients based on the conflicting research and unclear actions of phytoestrogens [72]. The main food sources for phytoestrogens include soybean products, cereals, grasses, legumes, fennel, anise, carrots, flaxseeds, sprouts, and many fruits and vegetables [73].

Black cohosh has been widely studied in Germany for use in the treatment of hot flashes [70]. It functions as an estrogen substitute and suppresses LH. It can be found in a standardized extract called Remifemin, which contains a specific amount of the active ingredient taken in 20 mg tablets, twice daily.

Sleep Disturbances

Endogenous estrogen supports sleep and temperature regulation and other central nervous system ef-

fects. Sleep problems associated with the menopause may be related to either hot flashes or a sleep-breathing disorder [74]. Sleep-breathing disorders are rare in premenopausal women and are found less frequently in women than men. The protection women have against sleep breathing disorders may be due to hormonal factors since these worsen after menopause. The menopausal woman with complaints of severe hot flashes is at risk for sleep disturbance, while the obese, loudly snoring or excessively sleepy menopausal woman is at risk for a sleep-breathing disorder.

Other factors not specifically related to menopause are also liable to account for sleep disturbance in menopausal women [74]. Irregular sleep schedules can contribute to problems. Even though women who do not work and whose children are grown may not be obliged to get out of bed at a particular time, they should arise at the same time daily. Arising late in the morning may also prompt depression. Any naps should be taken at the same time. In-bed times should be governed by total sleep hours since longer in-bed times provoke broken, light sleep. Avoidance of substances that act on the central nervous system is important. Caffeine's duration of action is 12–20 hours; alcohol increases middle-of-the-night waking; and nicotine lessens sleep quality. Other offenders include nasal decongestants, stimulating antidepressants, beta-blockers, antibronchospastics, chronic use of sedatives, and steroids [74].

Sleep problems that are accompanied by diminished enthusiasm and capacity to enjoy, energy loss, appetite disturbance, increased somatic complaints, and poorly diagnosable physical problems may be symptoms of major depression and may be wrongly attributed to the psychological meanings of loss in menopause [74]. Major depression must be considered as an alternative differential diagnosis. In fact, almost any chronic disease—e.g., hyperthyroidism, seizure disorders, and autoimmune disorders—has the potential to disrupt sleep and diminish sleep quality as does arthritic pain and medication side effects.

Some women report that they awaken frequently with hot flashes, sweating, or feelings of panic or restlessness. These phenomena occur with varying frequency even in the same woman and can cause severe daytime fatigue, irritability, and inability to concentrate due to sleep deprivation. For some women, night sweats are the most problematic part of the menopausal transition. For a woman with severe sleep disruption, alteration in psychological and mental functioning can occur, and she is likely to have trouble with daily activities the next day.

Avoidance of caffeine, alcohol, and stressful activities prior to bedtime may help. Daily exercise, a regular bedtime, a warm bath in the evening, or having a glass of milk or yogurt just before sleep also can be helpful. Serotonin is synthesized from tryptophan, an essential amino acid that has been shown to promote restful sleep. Good sources of tryptophan are milk and chamomile tea. Valerian root is used in traditional medicine for hot flashes when related to sleep. Because of its bitter taste, it is more palatable when taken in capsule form. Estrogen therapy has also been found to greatly improve sleep patterns. Taking oral estrogen preparations at night can often lead to significant improvement in sleep disturbances and have a positive cascade effect on a woman's subjective quality of life. Fortunately, most often, severe sleep changes resolve after a period of six to twelve months.

Atrophic Changes

Because estrogen functions as the major growth factor of the female reproductive tract, there are changes in the appearance of all the reproductive organs. Women demonstrate great variability in the degree of sensitivity to these changes [75]. Studies looking at the gynourinary system during the climacteric suffer from lack of defined variables [76]. For example, many women who claim to suffer with incontinence may experience it only at certain times such as when coughing with bronchitis. Incontinence is also related to parity, obesity, hysterectomy, and a family history of diabetes and may have only limited association with menopause itself.

Long-term effects of decreased estrogen levels include thinning of the epithelium of the vagina and cervix; the capillary bed becomes more visible as diffuse or patchy reddening. In some women, local bacterial infection is likely to produce vaginal burning or pruritis and leukorrhea. Eventually, further atrophy of the epithelium leads to an increasingly sparse capillary bed leading to a smooth, shiny, pale surface. The cervix usually decreases in size with a reduction in mucus production that can lead to dyspareunia. Reduction of the uterine endometrium and myometrium leads to shrinkage in the size of small to moderate size myomas. Also, adenomyosis and endometriosis usually become asymptomatic after menopause. Once follicular activity is finished, hormonal stimulation of the endometrium also halts. The tissue becomes atrophic and inactive

both inside the uterus and at endometrial sites outside of the uterus.

Since the ovaries also become smaller in the postmenopausal woman, palpating them on bimanual exam becomes more difficult. If ovaries are palpated during the pelvic exam, an ovarian neoplasm must be ruled out [63].

The urinary tract also shows changes after menopause. Some women experience atrophic cystitis, characterized by urinary urgency, frequency, and incontinence usually without dysuria or pyuria. Most postmenopausal women experience some atrophic changes of the genitourinary tract. Symptoms can include dryness or itching of the vulva and vagina or dyspareunia. When symptoms are extreme, they can affect the woman's quality of life. Cystocele, rectocele, or uterine prolapse are experienced by some women but are more related to parity, pelvic architecture, and aging than the result of reduced estrogen levels [2].

Use of hormone therapy, either topically or systemically, often affords relief of vulvar and vaginal pain or itching. Use of vaginal moisturizers (Replens) or water-based lubricants (Astroglide or A & D Ointment) can also be helpful. Since arousal time is slower with aging for both women and men, increased opportunity for foreplay is a helpful recommendation. Sexual activity itself improves blood supply to the pelvis and the vaginal tissues; consequently, sexually active older women often have less atrophy than other women.

To relieve potential problems related to decreased moisture throughout the body (the skin, mucous membranes) as well as the reproductive system, women can humidify their homes and ensure that they drink at least eight glasses of fluid each day. Vitamin E liquid or suppositories might be used for additional lubrication. Water-based lubricants or moisturizing gels may also be helpful to relieve dryness, itching, or dyspareunia. Women should be reminded not to use oil-based products (such as baby oil or Vaseline), which can coat the vaginal lining and prevent release of endogenous secretions. These are different from vitamin E oil or massage oil, which are vegetable oil based, not petroleum based. Oil-based lubricants can, however, cause condom breakage and should be avoided entirely if condoms are being used. Other suggestions include avoidance of antihistamines and other over-the-counter drugs that might have a drying effect. Avoidance of douches, sprays, and colored or perfumed toilet paper and soaps can also have a significant positive effect in reducing itchiness or excessive dryness.

Whereas some of the changes occurring in the reproductive system are directly or indirectly related to the change in hormonal milieu, others are most likely related to the effects of aging than menopause. Two examples are loss of fat deposits and the loss of elastic tissue causing wrinkling in the vulvar area. Use of hormones will not reverse these changes.

Psychophysiological Changes

For many decades, menopause has been associated with psychological problems. Information on the psychological aspects of menopause has highlighted morbidity, pathology, and medical treatments [77]. Much of what were considered valid descriptions of menopause were found to rely upon reports from anecdotal situations or from care-seeking populations (i.e., women who present to clinics or practices). Findings from these women's experiences are different from population-based studies such as the Massachusetts Women's Health Study [78]. Patient-based samples can be biased in terms of education, socioeconomic status, and other health problems such as depression. Much of what has been reported has been considered to be the result of estrogen deprivation; these findings have been generalized to the larger population of healthy women as a whole. Longitudinal studies, on the other hand, indicate that the increase in symptom reporting and problems of middle age often reflect social and personal circumstances rather than endocrine changes of menopause [35, 79, 80]. Surveys of the general population, rather than of women attending menopause clinics, contradict assertions that menopause has a negative effect on mental health [81]. Women who seek medical help for menopausal symptoms differ in many ways from women of the same age and menopausal status who do not seek help, and are more likely to report distress [82, 83]. No increased incidence in major depression has been found to be associated with menopause [84], although McKinlay, McKinlay, and Brambilla [82], who also found no association between natural menopause and depression, did find an association between depression and surgical menopause.

Dennerstein, Smith, and Morse conducted one of the few studies that addressed psychological well-being instead of using illness measures [77]. The authors found that menopausal status is not related to well-being in any of its dimensions. In contrast, endocrinologists postulate that ovarian hormones may be responsible for the difference in

rates of depression in women as compared to men [63]. The occurrence of depressive illness at times when there are extreme changes in the hormone levels—during the climacteric, after pregnancy, and in association with the ever-changing effects of the menstrual cycle—suggest that it is the *change* in the levels of hormones (probably the decline) that is more important, rather than the absolute values. Smith and Judd [63] assert that this hypothesis is further supported by the fact that women show relatively low incidences of depression at times of stable hormone levels—for example, during the high levels found in pregnancy or the low levels found in postmenopausal women [63]. Recent data imply that estrogens share many neuropharmacological actions in common with clinically effective antidepressants [85, 86]. However, antidepressants are more effective than treatment with estrogens for mood disorders, postpartum depression, premenstrual depression, and climacteric depression [84].

The triad of psychological symptoms often cited in connection with menopause—depressed mood, insomnia, and decreased sexual interest—has provided the basis for the attribution of a depressive syndrome in perimenopausal women [87]. Yet, there are differences between true insomnia and the sleep changes associated with severe night sweats. Loss of libido can be influenced by a number of factors, including increased depression or anxiety. Finally, many life factors can increase the risk of depressed mood. Examples include death or illness of family members, children leaving or returning home, health problems that include the onset of chronic disease, and the prospects of aging in a society which places little value in its elders. Many of the early reports of improvements in psychological symptoms as a result of estrogen therapy are attributed to the "domino effect" of treating hot flashes and what the reduction of hot flashes does to improve other symptoms.

Weight Changes

Menopause is often blamed for weight gain in middle-aged women. However, it should be remembered that both men and women have a tendency to gain weight in their middle years. Moreover, each woman has her own unique body shape and size and energy level, which Western women often fruitlessly try to change in an effort to adhere to society's "ideal thinness." Many women suffer from feeling overweight when they actually are not. Women benefit from attention paid to an excellent diet that is healthy and meets necessary requirements, rather than attempting to lose weight by avoiding healthful foods that are thought to be fattening.

While still menstruating, women have the seesaw effect of the two hormones, estrogen in the follicular phase and progesterone in the luteal phase. If a woman experiences a weight gain of a few pounds prior to her menses from the progesterone effect, she looks forward to losing them again after its onset. After menopause, women lose the cyclic effect of the hormones and must balance food intake with exercise. This means eating wisely (whole grains, vegetables, fruits, and skim milk products and avoiding fats, sugars, refined flours, and rich meats) and actively walking, bending, and engaging in other forms of exercise. Weight gain during menopause is thought to be the norm; however, few studies have simultaneously considered both age and menopausal status in relation to weight gain. Longitudinal studies of weight suggest no relationship of change in weight with menopause after adjusting for age [88, 89]. In many societies, where healthy lifestyle practices are the norm, women are often thinner after menopause rather than fatter.

Based on longitudinal studies, as women enter the menopausal transition, some body changes affecting fat deposits occur, including breast enlargement, thickening around the waist, fat deposits on the upper spine, and replacement of muscle tissue by fatty tissue. More studies are needed that take into account infrequently considered factors such as ethnicity, baseline weight, use of HRT, smoking behavior, and socioeconomic status. Since it takes less energy to maintain fat cells than muscle tissue, caloric intake should be reduced by 10 to 15 percent from age 20 to 60 just to maintain the same weight.

Recommendations for increased exercise and a *healthy* diet that includes watching caloric and fat intake (if these are a problem) should be made to women as they grow older. Exercise has the added effects of increasing muscle tone, strengthening bone, stimulating metabolism, and relieving some mood alterations.

Aside from not smoking, maintaining ideal weight is the most important health measure for reducing coronary heart disease [90]. Maintaining ideal weight helps lower the level of low-density lipoprotein (LDL) and increase the level of high-density lipoprotein (HDL) [91]. Conversely, it is important to stress to women going through menopause and in their older years that they should avoid being excessively thin because of the possible

increase in hot flashes and the increased risk of osteoporosis. Hypothyroidism plays no role in obesity; rather the weight gain associated with hypothyroidism is the result of the fluid accumulation of myxedema [92].

Skin Changes

Most skin changes women notice at menopause are the result of photoaging (sun damage) and, secondarily, intrinsic aging [93]. Other changes include dryness, increased sweating, sagging, altered barrier function, thinning, and decreased wound healing, all of which may contribute to psychological distress or altered body image. Prevention of sun damage over the lifetime by the use of protective clothing or sunscreen with a sun protective factor (SPF) of at least 15 is the best prescription to ward off the affects of photoaging. Prescription preparations such as tretinoin cream (Avita, Renova, Retin-A) offer some improvements to sun-damaged skin by reducing fine wrinkles, tactile roughness, and hyperpigmentation. Use of such preparations can cause dryness and peeling which can be managed with moisturizing creams or by using the preparations less frequently.

Dry skin with accompanying pruritis is a common problem caused by the loss of an effective water barrier to prevent evaporation of water from the epidermis. Ordinarily, sebum provides protection from water loss but its production diminishes at menopause. Both the dryness and the resultant itching can be alleviated to some degree by controlling the humidity in the environment and use of mild soaps (Dove, Caress, Oil of Olay) and moisturizers. Emollients with 10 to 20 percent urea (Uremol) or lactic acid (Lachydrin) will do the most to hydrate the skin. For severe pruitis, symptomatic relief can be found by use of soothing (menthol or phenol) or anti-inflammatory (hydrocortisone) agents. Antihistamines such as hydroxizine (Atarax) or Benadryl can be used in more problematic cases.

Hair changes that are seen in the climacteric include graying, baldness, and increased facial hair. By age fifty, 50 percent of the population will have gray hair [93]. Balding, although much more rare, is cause for distress in the women who experience it. Women usually develop diffuse parietal thinning of scalp hair with retention of the frontal hairline. Topical minoxidil (Rogaine) is now approved for use in women with androgenic alopecia and is generally safe and well tolerated. For excessive facial hair, commercial preparations such as bleaches and chemical hair removers are available. Other options include shaving, waxing, plucking, and electrolysis. Although electrolysis is considered permanent, regrowth can be as high as 60 percent after a single treatment [93].

Nail growth slows between early and late adulthood by 30 to 50 percent [94]. Brittle nails are the result of longitudinal ridging, separation of the distal nail plate, and loss of water content of the nail plates [95]. Treatment includes trauma prevention, avoidance of excessive use of nail polish, soaking in oil, and moisturizing phospholipid cream (Complex-15). Improvement in brittle nails with a daily oral dose of 2.5 mg of biotin has been reported [96].

Skin tags (fibroepitheliomas) are benign, soft, brown, pedunculated polyps usually found on eyelids and the neck. Other benign lesions commonly found include seborrheic keratosis, sharply defined, flat, light or dark brown papules usually found on the trunk; and DeMorgan's spots (cherry angiomas), red dome-shaped papules found mainly on the trunk. Acne rosacea, an inflammatory condition of the sebaceous glands, has an increased incidence with age and can be treated with topical antibiotics such as benzoyl peroxide, erythromycin, and metronidazole (Metrogel).

When examining the skin of a person of any age, malignancies must be considered in order to facilitate early diagnosis and treatment. Basal cell carcinoma, which accounts for more than 75 percent of all skin cancers, presents variously as a flesh colored papule, or a superficial erythematous plaque, or a pigmented or ulcerative papule, plaque, or nodule. This slow-growing cancer almost never metastasizes but can invade surrounding tissues and destroy bone and cartilage if left untreated [97]. Basal cell carcinoma usually develops on the face, ears, neck, scalp, hands, or arms.

Squamous cell carcinoma, which has a 95 percent survival rate, accounts for another 20 percent of skin cancers. Individuals with a history of treatment for psoriasis or acne with ultraviolet light, as well as those with exposure to paraffin, tar, or coal are at increased risk. Women with albinism and vitiligo also are at higher risk [98]. Actinic keratoses are tan, scaly, erythematous, gritty lesions that can be a precursor to squamous cell carcinoma and should be examined for changes on a regular basis.

All pigmented lesions should be examined with the consideration of possible melanoma. Suspicion should rise when a woman presents with a new mole or an existing one that has recently changed in size, shape, or color. Variegated color, irregularity

of the border, and/or inflammatory signs of a lesion should alert the midwife to the possibility of melanoma. Prognosis depends in large part on tumor thickness.

Sexuality

Satisfactory sexual functioning is an integral part of a woman's health and well-being at any age. Myths abound about sex and aging. Stereotypes in Western culture often serve to limit useful communication about sex and take a toll upon the self-concept of women in sexual matters as they move through the menopausal transition. For many years, it was assumed that as women grew older their sexual interest and responsiveness waned. According to the Kinsey report in the early 1950s, women reach their sexual peak, in terms of both activity and enjoyment, about the age of 35 [99]. Nachtigall [100] reports, however, that although there is a decrease in sexual activity after age 35, it is either because of "burnout" or male disinterest. The majority of women who experience natural menopause do not report declines in sexual desire, erotic pleasure, or orgasm [101], and sexual potential declines less in women than men with aging [102].

The myth that older people are not interested in sex springs from the connections that are made in our society between attractiveness and youth, and of sexuality with romantic love or fertility [100, 103]. Sex can be enjoyed for a variety of reasons including feeling feminine, reducing tension, improving sleep, as an outlet for emotions, and for feelings of intimacy. A newer illusion to which many women and practitioners succumb is that since women have reduced estrogen levels it is to be expected that sexual activity will necessarily become uncomfortable, a burden, or at least unpleasant. This goes along with the idea that women once past their childbearing potential lose their desire and desirability. For many couples, sex continues to improve with aging and lifestyle changes for both men and women. With more leisure time, the children gone, and responsibilities changing, sex can become a wonderful adventure.

Arousal time is increased for both women and men with aging. Increased time for foreplay is often required. Sexual responses have a similar "slowing" as do other physiological processes throughout the body. It is important to remind women and their partners that changes are not always catastrophes but, rather, can lead to unpredictable pleasures.

There is extensive evidence that estrogen replacement can be beneficial for problems of postmenopausal vaginal dryness and dyspareunia by reversing atrophic vaginitis [104]. Estrogen's effect on libido is unclear [105]. Androgen therapy, however, is considered safe and effective for lowered libido when taken in appropriate dose levels for women undergoing a natural menopause [106]. The risks and benefits of using any hormone replacement must be discussed with each woman to develop an optimal plan for her.

In order to provide a holistic and comprehensive approach to treating sexual changes during the climacteric, it is important to consider significant issues in a woman's life, including her health status, physical and social environment, past experiences, expectations, and cultural milieu [107]. Consideration should also be given to the quality of each woman's relationships, the sexual performance of her partner, and age-related changes in self-image [108]. For many women, the worst aspect of the climacteric is the lack of information and uncertainty about changes. Midwives can make an impact by supplying information, effective counseling around common changes, and offering personalized treatment options for women experiencing negative changes in their sexual lives. The majority of providers do not routinely ask questions regarding sexual health and women often do not feel comfortable initiating questions about the topic. A 1990 survey of more than 1000 primary care providers showed that only 10 percent routinely obtained a sexual history and only about 10 percent of patients were assertive enough to ask questions about their sexuality [109]. Many providers do not want to be too intrusive when asking personal questions, although 90 percent of patients feel that a sexual history is an entirely appropriate and necessary part of a health evaluation. Questions should address sexual adjustment, problems, and information needs. Open-ended questions about sex may lead to the woman's interest in discussing her questions or problems in the sexual realm. She should be asked about vaginal changes, including moisture or dryness, itching or pain, as well as more direct questions about anything she wants to ask or discuss about her sex life or sexuality. If a woman has had a hysterectomy or mastectomy, she may have additional queries, and time must be taken to inquire about these in relation to sexual adjustment. Anxiety or depression can cause problems with arousal phase disorders. Medications such as antidepressants and antihypertensives may also contribute to sexual dysfunction.

Another consideration for older women is the lack of available sexual partners due to divorce or death. For some women this means exploring other relationships with new partners or satisfying their sexual needs alone with masturbation or fantasy. In some circumstances, the lack of sexual partners means a life of a reduced level of sexual activity.

Caring for women's sexual concerns should include explaining the physiology of aging as it relates to sexuality and correcting problems when possible. It is helpful to explain the psychology of aging and its "norms"; and that women are capable of "different" and sometimes improved sexuality. Offering alternate, noncoital activities either with or without a partner is helpful. Referring women of any age for sex therapy when appropriate should be considered, especially when there is long-standing sexual dysfunction, current or past abuse, or an acute psychological event. Finally, it must be considered that for some women a decreased sexual interest may not be perceived as a problem at all so no intervention is necessary.

Changes in Thyroid Function

Thyroid dysfunction becomes more common as women age. While it is not cost effective to screen younger women for thyroid problems, it appears to be cost effective as women approach the age of 60 [110]. As many as 8 to 12 percent of older women have overt hypothyroidism [111]. Diagnosis of thyroid disease as women age may be complicated because of a lack of classic symptoms. Often women present with symptoms that mimic other chronic problems, such as depression, congestive heart failure, or early dementia [110]. For example, women with hyperthyroidism may complain of lethargy or confusion and may resemble women with hypothyroidism. Women with hypothyroidism may be ataxic or confused or present with hoarseness from thyroid enlargement. Medications may alter thyroid function as well. It is important for the midwife to have a high index of suspicion to diagnose and treat thyroid disease early in the older woman.

Breast Cancer

Adenocarcinoma of the breast is the most common cancer and the second leading cause of cancer death among American women [112]. There is mounting evidence from epidemiologic studies indicating a positive relationship between (1) estrogen levels, (2) markers of estrogen exposure such as early menarche and late menopause, and (3) the use of exogenous estrogens after menopause and an increased risk of breast cancer [113]. Experts suggest that estrogen plays an important role in the pathogenesis of breast cancer [114]. The period from menarche to menopause marks the lifetime exposure of women to significant levels of reproductive hormones. For every one-year increase in age at time of menopause, the risk of breast cancer increases by about 3 percent [115]. Timing of pregnancies also affects risk: late pregnancies are associated with increased risk, while early pregnancies are protective. It is theorized that a woman's first pregnancy is associated with terminal differentiation of breast cells and that the cell cycle is longer after a woman's first pregnancy, allowing more time for DNA repair [116]. Such reproductive milestones as markers of estrogen exposure are now thought to influence the rate of breast cell growth and the accumulation of DNA damage [113]. Seemingly, postmenopausal women with elevated estrogen levels have the highest risk of breast cancer [117, 118]. Obesity, for example, is positively related to hormone levels, reflecting the biologic function of fat cells to metabolize androgens to estrogens in postmenopausal women [119, 120]. Premenopausal obesity is also positively associated with increased risk of breast cancer mortality in most case-control and prospective studies [121]. The relationship between postmenopausal obesity and breast cancer is less clear. Body mass index (BMI) has been positively associated with postmenopausal breast cancer in case control studies [122, 123], but prospective studies generally show a relatively weak association, if any [124–126]. Conversely, thin women have both lower estrogen levels and lower age-specific risk for postmenopausal breast cancer [127]. Having a first-degree relative (mother or sister) with breast cancer is also considered a risk factor for breast cancer and should be included in a health history.

The association between hormone therapy and breast cancer concerns most women. Colditz and colleagues performed a review of the literature to determine the strength of the evidence suggesting that endogenous estrogen and postmenopausal replacement play a role in the development of breast cancer. A causal relationship was found based on the criteria of consistency, dose-response pattern, biologic plausibility, temporality, strength of association, and coherence [113]. The authors report the magnitude of the increase in breast cancer risk per year of hormone use to be comparable to that asso-

ciated with delaying menopause by a year. They theorize that hormones may act to promote the late stages of carcinogenesis and facilitate the proliferation of malignant cells [113].

Since all women are potentially at risk for breast cancer, midwives must consider carefully the possibility of the woman developing breast cancer when assisting her to make informed decisions about hormone therapy. When helping a woman along the decision-making path, risks such as cardiovascular disease and osteoporosis as well as factors such as severity of hot flashes or sleep loss must be considered and balanced with the risk of breast cancer. The risk of breast cancer for each year of replacement use increases 2.3 percent (95% confidence interval [CI]=1.1%–3.6%, p=.0002); the findings do not vary significantly between studies [128]. How varying formulations and prescribing regimens influence women's risk remains uncertain. Additionally, many of the older studies that examined the association between breast cancer risk and hormone use were on "ever users" who generally used HRT for short-term relief of symptoms.

The WHI was stopped primarily because of the increased risk of invasive breast cancer for women taking the combination of estrogen and progestin. This was the first randomized, controlled trial that confirmed that the combined HRT (CEE plus MPA) does increase the risk of breast cancer and to quantify the degree of risk [129]. There was a 26 percent increase observed in the estrogen plus progestin group for invasive breast cancer (hazard ratio [HR] 1.26, 95% confidence interval [CI] 1.00–1.59). There was no difference between treatment and placebo groups for noninvasive (in situ) breast cancers. After an average follow-up of about five years, the adverse effect on breast cancer had crossed the predetermined safety boundary and the study was halted.

Even before the WHI results were made public, Colditz proposed that risk for breast cancer has been underestimated due to methodologic biases of observational studies [113]. He suggests that women with menopause symptoms have lower estrogen levels at menopause than women without symptoms—that is, they are more likely to report hot flashes and thus choose to take HRT. Thus women who take hormones may be at lower risk of breast cancer at the time of menopause leading to an underestimation of true breast cancer risk with HRT. Colditz and others suggest that previous analyses have not controlled for age at menopause with sufficient rigor to remove bias in estimates of risk of HRT use and breast cancer [128]. Women who enter menopause at a younger age are at substantially decreased risk of breast cancer, yet they are more likely to use HRT and to do so for a longer duration. Moreover, users of HRT are at lower risk on average of breast cancer at the start of menopause, than nonusers of the same age once other risk factors are controlled for. Many epidemiologic studies are confounded by factors including data showing that women taking hormones for longer duration will have had earlier menopause (and so be at lower risk for breast cancer) than the women taking hormones for a shorter duration. This may have led researchers and clinicians to underestimate the adverse effect of hormones on breast cancer risk [113]. Colditz suggests that the association is stronger between estrogen levels and the risk of breast cancer than that between cholesterol levels and heart disease. Conversely, other factors such as higher rates of mammography in women using HRT can lead to a higher reported incidence of breast cancer. Women who use hormones are often in higher socioeconomic circumstances and more likely to consume alcohol, both of which have increased association with breast cancer [43, 130]. Such factors may lead to overestimating the underlying relationship between hormone use and breast cancer [131].

Hormone Replacement and Risk of Breast Cancer

Certain characteristics of women who use hormones are known. Women who experience symptoms at menopause have lower levels of circulating estradiol [132–134]. Thin women are more likely to use hormone therapy [132] and to report hot flashes [134]. Bone density is lower in women when they begin to take hormones than in women who choose not to use hormones [135]. All of these point to the fact that women at lower risk of breast cancer are more likely to use hormones [113]. Upon recalculation of the potential association of risk for breast cancer with HRT use, investigators in 1997 attributed a profound impact to incomplete analytic control for time since menopause in previous reports of epidemiologic data [128]. They noted an increase in the risk of breast cancer associated with duration of use was 0.8 percent per year (p = .10) if no correction was made, compared with an increase in risk of 2.3 percent per year (p = .0002) when full statistical control was used. In this reanalysis of 51 epidemiologic studies, of more than 52,000 women with breast cancer and more than 100,000 women without breast cancer, the authors estimated that

for every 1000 women who begin to take postmenopausal hormones at age 50 and who take them for 10 years, there are six more cases of breast cancer than expected; for 15 years of use, there are 12 additional cases.

In the mid-1970s progesterone was added to estrogen regimens to protect against endometrial cancer. It was proposed that progesterone offered similar protection against breast cancer [136]; however, accumulating evidence has not supported this view [128] and it is more likely that progesterone increases the breast cancer risk above that associated with estrogen alone [137, 138]. What is not known is whether sustained progestin levels with continuous administration of progestins as part of continuous, combined HRT (daily estrogen and daily progestin) may move breast cells into a phase of reduced division. The answer awaits more experience and trials of continuous combined HRT use. Continuous combined HRT has been used only in recent years. Data on risks for breast cancer with continuous combined HRT use is sparse, and long-term, prospective, controlled trials are needed before we can have clinical clarity.

Breast Cancer Survivors and HRT

It is assumed because of the relationship between estrogen and breast cancer that HRT will promote breast cancer, hasten recurrences, and increase metastases. Women who survive breast cancer are often left with debilitating symptoms of estrogen withdrawal or health problems such as osteoporosis, because of the consensus that HRT should be avoided in women with breast cancer. A challenging question to providers is how to alleviate menopause symptoms such as hot flashes when up to 60 percent of women undergoing adjuvant breast cancer therapy suffer these side effects [139–141]. At the present time, hormone therapy is by and large avoided for fear of stimulating disease recurrence.

DeSaia and colleagues conducted a cohort study published in 1996 comparing breast cancer patients who received HRT with matched comparison patients who did not receive HRT [142]. The results showed no difference in survival time or disease-free time in the two groups. In 1999 Natrajan and colleagues followed 76 women with breast cancer, 50 who had used ERT for up to 32 years, some of whom had also used androgens, progestins, or tamoxifen [143]. The authors found no increase in recurrences or mortality rates and a possible decrease in recurrences with progestins. The study was retrospective and nonrandomized, the study groups were small, and the HRT used was variable. Both studies point to the need for data from prospective randomized trials. Before recommending HRT for the patient having a history of breast cancer, a full explanation of risks, benefits, and controversies must be shared with the individual woman.

No Consensus on the Breast Cancer Question

Why had there been no consensus regarding HRT and breast cancer prior to the Women's Health Initiative? Speroff points out that when the impact of an association is large, it is relatively easy to demonstrate an association with case-control studies or cohort (observational) studies [144]. In addition, observational studies cannot overcome their inherent biases and confounding factors unless the studied effect is large. Compounding the dilemma is the fact that most trials involving hormone replacement therapy were conducted when estrogen was used without progestins. While observational studies show little uniformity and consistency about the association between breast cancer and HRT, the results from the Women's Health Initiative will likely influence the opinions of health care providers when it comes to prescribing HRT for long-term protection, particularly because of the confirmed risk of breast cancer with its use.

In any event, instructions for breast self-examination, clinical breast assessment, and routine annual screening mammography should be part of the health care for all women over age 50. McCool reports that older women view breast self-examinations as difficult, despite the decrease in complexity of the breast (ending menstrual cycle changes, atrophy of the mammary glands and ducts, and decrease in fibrocystic structures), and also because of embarrassment, lack of confidence, and disbelief in the potential for detecting abnormal findings [145]. Midwives can make a profound difference in breast care in older women. Midwives should take advantage of every opportunity for breast health education—self-breast exam, and screening tests—mammography, and clinical breast exam. Some providers fail aging women, believing that such steps are not crucial to health care provision [145]. Yet midwives can make a difference by taking older women's health needs seriously. Midlife women are very concerned about breast health and disease. It is often what brings them to seek care. Until a consensus is reached regarding the new information from the WHI, women will still need help to sift through the confusing information and recommendations to which they have been exposed.

When caring for a woman who is concerned about the relationship between hormone use and breast cancer, the midwife needs to help her to weigh the advantages and the risks of use. The midwife can ask her how frightened she is regarding any increase in breast cancer risk and if the benefits of hormone use for symptom control outweigh these risks. Whether her decision is made within the context of "scientific evidence" or her own ideas and feelings about breast cancer risk, it is a valid decision that must be honored.

Cardiovascular Disease

Cardiovascular disease, including coronary heart disease, cerebral vascular disease, hypertension, and peripheral vascular disease, is the most common cause of death in the United States for both men and women, with some 500,000 women dying from it each year [146]. Risk factors for both men and women include hypertension, smoking, diabetes mellitus, and obesity. However, prior to menopause women enjoy protection against heart disease provided by estrogen; consequently they lag behind men in the incidence of coronary heart disease by ten years, and for myocardial infarction and sudden death, by twenty years [147]. Whether menopause per se is responsible for this increased risk which women experience as they pass through it is unclear [148] yet remains the most important question. Most studies on menopause in the literature focus on the biological process and exclude the broader psychosocial contexts of women's lives [149]. Women who undergo early menopause or bilateral oophorectomy prior to menopause have been shown to have an increased risk of heart disease [147]. However, the most important risk factors for heart disease—diabetes, obesity, smoking, and high cholesterol—are often established well before menopause. Moreover, there is evidence that cardiovascular disease is present in terms of myocardial infarcts in women's fourth and fifth decades before menopause [150]. Reported rates of cardiovascular disease mortality in women from many countries indicate smooth, exponential trends with age, similar to those in men. Longitudinal data from a population-based study suggests that age-related factors such as body mass and exercise are much more strongly related to cardiovascular risk than is menopause status [151].

Risks may be related to a number of factors including changes in lipids and lipoproteins. Total cholesterol, low-density (LDL) cholesterol, apolipoprotein A-I, apolipoprotein B, and triglycerides are significantly higher in postmenopausal than premenopausal women of similar age, whereas high-density (HDL) cholesterol is decreased [152]. Postmenopausal women as well as men are also more prone to hypertension as they grow older. Since most studies on heart disease have been with male subjects, extrapolating results and making recommendations about treatment require caution. Postmenopausal hormone treatment is recommended as a legitimate component of preventive health care against heart disease for women, but this must be considered within the context of lifestyle factors such as smoking cessation, good diet, regular exercise, blood pressure reduction, and other interventions on which excellent epidemiologic data are available. There is a growing scientific basis that supports preventive medicine and health promotion efforts as a valuable component of effective health care; their value should be emphasized, not minimized.

Much of the enthusiasm to recommend hormone use to women stems from the strong link from observational studies between menopause and an increased incidence of cardiovascular disease. Such studies suggest that postmenopausal hormone replacement therapy reduces cardiovascular disease risk by about half [153]. Estrogen use in women has been shown to be effective in lipid lowering which is believed to predict reductions in the risk of cardiovascular heart disease (CHD) so that lipid lowering can be used as a surrogate endpoint for CHD. Studies published in the last decade show positive effects of hormone therapy on cardiovascular risk factors as well [154, 155] but these need to be reexamined in light of the results of the Women's Health Initiative.

At the same time, there is growing evidence that thrombotic phenomena play an important role in acute coronary syndromes [156]. Both unopposed estrogen replacement therapy (ERT) and hormone replacement therapy (HRT) increase the risk of venous thrombosis [157–161], but some studies also show that estrogen may slow the progression of existing coronary artery disease in postmenopausal women [162]. However, many of these studies suffer from the limitations of small patient numbers and demographic differences between treatment groups; women who take estrogen are on average better educated, have higher incomes, and better access to health care and are healthier prior to use [43, 163]. The conflicting evidence presented con-

cerning the cardiovascular benefits of hormone use, along with increased risk of breast and endometrial cancer and venous thromboembolism, has created concern among health care providers about whether use of hormones is essentially beneficial or putting women at risk [164].

The Heart and Estrogen/Progestin Replacement Study (HERS) of 2763 women published in 1998 was the first large-scale randomized clinical trial in older postmenopausal women with established heart disease to test the efficacy and safety of hormone replacement therapy on clinical cardiovascular outcomes [157]. Participants were followed for 4.1 years for the main end point of nonfatal myocardial infarction (MI) or cardiovascular death. At the end of the study, no significant differences were seen between the two groups. The results revealed that, while the risk for coronary heart disease was reduced in the third through fifth years, the reduction was offset by an unexpected 50 percent increase in risk for CHD in the first year of use. This null effect has shaken the foundation on which recommendations for widespread use of estrogen replacement were built.

HERS illustrates the importance of trials that use clinical end points to establish the overall effects of a treatment. Herrington points out that the HERS results demonstrate how incomplete our understanding of estrogen action and the pathogenesis of coronary heart disease remains [165]. The author suggests that HERS does not support initiation of conjugated equine estrogens (CEE) combined with medroxyprogesterone acetate (MPA) in older women with confirmed heart disease. For women with CHD already on ERT for a year or more, the consensus panel for the American Heart Association suggests that it is reasonable to continue therapy while awaiting the results of a HERS follow-up study and other ongoing trials of therapy with clinical end points [166]. The statement points out that while the results of the HERS trial pertain to women with established heart disease the results *may not apply to women without underlying vascular disease*.

The epidemiologic study most often quoted by experts and the lay press, the Nurses' Health Study, began in 1976 when 121,700 female nurses between the ages of 30 and 55 were mailed a questionnaire about use of hormone therapy and medical history, including cardiovascular disease and risk factors. These data were updated biannually and in 1980 questions on diet and physical activity were added. In 1996, a 16-year follow-up of 59,337 women was published and looked for the first time at any association between heart disease and adding progestins to hormone replacement. Current hormone users had a lower risk of death (relative risk, 0.631, 95% CI, 0.56–0.70) than nonusers. However, the apparent protection decreased with long-term use as the risk of breast cancer increased after more than ten years [167]. The authors concluded that the addition of progestin to estrogen does not appear to attenuate the protective effects of hormone therapy in relatively young postmenopausal women but must be evaluated within the context of possible risks such as breast cancer. Women who benefited the most from hormone use were those who had the most risk factors for heart disease, while those with few risk factors had little decrease in risk of heart disease with hormone use. This study found no increasing benefit with increasing duration of use; in contrast, the benefits were attenuated after ten or more years of current hormone use. At the same time the risk of breast cancer mortality in the hormone-using population was elevated by 43 percent after ten years of hormone use [167].

In the Postmenopausal Estrogen/Progestin Intervention (PEPI) trial [168] published in 1995, 875 women were randomly assigned to receive placebo, oral estrogen alone, or one of three estrogen-progestin regimens [169]. HDL cholesterol levels were increased and LDL cholesterol levels were decreased in all the treatment groups. The decreases in LDL cholesterol levels were similar for all regimens but the HDL cholesterol levels were significantly less elevated in the women who took estrogen with medroxyprogesterone (MPA) compared to those who took estrogen alone. In a more recent analysis of the PEPI data, it was reported that conjugated equine estrogen (CEE) therapy with or without progestins leads to long-term stable average decreases in lipoproteins of 20 to 30 percent for women who adhere to its use [170]. Other studies have also shown an inverse association between estrogen plus progestin regimens and cardiovascular disease [171–174].

Stroke

The association between hormone therapy and stroke had been unclear until the WHI results pointed to a significant increased risk with combined HRT. Previously, the Leisure World Study published in 1991 showed a relative risk of 0.3 among current estrogen users as compared with women who had never used estrogen ($p<0.05$)

[175]. Falkeborn and colleagues reported that the relative risk of stroke was 0.72 among women taking estrogen and 0.61 for women using combined therapy [171]. In the Nurses' Health Study, Grodstein and colleagues reported no decrease in the incidence of stroke among hormone users whether or not the women used estrogen alone or in combination with a progestin [176]. An increased risk associated with high doses of estrogen had also been suggested. The WHI data showed a 41 percent (HR 1.41, 95% CI 1.07–1.85) increased risk of stroke for women using combined HRT compared to the placebo group [129].

The biological potency of postmenopausal hormone therapy is equivalent to 20 to 25 percent of that found in modern oral contraceptives [177]. Until recently it was believed that low dose estrogen treatment was not associated with any increased risk for deep vein thrombosis (DVT) or embolism. However, data from observational studies published from 1996 to 1998 have suggested that hormone therapy increases risk for both [158, 161, 178]. The WHI showed an increased risk (HR 2.13, 95% CI 1.39–3.25) for pulmonary embolism. Women using combined HRT also had twofold greater rates on VTE [129].

Until recently, because of the known adverse effects of oral contraceptives, the use of HRT was considered contraindicated in women who had hypertension [179]. Consequently, there are few data regarding the association between HRT and hypertension. The PEPI study results, however, were reassuring in that blood pressures did not rise in women receiving estrogen when compared to those receiving placebo [169]. In the WHI, data showed no increase in blood pressure values with HRT use. Indirect evidence shows that HRT protects women from increased blood pressure [179]. While most women will not have adverse effects on blood pressure from HRT use once therapy is initiated, blood pressure should be monitored every 6 to 12 months. If hypertension arises, it is unlikely to be the result of HRT use, except in rare instances [179]. In most cases antihypertensive therapy may be initiated without discontinuance of HRT.

After the HERS study, the WHI is only the second randomized controlled study to call into question the protective effects of HRT on the risk of heart disease. The increased risk demonstrated by the WHI will likely completely change how women and providers view the use of HRT. While women using HRT had lower LDL levels (–12.7 percent) and higher HDL levels (+7.3%) at one year into the study, the ratio of women experiencing CHD events was increased by 29% for women using the combined HRT [129].

Osteoporosis

The skeleton consists of 80 percent cortical bone, while trabecular bone (the bone of the spinal column and the ends of the long bones) makes up the rest. Osteoporosis is characterized by a reduction in bone quantity occurring primarily in the trabecular bone and is most noticeable in the vertebrae and the distal radius. Bone mass is accumulated throughout childhood and early adulthood, peaking in the late twenties to early thirties. Osteoporosis, affecting approximately 28 million Americans and costing about $14 billion a year, is characterized by bone fragility such that fractures can occur with little trauma, including normal activities of living [180]. The risk of fracture resulting from osteoporosis depends upon two factors: the bone mass achieved at maturity and the subsequent rate of bone loss. In the first 10 to 15 years following menopause, women have accelerated loss of bone, after which the rate of bone loss is considerably diminished but persists. Other contributing factors include reduced bone mass, poor bone architecture, accumulating damage from wear and tear on the skeleton, and low calcium intake [181]. Lack of exercise and poor balance both contribute to the incidence of osteoporosis fractures because individuals with poor proprioception are at higher risk for falls. Hip fractures resulting from osteoporosis begin 10 to 15 years following menopause with complications that have great personal and public health consequences. The morbidity and mortality associated with osteoporosis are related to fractures. The disease takes decades to develop and is difficult to treat, and therefore public health strategy has been placed on prevention.

Osteoporosis is epidemic in the United States, partly due to an increase in the life expectancy but also due to factors such as more sedentary lifestyles, lower parity, and effects of smoking and changes in diet [182]. While osteoporosis affects one in three postmenopausal women, not all will require intervention. There are no definitive methods to predict who will develop osteoporosis severe enough to be a health risk—that is, experience painful symptoms or reach the fracture threshold. Significant health problems resulting from osteoporosis include frac-

tures of the hip, upper femur, forearm, ribs, and compression fractures of the spine. The 1990 figures from the National Osteoporosis Foundation show that osteoporosis is responsible for 1.5 million fractures per year and that more than 20 million women are affected. More than 275,000 hip fractures occur annually in the United States at a cost of more than $10 billion per year, affecting women two to three times more than men. The mortality rate associated with hip fractures is between 5 and 20 percent within the 12 months following the fracture, with as many as 15 to 25% of women with hip fractures becoming permanently disabled. These incidences often translate into chronic complications: many of the women affected require help with daily activities, and up to 15 or 25 percent require institutionalization.

Clinical profiles of those who are most affected are sometimes helpful but do not present a clear picture of the woman who is at risk for osteoporosis. Chronological age, body mass, smoking, exercise, and other lifestyle factors may play a larger role than does menopause [148]. Reliable estimates of the impact of bone density and prior rates of loss on fractures are not available, in part because fractures occur 15 years or more after menopause. The risk of falling related to factors such as poor vision, obstacles in living areas, and side effects from medications appears to contribute predictive information to later fracture, independent of bone density [183–185]. Heredity probably also plays an important role in premenopausal bone density [186–188]. Yet Bradsher and McKinlay point out, "Available information on cultural variations in bone density and risk of hip fracture reveals the contradictions that underscore, first, the inability of bone density and rate of loss to predict fracture and, second, the multiple risk factors likely to predict fracture." [148, p. 205] Some factors that have been reported to have an effect on accelerated bone loss include smoking, lack of parity, later age at menarche, lower body weight, and lower age at first pregnancy [187].

Osteoporosis Screening

Bone density measurements and in particular dual-energy x-ray absorptiometry (DXA) have revolutionized the field of osteoporosis management. Despite its limitations, bone density measurements are still the best way to identify individuals at risk for osteoporosis. Suggestions regarding who should use DXA are quite broad. The National Osteoporosis Foundation 1998 Practice Guidelines (revised in 1999) recommend bone mineral density (BMD) testing in women considering treatment who are aged 65 years or older, and in younger postmenopausal women considering treatment who have one or more risk factors for osteoporotic fracture other than menopause [189]. The clinical challenge is to identify those most at risk for fracture while limiting unnecessary testing in women with normal BMD who have a low risk for fracture. Since most women have one or more risk factors, the question then becomes who not to test.

DXA Interpretation Every reduction of 1 standard deviation in bone density equates to a 2 to $2^1/_2$ fold increase in the likelihood of fracture [190]. The "Z" score relates the measure of bone mineral density figure to the mean value expected for a healthy normal subject matched for age, sex, and race. This score expresses the difference between a woman's bone mineral density and the age-matched mean in units for the population standard deviation. The "T" score is similar but indicates the difference between the individual's BMD and the ideal peak bone mass achieved by a young adult. Bone density measurements are standard deviations (SDs) below the mean of what would be normal for a younger woman. All bone density numbers are on the negative side of 0. According to the World Health Organization, a "T" score at the hip, spine, or forearm greater than or equal to 2.5 defines osteoporosis (a reduction in the mass of bone per unit volume enough to lead to fractures with little or no trauma). The number 2.5 indicates 2.5 standard deviations (SDs) below the mean for a young adult woman. A score between 2.5 and 1 (2.5 to 1 SDs less than the mean for a young woman) denotes osteopenia (a radiologic term indicating a reduced amount of bone that encompasses both osteomalacia—reduced mineralization in bone—and osteoporosis). A score of 1 (1 SD less than the mean for a young woman) is regarded as normal. No one ever has a "T" score on the positive side of 0 because all midlife and aging women have lost bone mass.

While bone density measurements are good at assessment of fracture risk, they do little to identify the woman who will sustain a fracture [191]. Suggestions for which women should be tested are quite broad. Since most women have 1 or more risk factors the question still remains who to test. Many experts do not recommend widespread screening for osteoporosis because precise identification of high-risk women does not emerge from the avail-

able evidence and because the efficacy of long-term treatment for prevention has come under scrutiny [192]. The main treatments are hormone replacement and bisphosphonates. Most women are unprepared to take hormones for the time required for protection. The bisphosphonates have undesirable side effects, must be taken while fasting, and are relatively expensive. Furthermore, there is no experience with long-term treatment. Ultrasonography may become an effective means of predicting risk of fracture [193, 194] but its worth in clinical screening has not yet been established [195].

Whether or not to use DXA for an individual woman depends on factors such as whether or not she is interested in treatment if the results show her to be at risk. If a woman is undecided about what interventions she will elect (hormone use, bisphosphonates, exercise, and other lifestyle changes), measuring bone density will help her understand her individual risks and will often clarify the issues for her. Other reasons to measure bone density include assessing response to therapy and to aid in treatment decisions.

Pharmacologic Treatment

Protection against osteoporosis has been the least controversial reason for use of hormone replacement therapy up to this point. The role of estrogen decline in bone loss has been largely inferred through the demonstrated beneficial effect of exogenous hormones in clinical trials [148]. However, the relationship between HRT and fracture prevention is open to question [196, 197]. In the past, HRT has been the standard of care for prevention of osteoporosis [197]. HRT was thought to have a stabilizing influence on loss of bone mass from both trabecular and cortical bone in women with established osteoporosis, which reduces fracture rates. Support for use of HRT comes from observational studies that consistently suggest that postmenopausal therapy reduces the risk of hip and other types of fractures [196]. Observational studies, however, are susceptible to selection bias and confounding. This is exaggerated if the women who use hormones are healthier, wealthier, and more active than nonusers. Consequently, even if observational studies are qualitatively correct, they may overestimate the degree of risk reduction attributed to HRT [196]. Although randomized trials have consistently shown that estrogen prevents postmenopausal bone loss, *bone density is an imperfect predictor of reduction in risk for fractures*. Fracture prevention remains the most common reason to prescribe HRT in women over age 60 years [198] because the data on skeletal protection have been the most accepted rationale for its use. Ideally, though, clinical practice should be based on evidence from large randomized blinded trials using fracture as the outcome measure [196]. Although the data from the WHI showed estrogen plus progestin reduced the observed hip and clinical vertebral fracture rate by one-third (both nominally significant), the authors considered this benefit not worth the risks incurred for heart disease and breast cancer [129].

It has been thought that the lowest dose adequate to produce bone effects is 0.625 mg conjugated equine estrogens (CEE) or its equivalent [199]. Several studies have shown a smaller bone-sparing effect of doses lower than 0.065 mg CEE [200–202]. Addition of a progestin along with 0.3 mg daily dose of CEE is reported to be bone sparing as well [203–205]. Recommended daily dosages for protection against osteoporosis include 0.625 mg conjugated estrogens, 1.25 mg piperazine estrone sulfate, 1 mg micronized estradiol, or 0.05 mg of transdermal estradiol.

Questions remain regarding the best timing for initiating HRT to protect against fracture, when it is too late to provide protection, and how long therapy must be continued to retain protection. The 1995 Study of Osteoporotic Fractures [206] showed that women who initiated therapy within five years of menopause and used HRT for more than ten years had the greatest reduction for risk of hip fracture. On the other hand, long-term users who had initiated therapy after five years of menopause had no significant reduction in the risk for all nonspinal fractures even though the mean length of use was 16 years. Current use was effective in reducing hip fractures among the oldest women, supporting the theory that estrogen can be used to prevent hip fractures in this age group. However, bone protection was not found in women older than age 75 in the 1993 Framingham Study with estrogen use for seven or more years [207]. In the 1997 Rancho Bernardo cohort, the bone mineral density for current users who began HRT after age 60 was similar to that of women who had begun earlier [208]. More recently the HERS study suggests that the effect of HRT on fractures for women starting therapy after the age of 60 may be reduced [197]. Case control studies suggest that at least five years of use are required to gain protection against fractures [209–212]. Although it is generally agreed that estrogen replacement confers

protection against the immediate loss of bone after menopause, once estrogen is stopped, bone loss is considerable and occurs quickly so that estrogen therapy must be used continuously to provide protection [213]. While the current use of estrogen may reduce the risk of osteoporotic fractures [214], as many as 30 years of HRT use is necessary to obtain this protective effect throughout a woman's lifetime. The authors of the WHI conclude that although fracture risk is reduced by HRT use, the attendant risks of breast cancer and CVD over time should be considered, and alternative therapies for prevention and treatment should be employed for prevention and treatment of fracture [129].

Other factors must be taken into account when contemplating use of HRT over an extended period of time. Estimates of compliance with long-term use of estrogen are low. In one study, fewer than 25 percent of women reported that they still used HRT two years after initiation of treatment [215]. There are also many contraindications to taking estrogen, as well as women who decline use for their own reasons. While long-term use may confer protection to the skeleton and the circulatory system, it is the duration of use that is implicated in worrisome increases in breast cancer. At this time, long-term evidence is not available for this practice. Since women in their fifties do not have osteoporosis and their risk of fracture is low, the benefit of long-term treatment with estrogen to prevent bone loss and fractures may not exceed the risks [196].

Alternative treatment options that retard bone resorption in individuals with osteoporosis include bisphosphonates such as alendronate (Fosamax) and risedronate (Actonel). These drugs are the most potent treatment for osteoporosis based on BMD and fracture studies [216, 217]. Bisphosphonates are indicated for short-term reduction in fracture risk. However, bisphosphonates cause inflammation and ulceration of the upper gastrointestinal tract. Chronic use may be associated with diarrhea and abdominal pain [218]. To aid absorption, these drugs are taken with a full glass of water upon awakening, before breakfast. The individual must remain in an upright position for at least 30 minutes following ingestion to avoid esophageal ulceration. Oral bisphosphonates are poorly absorbed (1 to 10 percent of a given dose); consequently, women should be told to avoid taking them with calcium supplements, food, or milk products that can further significantly inhibit absorption [219]. Alendronate (Fosamax) is approved at 2.5 mg daily [217] for osteoporosis prevention and 5 mg daily for osteoporosis treatment [220]. The best protection is seen in patients with the greatest short-term fracture risk, such as patients with "T" scores greater than 2.5 or preexisting vertebral fractures [221]. Risedronate sodium (Actonel) is also approved by the FDA at 5 mg for both prevention and treatment of osteoporosis.

Selective estrogen receptor modulators (SERMs) are antiestrogens that possess agonist action on bone, lipids, and lipoproteins and antagonistic action in the endometrium and the breast. Thus in theory these drugs may preserve bone density and reduce the risk of osteoporotic fracture and coronary heart disease and at the same time lower the risk of endometrial and breast neoplasms [222]. The FDA has approved 60 mg of raloxifene (Evista), a SERM, daily for prevention of osteoporosis. Some women prefer raloxifene to estrogen with its side effects and risks. Unlike tamoxifen (for breast cancer recurrence protection), raloxifene does not exert stimulatory activity on the endometrium [223]. Raloxifene may be appropriate for use in women who are interested in breast cancer risk reduction. Raloxifene seems to be causally related to deep vein thrombosis (DVT) and pulmonary embolism with an incidence of 1 percent in dose levels of 60 mg and 120 mg similar to women using HRT [224]. The Multiple Outcomes of Raloxifene Evaluation (MORE) study, a recent large examination of raloxifene treatment for *established* osteoporosis, has shown that bone density significantly increased in the spine and hip and the risk of new vertebral fracture was reduced by 40 percent [224]. Raloxifene produces some improvements in lipid profiles but not to the extent found with estrogen. Short-term data suggest that raloxifene preserves bone and causes lipid profiles that are less atherogenic [114, 224, 225]. Long-term studies are needed to confirm the effect on fracture protection as well as whether there is any decrease of breast or endometrial cancer. Unfortunately, as many as 20 percent of women who use SERMs will experience classic symptoms of antiestrogens such as hot flashes [225].

Calcitonin (Calcimar, Miacalcin), which directly inhibits osteoclasts and thus can slow bone loss, is the least potent of the options for osteoporosis treatment [221]. Calcitonin is ineffective orally. Injectable calcitonin is the route that offers the best absorption but is inconvenient. Intranasal calcitonin, 200 IU/d, is widely used and is acceptable to patients. Calcitonin has analgesic properties in addition to the anti-bone absorption effect and can be

prescribed for women with severe pain of compression fractures [226]. One study showed the effect of calcitonin on bone mineral density (BMD) and bone markers to be significantly less than that of alendronate and not significantly different from placebo for most skeletal sites [227]. Calcitonin may be suitable for patients with acute vertebral fracture who are bedridden or experiencing serious pain or the woman who needs to avoid bisphosphonates because of risk of esophageal injury or avoid estrogen because of venous thromboembolism.

The Food and Drug Administration (FDA) has approved SERMs, bisphosphonates, and calcitonin for prevention and treatment of osteoporosis. However, no trial has been performed to determine the effect of estrogen on risk of fracture in women with established osteoporosis. Because of this, the FDA approves estrogen for prevention but not for treatment. In a recent meta-analysis of 22 trials [197], the evidence about the efficacy of postmenopausal estrogen for prevention of osteoporotic fractures was weak [196], in comparison to other FDA-approved treatments. Observational studies suggest that ten years or more of estrogen use are required to reduce the risk of fractures, and, at that point, the risk of breast cancer from exposure to estrogen is increased substantially [228]. Additionally, estrogen therapy increases the risk of thromboembolic events [229] and gallbladder disease [157]. The question must be asked whether estrogen reduces risk of fracture as much as treatment with bisphosphonates. Until such time, the first choice for older women should be treatments other than estrogen.

Exercise

Regular exercise might be the only method that may prevent osteoporosis fracture, by preventing both osteoporosis and falls [230]. Physical activity increases bone mass, density, and strength [231]. Exercise in adults seems better at preserving bone than increasing bone mass [232, 233]. However, this bone preserving action of exercise may be important in maintaining bone strength and preventing osteoporotic fractures since only small percentages of bone mass and density preserved result in significant reductions in risk of fracture [234]. Regular sports such as aerobics, tennis, basketball, or weight and power training provide versatile strain distribution throughout the bone structure that best improves bone strength [232]. For older individuals, brisk walking, climbing up and down stairs, dancing, and adult age gymnastics and calisthenics are appropriate [235, 236]. Secondarily, exercise improves gait, balance, coordination, proprioception, reaction time, and muscle strength even in the very elderly and frail. Epidemiologic (case-control and prospective cohort follow-up) studies consistently show that past and current physical activity protects against hip fracture, reducing the risk by up to 50 percent [235–237]. Regular physical activity, especially if started early in life, is cheap, safe, and readily available. It is an acceptable way of improving bone strength and preventing the tendency to fall. Midwives should get women, young and old, moving to protect their bones and accrue all the other benefits that accompany physical activity.

Other factors that can lead to increased risk for fracture include poor visual acuity (due either to wearing inappropriate correction or no correction whatsoever) and cataracts. The aging process affects all bodily functions. Consequently, it is unknown whether correcting visual acuity will decrease fracture rates since impaired vision may be a marker for aging of other systems as well [235–237].

Diet

A systematic review in 1990 concluded that calcium supplementation has a positive influence on the skeletal system at all ages, particularly in childhood, adolescence, and the perimenopause [238]. The role of calcium and vitamin D in the elderly is not so clear-cut. For example, there may be an association between long-term treatment with vitamin D and increased vascular calcification [239]. Although calcium and vitamin D probably play an important role in bone metabolism and fracture risk, it is feasible that other nutrients may also have value in influencing fracture risk [240]. Rather than focus on individual nutrients, an alternative way to investigate the effect of diet on disease is to study the effect of food patterns and food groups. It has been suggested that a diet rich in fruits and vegetables and other nutrients may be associated with higher bone mass [241, 242]. Dietary habits could exert their influence through the nutrients contained in the foods (vitamins, minerals) or through other components in the foods such as antioxidants or phytoestrogens [240].

Perimenopausal women in the United States generally have a daily dietary intake of calcium of about 500 mg. In order to maintain a zero calcium balance, these women require supplementation

with 1000 mg [92]. These effects are best realized when women also make other healthy lifestyle changes, such as frequent weight-bearing exercise that strengthens the skeleton.

The Perimenopausal Visit

Very often, the woman who presents to a woman's midlife clinic or practice is still having menses. Typically, she has been an active participant in her own previous health care decisions whether regarding childbirth, contraception, or other matters, and she desires information, recommendations, options, and support for her health decisions. Frequently, the woman in her late thirties or forties is experiencing hot flashes, cycle variations, or other changes about which she has questions or concerns. For many women their lack of knowledge about what to expect is disconcerting, and what women are told to expect is often conflicting. This may lead to anxiety in some women, who are frightened that something is wrong. For the woman who experiences irregular menses in the perimenopause, the fear of cancer or other pathology can be greatly out of proportion to actual risk. The midwife can offer information in order to help women sort out their own risks or benefits and make the best decisions about health care and lifestyle practices.

History

As well as the routine history and health questions asked of women of any age, the midwife needs to obtain historical information related to changes and specific risk factors associated with the following:

1. reproductive tract
2. urinary tract
3. breasts
4. vasomotor system (hot flashes, night sweats)
5. skeletal system
6. cardiovascular system
7. psychological changes

Instead of signs of reduced estrogen, some women present during the perimenopause with symptoms of estrogen excess, including uterine bleeding, bloating, growth of uterine fibroids, and endometriosis, any of which should be investigated. Assessment of the midlife woman should also focus on early detection of any of the major chronic diseases of midlife, including hypertension, heart disease, diabetes mellitus, and cancer. Finally, each of the following should be investigated before making a management plan:

1. impairments of vision
2. impairments of hearing
3. dental health
4. nutritional status
5. physical activities or limitations
6. injury prevention: seat belts, avoidance of drinking and driving
7. environmental risks
8. occupational, sexual, marital, relationship, and parental problems
9. use of cigarettes, alcohol, and other substances
10. contraceptive needs
11. immunization status

Midwives should help low-income or underinsured women find resources to explore and prioritize these health care needs, especially in the context of the changing managed health care milieu.

Perimenopause Physical Exam

Examination of the woman going through the changes of the climacteric is an opportunity for appropriate historical inquiries, risk assessment, identification of unreported illnesses, and reinforcement of preventive health measures. For example, when examining the mouth, the midwife has the opportunity to discuss many topics including dental checkups, nutrition, family interactions around meals, and food preparation.

The initial or annual examination should include the following:

1. *Height:* Most women have not had their height measured in decades and often have lost an inch or more. Measuring height provides an opportunity to discuss posture, body mechanics, exercise, and osteoporosis.
2. *Skin:* The skin should be evaluated for integrity, lesions, and changes in moles. The incidence of skin cancers increases with aging and many women have no other providers who assess their skin.
3. *Mouth, teeth, gums:* The incidence of periodontal and other oral diseases increases with age.
4. *Pelvic examination:* A pelvic examination should be conducted with attention paid to the expected changes that accompany aging as well as to any changes the woman has brought to your attention. Use of a Pederson speculum is usually optimal for postmenopausal women because of atrophic changes that may have occurred in the vagina.

5. *Rectum:* The rectum should be examined for masses and fissures.

Laboratory and Other Tests

Which tests the midwife performs or orders depends on the symptoms with which the woman presents, the cost effectiveness of the tests, the risks and benefits involved with the test, and the woman's goals, preferences, and personal risk factors. The following is a list that can be used as a guide, keeping in mind the above criteria.

Tests for Routine Screening, Initial, or Annual Examinations

1. Urinalysis/urine dipstick.
2. Pap smear with maturation index.
3. Mammography: every 1 and 2 years between 40 and 49; annually from age 50 (American Cancer Society; American College of Radiology; American College of Obstetrics and Gynecology).
4. Stool for occult blood.
5. Fasting plasma cholesterol, triglycerides, and lipid profile: every three to five years if normal.
6. TSH at age 45 and then every other year [92]. There is an increased incidence in hypothyroidism (Hashimoto's thyroiditis) with aging.

Other Tests (Use varies according to clinical profile and individual risk factors)

1. *Pituitary gonadotropins:* Used to establish menopausal status. FSH levels are typically 4–30 mIU/mL with a pre-ovulatory surge to 50 mIU/mL in the reproductive years; >100 mIU/mL in the postmenopause. FSH rises earlier after the menopause and to higher levels than LH. LH levels are typically 4–30 mIU/mL with pre-ovulatory surge to 100 mIU/mL in the reproductive years; >100 mIU/mL in the postmenopause.
2. *Estrogens:* Used to evaluate menopausal status and the effects of hormone therapy on circulating levels of estradiol. Estradiol levels are typically 50–350 pg/mL (picograms per milliliter) in the reproductive years and 5–25 pg/mL in the postmenopause. Since these latter levels do not overlap with premenopause levels, measurements of <25 pg/mL can be helpful in diagnosis of menopause. Estrone levels are typically 20–70 pg/mL. There is substantial overlap in levels between younger and older women, so measurement of estrone is not helpful as a diagnostic tool.
3. *Fasting and two-hour postprandial glucose levels:* Useful when risk factors are present for diabetes.
4. *Liver function tests:* Done prior to prescribing hormone therapy when liver disease is present or suspected (e.g., because of alcoholism).
5. *Endometrial biopsy:* Appropriate for ruling out endometrial hyperplasia and cancer in a postmenopausal woman who has uterine bleeding after more than a year of amenorrhea. It is also useful in ruling out pathology resulting from exogenous estrogen excess that is seen clinically in unscheduled bleeding with HRT use. An endometrial biopsy is not needed (1) for normal cycle changes accompanying the premenopause, (2) with a normal pelvic exam and no risk factors for endometrial hyperplasia and cancer, or (3) prior to initiation of hormone therapy [2].
6. *Transvaginal ultrasonography:* Used for evaluation of pelvic masses and for unscheduled bleeding to rule out endometrial pathology. The thickness of the postmenopausal endometrium correlates with the presence or absence of pathology such as neoplasia, myomas, or polyps. It also has the advantage of evaluating the ovaries for masses or neoplasia.
7. *Dual energy x-ray absorptiometry (DXA):* Useful when a woman is undecided on which therapeutic plan to follow (HRT, bisphosphonates, exercise, or calcium supplements), and another level of data will help her make a clinical decision about this choice.

Postmenopausal and Older Woman Visit

For the postmenopausal woman who seeks care from the midwife, symptoms have often subsided and a new equilibrium has been established in the various aspects of her life. She may feel better with the transition complete. Results from the Massachusetts Women's Health Study, a longitudinal, population-based study, showed that women's attitudes toward menopause become more positive after they experience the menopause [243]. For the postmenopausal woman who is not having problems, the visit is still important for health promotion, screening, and general surveillance. Gynecology visits with the midwife are an opportunity to get the older woman back into the health care system, maintain continuity of care, arrange referrals as appropriate, and involve her in a preventive health care program. While the chance of illness is higher in this age group, the impact of any therapeutic changes she makes is much greater.

Many of the components of the visit are similar in scope and breadth to the woman in the midst of the climacteric transition. Life expectancy is greater today, largely due to the elimination of premature death from infectious disease. The major determinant of life expectancy at this time is chronic disease, affected by genetics, lifestyle, the environment, and aging itself. Great strides have been made in the treatment of cardiovascular diseases. What the midwife can offer is her knowledge of menopause to educate the individual regarding her genetics, her lifestyle and environment, and the role these factors play in her health, her life expectancy, and her quality of life. An individual woman may not know about her hypertension. By taking a careful history and performing a careful physical exam, the midwife can show the woman exactly how her blood pressure, weight, lifestyle practices, and family history all fit together. The postmenopausal visit is an opportunity to offer specific recommendations that the woman can take home with her. The impact of personal recommendations is a much more powerful message than reading an article or listening to a public service message on television. The midwife can help each woman achieve the best health possible by maintaining physical and cognitive functions as long as possible. Explained in another way, the goal is to maximize "active life expectancy," the duration of functional well-being, and the maintenance of independence in the activities of daily living [244].

Since chronic illnesses are incremental in nature, the best health strategy is to change the rate at which illnesses develop. Disease is now seen as something that can be prevented or postponed rather than treated only with medication [92]. The effect of postponing illness by smoking cessation and eliminating obesity is now known. Aging and the stereotypes that go along with it affect self-determination and feeling in control. When older people are given choices about their lives and the decisions that affect them, there are fewer declines in health and psychological status.

When women are between the ages of 40 and 49 years, gynecology visits yearly are recommended to include breast and pelvic/rectal exams and to order screening mammograms. A complete physical exam, medical history and tests for chronic illnesses, immunizations, counseling for nutrition, physical needs, injury prevention, substance use, and dental prophylaxis should be done at least every five years [92]. For women over age 50, annual tests for hypertension and obesity are recommended. There is insufficient evidence to recommend for or against routine screening for diabetes mellitus in asymptomatic adults [245]. Clinicians may decide to screen persons at high risk for diabetes, however. In a 2001 update, the U.S. Preventive Services Task Force strongly recommended routine screening for lipid disorders in women age 45 and older to include total cholesterol and high-density lipoprotein cholesterol (HDL-C) [246]. Routine screening for ovarian cancer by ultrasound, measurement of tumor markers, or pelvic examination is not recommended by the task force because of insufficient evidence of improved outcomes in asymptomatic women. Although the task force does not recommend routine screening for thyroid disease for asymptomatic adults, it notes that recommendations for such can be made on other grounds. Since thyroid disease can mimic other conditions such as depression, lethargy/confusion, congestive heart failure, atrial fibrillation, and menopause changes, thyroid function tests are recommended every other year after the age of 60 [92].

Routine screening for cervical cancer by Pap smears is recommended for all sexually active women at least every three years [245]. There is insufficient evidence to recommend for or against an upper age limit for Pap testing but recommendations can be made on other grounds to discontinue regular testing after age 65 in women who have had regular previous screenings that have been consistently normal [245]. Pap smears should be done yearly if the woman has a recent history of an abnormal Pap. However, if a woman has never had an abnormal Pap and no other risk factors, she no longer needs to have yearly smears. This is further supported by the fact that the incidence of infection with human papillomavirus (HPV) declines with increasing age irrespective of risk factors [247]. For women who have had a hysterectomy for cancer of the cervix or endometrium, Pap smears should be continued on the same schedule as above. If a woman had a hysterectomy for reasons other than cancer, Pap smear screening of the vaginal wall is no longer necessary after menopause. The woman should be advised that a pelvic exam is still important to detect other problems. Screening for colorectal cancer is recommended for all persons age 50 and older, including annual fecal occult blood testing and sigmoidoscopy every five years [245].

For women between the ages of 60 and 74 years, professional visits should occur every one to two years and include the same points listed for the perimenopausal woman. Additionally, they should

receive immunizations against influenza annually and be vaccinated against pneumonia every three to five years [248].

When a woman is 75 years or older, it is important to try to support her to live independently and avoid institutionalization as long as possible. She should be encouraged to maintain activity, avoid inactivity, and be helped to minimize discomfort from chronic conditions. The midwife needs to pay attention to signs of elder abuse such as bruising or weight loss.

Decisions about health care should be made on patient preferences and the presence of chronic illnesses, not on chronological age alone. Risks of treatment must be weighed against potential benefits. For example, a high-risk procedure might prevent irreversible loss of functional independence, so it might be worth the risk. Prevention interventions also vary with age. A good example is the cholesterol level in elderly women. The strength of the association between cholesterol and heart disease decreases in older women. By age 80 it may not be worth intervening in women with high levels [92]. Finally, some problems may not be easily recognizable in older patients. As discussed in previous sections of this chapter, it is important for the midwife to evaluate for sexual dysfunction, alcoholism, musculoskeletal problems, dementia, incontinence, depression, hearing and visual losses, and predilection to falls.

Assessment

When assessing the midlife or aging woman, the midwife must take into account all the data that have been collected and help the individual woman make health decisions that are in her best interest. Many of these decisions are not clear-cut or easy to make. Midlife women are overwhelmed by information from the media and the medical establishment about how to manage their menopause. Because much of the information these women receive is contradictory, the choice for intervention or nonintervention is not clear and can be associated with ambivalent feelings. The choice at midlife to take responsibility for changes in lifestyle toward more health promotive behaviors is a monumental one for many women. These women need information, clarification, and support for their decisions, and they should not be made to feel guilty about their choices. The decision to take hormones for troublesome physical changes or for prevention of future diseases also causes anxiety for many women. The midwife needs to be able to personally tailor the evaluation and management decisions to a woman's particular needs, risks, and opinions. This means putting the data within the context of a woman's culture and her peer group, taking into account her fears, family, and personal histories. Designing a course of action requires time, skill in listening to the woman, and being up-to-date on both the lay (feminist and traditional) and scientific literature. This is especially important because they are so often in conflict. To accomplish this daunting task, the midwife needs first to acknowledge her own biases; then she must identify areas in which the woman wants the midwife's help and determine if the woman has any fears about the climacteric or possible interventions. When these are identified, the midwife can sort through the woman's concerns and assist with genuine problem solving by giving relevant information and reasonable explanations of the state-of-the-art knowledge regarding menopause.

A test called the *maturation index* (MI) is also recommended for postmenopausal women. It is often included as part of the routine Pap smear, but it may have to be requested. When the cytologist is evaluating the smear, the individual woman's history including age, LMP, hormone use, or postmenopausal without hormone use should be reflected in the estrogen effect seen on the slide. For example, if the cells on the slide of a postmenopausal woman using no hormones reflect a high estrogen effect inconsistent with her history, the cytologist will comment that the estrogen effect does not match the history. Some laboratories report maturation index as a series of three numbers representing the three layers of squamous cells: parabasal, intermediate, and superficial cells in that order expressed in percentages (for example, 5/70/25). This is an expression of estrogenic influence, but it is only a very crude measure of estrogenic status and can be misleading. This examination cannot predict whether or not a woman is experiencing climacteric signs (it is more accurate to ask her), and it cannot be used as a sole guide to hormone therapy. It can be used to determine the dose of estrogen needed to reverse vaginal atrophy. It is also helpful to identify the woman whose maturation index (estrogenicity level) is higher than would be expected for the clinical picture of the woman. For example, in a woman ten years postmenopause, you would expect her vaginal mucosa to have scant estrogen influence. If her MI is elevated, either she is reacting to very low levels

of endogenous estrogen with a greater than usual response or she has an elevated endogenous estrogen level, perhaps from obesity and consequent aromatization of androstenedione to estrone from adipose tissue. This woman may present with postmenopausal bleeding, which would then need to be investigated by endometrial surveillance such as endometrial biopsy, transvaginal ultrasound, or both.

As women reach their sixties, seventies, or eighties, issues such as chronic diseases must be identified. Heart disease, hypertension, stroke and diabetes become more common. Cancers of nearly all kinds occur with greater frequency as women age. Joint and muscle pain, arthritis, and rheumatic disorders have significant impacts on women's daily lives. Changes in vision, hearing, and other sensory losses are associated with aging and their insidious onset may be unrecognized. Memory losses can be insidious as well, recognized by family members before the individual herself. Are these changes indicative of benign senescent forgetfulness or of more ominous conditions such as Alzheimer's disease? Mood disorders such as depression are widely unrecognized in older women who may be suffering from loneliness, depression regarding changes in ability to function both physically and mentally, lack of stimulation, medicinal or alcohol side effects, to name a few causes. Midwives have the opportunity to help identify developing medical problems and to work with women and their families to obtain appropriate evaluation and health care. Whether or not to begin medications such as HRT for fracture prevention or for memory protection at age 70 are the kinds of questions for which there are no answers.

Menopausal Therapeutic Interventions, Preventive Measures, and Health Promotion

Self-Determination in Menopause

Menopause has been experienced and managed by women throughout the ages. Women rely on their own intuition, common sense, family traditions, and each other to make safe passage through each of the developmental stages of life. In the past century, as scientific advances have done much to improve longevity and quality of lives, many women have been gradually losing touch with the processes occurring in their bodies and becoming more dependent upon "medical authority" as the true guide for health decisions. Much has been gained from medical advances, but women often need support to retain as much control over their destinies as is desired. Often women have ideas and feelings about what decisions they should make, yet their ability to listen to their inner voices becomes more and more difficult as time goes on. Just as the medicalization of pregnancy has had certain adverse consequences, medical "management" of the menopause can separate women from their strengths and vitality. Women have reclaimed many of the processes of pregnancy and childbirth, and midwives need to support women as they make choices for self-help when dealing with issues of midlife. Women are calling on health care providers to help them assess both the benefits and risks of action or nonaction. Midwives can help them make their own decisions, without pressure and biases but with empathy and an understanding of the wide personal differences that women bring to the issues of aging, midlife sexuality, menopause, and hormone use [249].

A midwife cannot assume that an acceptable risk for a sick person is an acceptable risk for a healthy woman. While a woman with breast cancer might well risk the side effects of using tamoxifen, it is entirely different to pressure a woman into making a decision to use a treatment with possibly harmful side effects in order to prevent possible future diseases. The unexpected results from the WHI demonstrate that the issue is a complex one that is apt to make both providers and women confused and anxious. Midwives are in an ideal position to provide judicious advice and personally tailored information that offers the balance that women need.

Hormones

Estrogen Replacement Currently, there is little evidence that one estrogen preparation is superior to another; the dose *and* duration and the use of a progestin are more important.

The lowest dose that offers relief of symptoms should be used. The question of whether HRT should be used at all for potential prevention of chronic diseases has been called into question since the WHI has been halted. In the years to come, there will certainly be additional knowledge and recommendations on the use of HRT for prevention of chronic illness that affect women in their later years. In a departure from recommendations over the previous decade, the Writing Group for the WHI recommended in 2002 that HRT not be prescribed at all for long-term use [129]. For any woman suffering with significant menopause symp-

toms in which her quality of life is impaired, the midwife will have to discuss with her whether the use of HRT for a few years is worth the risk.

When the decision is made to use hormones, many confounding factors influence the choice of product, including market forces and the latest research. New products are coming on the market all the time. There is often some trial and error to arrive at a product or regimen that is right for a particular woman. Most prescriptions are written for HRT in pill form but estrogen products are also available in vaginal creams, vaginal rings, and skin patches.

In previous decades, HRT was prescribed three weeks on, one week off to mimic the menstrual cycle. A progestin was added the third week to ten days to protect the endometrium from overgrowth. Withdrawal of both hormones allowed for sloughing of the lining on a regular basis. Women appreciated the "normalcy" of this method because it led to infrequent unscheduled bleeding episodes. Unfortunately, many women developed symptoms such as hot flashes during the week off hormones. To avoid this problem, estrogen was prescribed 365 days a year plus the progestin (to protect the endometrium from unopposed estrogen effect) was prescribed from 10 to 14 days each month. Many women prefer not to get any menses whatsoever after menopause, and most women are upset with unscheduled bleeding. In order to develop an atrophic endometrial lining and stop bleeding altogether, HRT is now often prescribed in a continuous regimen where the woman takes both estrogen and a progestin every day. This may produce unscheduled bleeding during the first months, but by one year most women have developed an atrophic endometrium that does not bleed. Women need to be counseled about this bleeding much in the same way that midwives counsel women using Depo-Provera. Recent additions to the market include combination products that contain both an estrogen and a progestin either continuously or cyclically or in a pulsed fashion (some days estrogen alone while other days a combination of estrogen and a progestin).

Estrogen products are listed in Table 13-1, some of which also include a progestin. The routes of administration and doses vary. The midwife should check in a recent drug reference book for accuracy of this information, remembering always to prescribe a progestin along with an estrogen product for a woman with an intact uterus. For women who have undergone a hysterectomy, no progestin is needed.

Most HRT is prescribed as oral tablets. A proposed physiological advantage of oral administration is that it passes first through the liver. This may account for improvement of lipid profiles [155, 170, 251]. Another advantage to oral administration includes ease of use. In Western culture, medicine is most often administered in this way, so it is acceptable to most women. Remembering to take it on a regular basis can be a problem for some women, especially if the primary reason is for long-term health benefits requiring many years of use. For women using HRT to relieve symptoms, just one night of hot flashes quickly reminds them of a missed dose.

Contraindications to the use of exogenous estrogen in menopausal women include estrogen-sensitive tumors of the reproductive system including the endometrium and breast. For women who have

TABLE 13-1 Estrogens

Conjugated Equine Estrogens (CEE)	Manufacturer	Route	Dose
Premarin	Wyeth-Ayerst	Oral caplets	0.3, 0.625, 0.9, 1.25, 2.5 mg
		Vaginal cream	0.625 mg/g (1 g 1–3 times a week)
PremPro (CEE plus MPA[a])		Oral caplets in blister pack	0.625 mg CEE plus 2.5 mg MPA; 0.625 mg CEE plus 5 mg MPA
Premphase (CEE plus MPA)		Oral caplets in blister pack	0.625 mg CEE for first 14 days of pill pack and 0.625 mg CEE plus 5 mg MPA next 14 days of pill pack

TABLE 13-1 Estrogens *(continued)*

Estradiol (E)	**Manufacturer**	**Route**	**Dose**
Activella (E plus norethindrone)	Pharmacia and Upjohn	Oral tablets	1 mg E plus 0.5 mg norethindrone
Estrace	Bristol-Meyers, Squibb	Oral tablets	0.5 mg, 1.0 mg, 2.0 mg
		Vaginal cream	1 g 1–3 times a week
OrthoPrefest (E plus norgestimate)	Ortho-McNeil	Oral tablets in blister pack (pulsed dosage)	3 days of 1 mg E (pink pills) followed by 3 days of combined 1 mg E plus 0.09 mg norgestimate; repeat
Estring	Pharmacia and Upjohn	Insert vaginal ring for 90 days; reinsert new ring	2 mg
Estraderm	Novartis	Transdermal patch; change twice a week	0.05, 0.1 mg
Climara	Berlex	Transdermal patch; change once a week	0.025, 0.05, 0.075, 0.1 mg
Vivelle	Novartis	Transdermal patch; change twice a week	0.025, 0.0375, 0.005, 0.075, 0.1 mg
Esclim	WomenFirst	Transdermal patch; change twice a week	0.025, 0.0375, 0.05, 0.1 mg
Combipatch (E plus NETA[b])	Aventis	Transdermal patch; change twice a week	0.05 mg E plus 0.14 mg NETA; 0.05 mg E plus 0.25 mg NETA
Alora	Watson	Transdermal patch; change twice a week	0.05, 0.075, 0.1 mg
Esterified Estrogen	**Manufacturer**	**Route**	**Dose**
Estratab	Solvay	Oral tablets	0.3, 0.625, 2.5 mg
Estratest (plus methlytestosterone)	Solvay	Oral tablets	1.25 mg esterified estrogens plus 2.5 mg methyltestosterone
Estratest HS (plus methlytestosterone)	Solvay	Oral tablets	0.625 mg esterified estrogens plus 1.25 mg methyltestosterone
Estropipate	**Manufacturer**	**Route**	**Dose**
Ogen	Pharmacia and Upjohn	Oral tablets (also available in vaginal cream)	0.625, 1.25, 2.5 mg
Ortho-Est	WomenFirst	Oral tablets	0.625, 1.25 mg
Ethinyl Estradiol (EE)	**Manufacturer**	**Route**	**Dose**
FemHRT (EE plus NETA)	Pfizer	Oral tablets	5 mcg EE plus 1 mg NETA
Estinyl	Schering	Oral tablets	0.02, 0.05, 0.5 mg
Synthetic Conjugated Estrogen	**Manufacturer**	**Route**	**Dose**
Cenestin	Duramed/Solvay	Oral tablets	0.625, 0.9, 1.25 mg

[a] Medroxyprogesterone acetate.
[b] Norethindrone acetate.

had a hysterectomy for endometrial cancer that is estrogen and progesterone receptor negative, immediate hormone therapy can be instituted; with receptor positive tumors, it is recommended to wait five years before starting hormone treatment to ensure no recurrence of the disease [2]. The breast cancer risk confirmed in the WHI certainly must be taken into account when deciding if the risk of treatment is worth the benefits as well as the increases in the risk of cardiovascular incidents, stroke, and thromboembolism. For women who have impaired liver function or acute current vascular disease, including embolus and thrombosis, hormone replacement is contraindicated. For women with migraines, the daily regimen of hormones may reduce the incidence of headaches by eliminating cyclic changes. Hypertension, diabetes, and varicose veins are not contraindications to hormone therapy in the perimenopausal period. Generally, fibroid tumors do not grow under the stimulation of hormone therapy; however, their surveillance by pelvic exam must be continued.

Progestins In 1976 the pathologic effect of unopposed estrogen on the uterine lining became known. Since that time progestins have been prescribed to offset this. The most commonly prescribed progestin has been medroxyprogesterone acetate (MPA), which is prescribed under the brand names Provera, Cycrin, and Amen. However, newer products have been introduced because many women who use MPA experience adverse side effects including breast tenderness, bloating, and depression or irritability. For decades, the standard dose for MPA was 10 mg. However, doses of 5 mg and 2.5 mg have also shown to be protective against pathologic changes in the endometrium when given daily or for 12 to 14 days a month. Days of exposure to a progestin have been shown to be more important than dose in protection of the lining.

Progestin products, some of which also contain estrogen, are listed in Table 13-2. The routes of administration and doses vary. The midwife should check in a recent drug reference book for accuracy of this information, remembering always to prescribe a progestin along with an estrogen product for a woman with an intact uterus. For women who have undergone a hysterectomy no progestin is needed.

Common practice now includes HRT prescribed as a continuous daily combination of both estrogen and a progestin. It is simpler to prescribe and for the woman to remember to take. For 80 percent of women, this way of prescribing leads to an atrophic endometrial lining and cessation of bleeding after one year. Breakthrough bleeding may be experienced by 40 to 60 percent of women during the first six months of continuous therapy. Management of such bleeding requires supporting the woman and providing explanations. Preparatory education and follow-up telephone support can often ease the situation. Although it may indeed be nothing more than a problem of missed pills, unscheduled bleeding with sequential dosing or bleeding after more than a year of amenorrhea with continuous dosing requires investigation with a pelvic exam and endometrial biopsy or transvaginal ultrasound to rule out pathology. The midwife trained to do endometrial biopsies passes a small instrument called a suction curette through the cervix to obtain a small amount of endometrial tissue. The biopsy determines the presence of proliferative endometrium, atrophic endometrium, hyperplasia, or neoplasia. It has been common practice for clinicians to perform biopsies prior to initiation of HRT to rule out pathology. However, it is not necessary to biopsy the endometrium prior to initiating hormone treatment [2] since abnormalities in asymptomatic women are very rare [252]. In order to limit pretreatment biopsies, only those women who are at risk for conditions associated with chronic estrogen exposure (obesity, dysfunctional uterine bleeding, anovulation or infertility, hirsutism, hepatic disease, and metabolic problems) should have biopsies prior to HRT use. Women on continuous combined therapy frequently experience early breakthrough bleeding during the first year of therapy. Women on sequential combined therapy have withdrawal bleeding, which is perceived as a period. Women who experience variation from either of these expected bleeding patterns need to be assessed.

Since progestins are not tolerated well by some women, they might elect to take unopposed estrogen. Women need to be informed or reminded of the increased risk of endometrial cancer accompanying this choice. Endometrial surveillance by biopsy or ultrasound at least once a year can be used to monitor women who decide to take unopposed estrogen.

Many women are particularly sensitive to medroxyprogesterone acetate (MPA), which is the progestin most commonly prescribed. Other progestin products now on the market include norethindrone, norethindrone acetate (NETA), norgestimate, and natural micronized progesterone. Some women experience fewer side effects from these alternatives. These options are listed in Table 13-2.

TABLE 13-2 Progestins

Medroxyprogesterone Acetate (MPA)	**Manufacturer**	**Route**	**Dose**
Provera	Pharmacia and Upjohn	Oral tablets	2.5, 5, 10 mg
Cycrin	ESI Lederle Generics	Oral tablets	2.5, 5, 10 mg
Amen	Carnrick Laboratories	Oral tablets	10 mg
PremPro (CEE[a] plus MPA)	Wyeth-Ayerst	Oral caplets in blister pack	0.625 mg CEE plus 2.5 mg MPA; 0.625 mg CEE plus 5 mg MPA
Premphase (CEE plus MPA)	Wyeth-Ayerst	Oral caplets in blister pack	0.625 mg CEE for first 14 days of pill pack and 0.625 mg CEE plus 5 mg MPA next 14 days of pill pack
Micronized Progesterone	**Manufacturer**	**Route**	**Dose**
Prometrium	Solvay	Oral tablets	100 mg BID for 12 consecutive days each cycle
Norethindrone	**Manufacturer**	**Route**	**Dose**
Activella	Pharmacia and Upjohn	Oral tablets	1 mg E[b] plus 0.5 mg norethindrone
Norethindrone Acetate (NETA)	**Manufacturer**	**Route**	**Dose**
Combipatch	Aventis/Novartis	Transdermal patch	0.05 mg E plus 0.14 mg NETA; 0.05 mg EE[c] plus 0.25 NETA
FemHRT	Pfizer	Oral tablets	5 mcg EE plus 1 mg NETA
Norgestimate	**Manufacturer**	**Route**	**Dose**
OrthoPrefest	Ortho-McNeil	Oral tablets in blister pack (pulsed dosage)	3 days of 1 mg E (pink pills) followed by 3 days of combined 1 mg E plus 0.09 mg norgestimate

[a] Conjugated equine estrogens.
[b] Estradiol.
[c] Ethinyl estradiol.

It has been well established that testosterone is an important determinant of female sexuality and that low circulating levels of testosterone are associated with diminished libido [107]. Estrogen replacement improves vasomotor symptoms, such as vaginal dryness and general well-being, which can affect sexuality; it has no direct effect on libido. The addition of testosterone to a hormone replacement regimen can result in improvement in several aspects of sexuality in a postmenopausal woman [106]. Unfortunately, dose guidelines have not been established for these products. Androgen replacement may be indicated when a woman has undergone a surgical menopause, or menopause induced by chemotherapy or radiation, or has low serum testosterone levels. Use of androgen replacement may be appropriate when use of ERT/HRT has not been effective in treating sexual issues and reduced libido cannot be attributed to other factors [253]. These benefits must be weighed against virilizing effects and possible adverse changes in lipid profiles. Testosterone replacement, however, appears to be safe as long as dosages are restricted to the normal physiologic range so that the benefits are achieved

without the risks [107]. Contraindications include current or previous breast cancer, uncontrolled hyperlipidemia, liver disease, acne, or hirsutism [254]. Products on the U.S. market include fluoxymesterone (Halotestin/Upjohn) which comes in doses of 2, 5, and 10 mg. Estratest and Estratest HS include methyltestosterone in doses of 2.5 mg and 1.25 mg, respectively.

Sleep Remedies

Avoidance of caffeine, alcohol, and stressful activities prior to bedtime may help. Daily exercise, a regular bedtime, a warm bath in the evening, or having a glass of milk or yogurt just before sleep can also be helpful.

For women who suffer sleep disturbances related to hot flashes, several preparations may be helpful [255, 256]. Serotonin is synthesized from tryptophan, an essential amino acid that has been shown to promote restful sleep. Good sources of tryptophan are milk and chamomile tea. Valerian root is used in traditional medicine for hot flashes when related to sleep. Because of its bitter taste, it is more palatable when taken in capsule form. Estrogen therapy has also been found to greatly improve sleep patterns [257]. Taking oral estrogen preparations at night can often lead to significant improvement in sleep disturbances and have a positive cascade effect on a woman's subjective quality of life. Fortunately, severe sleep changes most often resolve after a period of six to twelve months.

Calcium Supplementation

The best source of calcium for optimal nutritional benefits is supplied by foods incorporated into a balanced diet. Low-fat or nonfat dairy products are the best sources but fortified foods and calcium supplements can help achieve the target goal of 1500 mg daily plus 400 to 800 IU of vitamin D [258]. The National Osteoporosis Foundation recommends pharmacological treatment of all postmenopausal women with "T" scores below 2.0 and those with "T" scores below 1.5 plus risk factors for osteoporosis [258]. For the same level of BMD, the fracture risk is much greater in older than younger women [234]. While older women with low bone mineral density (BMD) and a history of osteoporotic fracture should be treated pharmacologically, the management is much less clear for other patients [221].

In the United States, the most common supplement is calcium carbonate, the active ingredient in Os-Cal, Caltrate, Tums, and the generic oyster shell preparations. Some reports have claimed that calcium citrate has better absorption [259], but most show that absorbability of calcium carbonate is very nearly the same [260].

The calcium dose should be administered in divided doses with meals because this is the normal way nutrients enter the body. Bedtime is an optimal time to take calcium to allow absorption during the sleeping hours. Side effects of calcium supplementation can include constipation and flatulence. Vitamin D deficiencies are found in women over the age of 70 so supplements are recommended for elderly populations [261]. The same holds true for women who live in climates with long cloudy winters with little opportunity for sun exposure [262].

The Menopause as Opportunity

The climacteric is a time, similar to pregnancy, when women often present to the health care system for help with changes, to gain knowledge of the processes occurring, and for routine health care. Midwives who care for women at midlife have the opportunity to offer preventive care, health screening, disease identification and treatment, maintenance of continuity of care, appropriate referrals, and supervision of cost-effective care. Menopause is a time to engage women in the health care system. In doing so it is possible to prolong the period of optimal physical, mental, and social activity, and to minimize handicaps and discomfort from the onset of chronic conditions [92]. Midwives can develop an individualized preventive health program for every midlife woman they care for. As primary care practitioners, midwives have an opportunity to provide leadership in the delivery of holistic, women-centered health care to women as they age and to influence society to accept more responsibility for the humane treatment of its aging population.

Finally, women of *all* ages hold the wonder and mystery of the universe. As health care providers to women, midwives can offer support to, and hold genuine appreciation of, the journey that women traverse from the climacteric through old age and celebrate each woman's strengths, struggles, decisions, and accomplishments. It is the women and what they give back to midwives that make participating in health care so golden.

CHAPTER

14

Common Diagnoses in Women's Gynecological Health

WILLIAM F. McCOOL, CNM, PhD, FACNM
DAWN DURAIN, CNM, MPH

The current motto of the American College of Nurse-Midwives—"With women, for a lifetime"—summarizes concisely the vast area of midwifery health care. While the name "midwife" conjures images of pregnancy care and attendance at birth, the fact is that for centuries midwives have been called upon to assist women in health care matters that have extended beyond childbearing. Historically, midwives have helped women with issues regarding menarche, menstruation, and menopause. And this historical role has not only extended throughout the twentieth century but has expanded further with health care practices of the twenty-first century.

The average number of children born to women over a lifetime today in the United States is 2.1 [1]. Many women never experience pregnancy or birth at all. Although exact figures are difficult to document, one recent investigation reported that 17 percent of a large sample of American women had primary or secondary infertility problems, and an additional 16 percent have never attempted conception [2]. Clearly, most women spend most of their lives in a state where gynecological health plays a large role in their well-being. This fact has not been lost on midwifery practice. Within the last decade, practicing CNMs/CMs have reported that 92 percent offer contraception care, 84 percent gynecological care, 71 percent primary care, and over half (53 percent) menopausal care [3]. As noted in the ACNM Philosophy, midwives' focus on "the needs of the individual and family for physical care, emotional and social support" should "extend to include gynecological care of women throughout the life cycle" [4].

As with health care in general, the list of potential problems or issues in the gynecological field approaches an endless number. Gynecology textbooks are thick with diagnoses ranging from difficulties with the brain to malformations of the genitalia. Fortunately, most of these conditions are rare, and better left with specialists who focus on the less-than-common maladies. For most women, and for the practitioners who work with them, the majority of gynecological health concerns are limited to a few general categories. This chapter will focus on the most common diagnoses found in gynecological care. These include issues related to the menstrual cycle, lower abdominal/pelvic pain, pelvic masses, the genitourinary system, and cancer screening/diagnoses. Other matters of adult women's health, including gynecology and primary care, are addressed in Chapters 3, 5–13, and 15. The focus here will be on assisting the midwife to offer comprehensive care to a woman throughout her lifespan, particularly when pregnancy is not the matter at hand.

Issues Concerning the Menstrual Cycle

Amenorrhea

A common change found at some point in most adult women's menstrual cycles is amenorrhea. Throughout an individual's life, the absence of

menses can be due to normal life events such as pregnancy, menopause, or the use of birth control methods. Yet, there are a number of events or conditions that are related to abnormal amenorrhea, and the challenge for the practitioner is to differentiate between normal and abnormal, and discover the cause of the latter.

The term amenorrhea is traditionally thought to be applicable to one of three clinical situations:

1. A young adolescent (14 years of age or younger) who has never experienced menses and who does not yet exhibit any physical signs of secondary sexual characteristics.
2. An adolescent (16 years of age or younger) who has never experienced menses, yet who does exhibit physical signs of secondary sexual characteristics.
3. A menstruating woman who experiences the absence of menses for a period of time ranging from 3 to 6 months [5].

The first two situations have been described as primary amenorrhea, while the third has been labeled as secondary amenorrhea. However, clinical scholars such as Speroff and colleagues [5] have cautioned against the use of these labels because they can lead the practitioner to omit certain diagnostic criteria that may be relevant to the absence of menses no matter when it occurs in an individual's life.

While there are a number of different approaches to understanding, diagnosing, and treating amenorrhea, one that has proven helpful to many clinicians is to think of the causes as occurring in one of four anatomical areas: (1) the outflow area of the genitalia (uterus and vagina), (2) the ovaries, (3) the pituitary gland, and (4) the central nervous system (CNS) [5, 6]. Generally, outflow area problems are obstructive in nature, while ovarian, pituitary, and CNS problems involve disruptions in the hypothalamic-pituitary-ovarian (HPO) axis that controls the neuroendocrine processes required for a normal menstrual cycle. Obstructions can generally be found on physical examination, while other causes usually are ruled out through laboratory analyses and the use of hormone therapy.

The primary step in diagnosing amenorrhea is first to rule out pregnancy. While this may seem obvious, the client's sexual and social history, as well as preconceived assumptions on the part of the clinician, can lull the practitioner into thinking that pregnancy is not a possible or likely determinant of the amenorrheic state (e.g., an adolescent who states she is not sexually active but is actually living in a sexually abusive environment). Discounting the possibility of pregnancy can lead to an expensive and anxiety-provoking amenorrheic workup that could have been avoided with clear and thorough history-taking followed by a simple urine HCG test. Matters such as abuse or sexual experimentation need to be broached before deciding pregnancy is not a possibility.

It is also important to remember that episodes of amenorrhea during the perimenopause are part of normal development. Oftentimes, a woman will begin to experience heavier and more frequent menses during the perimenopause but will eventually have fewer and lighter menses as menopause itself nears. These periods of amenorrhea are normal and usually do not require any intervention beyond a thorough history and discussion with the client about such matters as birth control and concurrent physiological changes associated with menopause.

In addition to assessing for pregnancy and perimenopause, the clinician must inquire about the client's overall health, nutritional and exercise status, recent weight changes, use of medications and/or herbs, and emotional state. These subjective findings should be followed with a confirmatory physical examination (PE). Chronic illness, anorexia nervosa, bulimia, crash dieting, and obesity all have been shown to result in amenorrhea, as have strenuous exercise, physically demanding activities, the use of certain medications and/or herbal preparations, and overall emotional stress (5). Diagnoses such as anorexia, bulimia, or emotional distress may be the outcome of visits for women whose chief complaint was absent or irregular menses. All of these potential causes of amenorrhea involve different types of disruptions along the HPO axis, and resolution usually occurs upon solving or removing the underlying health, nutritional, physical, medicinal/herbal, or emotional problem. However, this is not always a simple task. For example, with a diagnosis of anorexia or emotional distress, the midwife will benefit from consulting with, or referring to, a clinician who has expertise in these areas. Certainly, the specific location of HPO axis disruption can be explored (see below), but usually the amenorrhea will resolve when the client begins to heal from the underlying illness or removes the causative factor.

Once pregnancy, breastfeeding, perimenopausal changes, use of hormonal contraception, general ill health, or nutritional, physical, medicinal/herbal,

and emotional problems have been ruled out, the next step is to measure levels of thyroid-stimulating hormone (TSH) and prolactin. An elevated TSH, often accompanied by an increased prolactin level, is indicative of hypothyroidism, which is readily treated with thyroid hormone replacement therapy. In addition, any type of hyperthyroidism (e.g., Graves' disease) can be the underlying cause of amenorrhea, and depending on the method of treatment, regular menstrual cycles will return upon control of thyroid functioning. Increased levels of prolactin, with normal levels of TSH, are found in hyperprolactinemic and galactorrheic conditions, which are often accompanied by amenorrhea. Causes of hyperprolactinemia and galactorrhea are many, and deciphering the etiology of an individual's symptoms can be arduous (see Speroff and colleagues [5]). Thus in most cases an elevated prolactin level will suggest to the midwife that a more extensive workup is required, often necessitating a referral to a practitioner specializing in endocrinology. Once the condition causing elevated prolactin levels is treated, menses should return.

If thyroid and pituitary functioning appear normal, the next step in diagnosing and treating amenorrhea is to initiate what is commonly known as a progesterone challenge. The purpose of this is twofold: to assess the presence of endogenous estrogen, which is required for healthy buildup of endometrial tissue, and to examine the patency of the genital outflow tract (uterus and vagina). Medroxyprogesterone acetate (Provera) (5–10 mg for 5–10 days) can be given po, or progesterone in oil can be administered IM (200 mg) or po in capsule form (Prometrium) as a single daily dose of 400 mg in the evening for 10 days. As early as two days after the medication is completed, and usually within a week, bleeding may occur, thus establishing the presence of endogenous estrogen and the patency of the outflow tract. The focus of the amenorrhea workup then becomes anovulation, with functioning of the ovaries, pituitary, or CNS requiring evaluation.

If the progesterone challenge results in a continued lack of flow, then the midwife needs to resume assessment for a lack of estrogen or outflow tract obstructions. This is accomplished by administering estrogen and progesterone over 21 days (estradiol [e.g., Estrace] 4.0 mg, or conjugated equine estrogen [e.g., Premarin] 2.5 mg, po for the entire 21 days, with medroxyprogesterone acetate [e.g., Provera] 10 mg po added for the last 5 days). If a menstrual flow occurs after cessation of the medication cycle, then the patency of the outflow tract can be established. If menstrual flow does not occur, then one should strongly suspect an obstruction of the outflow tract, and refer appropriately. It should be noted, however, that such obstructions are quite rare, and if present, are often found on PE. Certainly, if a young adolescent has secondary sexual characteristics, but no established flow, or a previously menstruating woman has a history of an intrauterine procedure (e.g., a dilatation and curettage [D&C] procedure) or infection, then obstruction should be considered. For the most part, amenorrhea will be found to be due to physiological causes at the ovarian, pituitary, or CNS level.

If the patency of the outflow tract has been established, then the midwife can assume that the woman's body is not producing enough estrogen to enable menstruation to occur. Using the previously described approach of diagnosing the cause of amenorrhea from one of four anatomical areas, the disruption of estrogen production is now known to be occurring at either the ovarian, pituitary, or CNS level. Therefore, the next step is to determine the level of gonadotropins to determine whether the lack of estrogen originates in the follicle of the ovary or along the pituitary-CNS axis.

Gonadotropin testing is accomplished by obtaining serum samples in order to assay follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels. Normal levels range from 5–30 IU/L for FSH and 5–20 IU/L for LH. Any levels outside of these ranges speak to one of a number of possibilities (see Table 14-1). Several factors are important to consider at this point. First, the midwife must remember that both FSH and LH surge approximately two to three times their base levels during a normal midcycle. Also, if the woman had been undergoing an estrogen/progesterone challenge, a delay of 2 weeks before drawing a gonadotropin assay is advisable to avoid artificially elevated values. Finally, at this point in the amenorrhea workup, the midwife may choose to refer the individual to a practitioner specializing in female endocrine disorders. While results of gonadotropin assays can better isolate the source of amenorrhea (high FSH and LH point to ovarian problems; low or normal FSH and LH indicate either pituitary or CNS problems), further differential diagnosis and subsequent treatment are, for the most part, beyond the scope of practice of the primary care clinician.

Obviously, the midwife should be supportive and informative throughout the entire amenorrhea workup. The experience can be frightening to the

TABLE 14-1 Disorders Associated with Amenorrhea

Genital Outflow Track (Uterus and Vagina)	Ovaries	Pituitary Gland	Hypothalamus (CNS)
Asherman's syndrome	Gonadal dysgenesis	Pituitary adenomas	Stress
Müllerian tube anomalies	Polycystic ovaries	Empty sella syndrome	Weight loss, eating disorders
Androgen insensitivity syndrome (testicular feminization)	Turner syndrome		Strenuous exercise
	Mosaicism		Posthormone use for birth control
	Premature ovarian shutdown		
	Side effects from radiation and/or chemotherapy		

individual woman, and the lack of definitive testing can cause frustration. Educating her about the potential causes and their likelihood can do much to alleviate the woman's anxiety. It is important to note that other remedies for amenorrhea have been suggested that are not traditionally prescribed by practitioners of allopathic medicine. For example, herbalists recommend blessed thistle or blue cohosh for the relief of amenorrhea. However, there currently are no published, evidence-based investigations that address the efficacy or safety of using such herbs for this condition.

Dysmenorrhea

Painful menstruation, particularly in the lower abdomen and back and usually of a cramping nature, is known as dysmenorrhea or menorrhalgia and has been reported in the United States to have been experienced by anywhere from 60 percent to 91 percent of women [5]. Dysmenorrhea is most prevalent in the first three years after menarche (primary dysmenorrhea), although it can arise later in any woman's reproductive life (secondary dysmenorrhea). Prior to the 1970s most practitioners viewed dysmenorrhea as being pyschosomatic in origin, and few resources were offered for relief [7]. More recent research has presented a clearer picture as to the nature and treatment of this potentially debilitating condition.

The principal cause of primary dysmenorrhea is the presence of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), which originates in the endometrium [5]. $PGF_{2\alpha}$ is necessary for stimulating uterine contractions during menstruation. In adolescents with dysmenorrhea, the amount of $PGF_{2\alpha}$ produced is greater than normal. Limiting the amount of available $PGF_{2\alpha}$ is the primary method of relief. Because combined hormonal contraceptives decrease prostaglandin synthesis, and offer birth control benefits, these drugs are frequently promoted as the first line of control of dysmenorrhea in adolescents [8].

For individuals unable to take hormonal contraceptives for medical or psychosocial reasons, dysmenorrhea can be limited through the use of nonsteroidal antiinflammatory drugs (NSAIDs) [9] and the newer class of drugs known as cyclooxygenase 2 (COX-2) inhibitors (Table 14-2). These medications should be taken for two to three days beginning on the first day of symptoms. Contrary to earlier beliefs, there is no evidence that initiation of medication two to three days prior to menstruation improves control of dysmenorrhea [5]. The benefits of NSAID therapy can take up to six months to be effective, so clients need to be made aware of this before abandoning this approach to dysmenorrhea control. On the other hand, long-

TABLE 14-2 Pharmaceutical Regimens for Treatment of Dysmenorrhea

Generic Drug	Sample Trade Drugs	Dosage*
Ibuprofen	Advil, Motrin, Nuprin	400 mg qid
Naproxen	Aleve, Anaprox, Naprosyn	275 mg qid
Fenamates	Ponstel	250 mg qid
Ketoprofen	Orudis	50 mg tid
Diclofenac	Cataflam	50 mg tid
Cyclooxygenase 2 inhibitors:†		
Celecoxib	Celebrex	200 mg bid
Rofecoxib	Vioxx	50 mg qd
Valdecoxib	Bextra	20 mg bid

* Medications should be initiated on the first day of symptoms and continued for 2 to 3 days.

† Cyclooxygenase 2 (COX-2) inhibitors are the most recent classification of drugs to receive FDA approval for the treatment of dysmenorrhea.

term therapy with such drugs as NSAIDs can have adverse effects on several systems of the body, thus necessitating a look at alternative therapies if dysmenorrhea continues for an extended period of time [10]. While aspirin has also been shown to offer some relief from dysmenorrhea, there is no evidence that acetaminophen is beneficial in eliminating menstrual pain [9].

Several nonpharmaceutical approaches to alleviating dysmenorrhea exist. These include homeopathy (e.g., belladonna and chamomilla), acupuncture, biofeedback, relaxation techniques, massage, exercise, aromatherapy (e.g., rose oil), and the use of certain herbs (e.g., black cohosh, raspberry leaf, shakuyaku-kanzo-to, semen coicus, and chaste berry [11–13]). As is the case with many nonallopathic approaches to care, there exists at this time limited scientific evidence as to the effectiveness of these various modalities. Thus, it benefits the midwife to learn as much as possible about the availability and effectiveness of these mechanisms, especially when a client is making use of a certain modality or asks about the value of doing so.

Secondary dysmenorrhea has been described as painful menstruation that arises later in a woman's life, after she has experienced menstrual cycles not associated with significant pain. However, in its current use the term has come to signify dysmenorrhea caused not by prostaglandins but by anatomical or pathological factors [7]. These factors include endometriosis, uterine myomas, endometrial polyps, uterine cancer, and the presence of pelvic inflammatory disease (PID). The presence of an intrauterine device (IUD) can contribute to dysmenorrhea. Finally, it has been suggested that having had a tubal ligation can subsequently cause painful menstruation [14], theoretically due to postsurgical reduction in blood supply to the ovaries, resulting in hormonal changes that affect menstruation. However, this notion of post–tubal ligation dysmenorrhea has been questioned in the literature [5]. Appropriate evaluation of secondary dysmenorrhea is accomplished through PE, ultrasound, and additional testing dependent on the suspected diagnosis. A potential diagnosis of PID requires the collection of cervical specimens. If endometrial cancer is suspected, an endometrial biopsy and referral are warranted. A suspicion of endometriosis may require referral for a laparoscopy.

Treatment of secondary dysmenorrhea is dependent on diagnosis. Endometrial cancers, benign tumors (myoma), and endometriosis are discussed later in the chapter. If an IUD is thought to be the source of dysmenorrhea, the midwife should discuss with the woman the use of NSAIDs or removal of the IUD. IUD removal should be accompanied with exploration of alternative birth control methods. As with primary dysmenorrhea, the use of NSAIDs or the nonpharmaceutical approaches mentioned above are often the initial therapy (see Table 14-2).

Menorrhagia

Menorrhagia is one of several menstrual states that have traditionally fallen under the label of dysfunctional uterine bleeding (DUB)—the term most often used to describe unusual menstrual patterns whose origins can be traced to alterations in the physiological mechanism of the HPO axis. However, the term DUB can be misleading because not all changes in menstrual flow or rate are necessarily dysfunctional (e.g., menorrhagia and polymenorrhea found at the time of perimenopause). In addition, the broader term of abnormal uterine bleeding (AUB) has been used to describe any form of uterine bleeding not related to normal menstrual bleeding [15], yet this too has the potential to label irregular, albeit healthy, flow as abnormal. Focusing on the woman's specific symptoms and avoiding generalized terms will facilitate prompt diagnosis and management.

Menorrhagia (sometimes referred to as hypermenorrhea) is defined as excessive bleeding, either in amount or duration, at the regular interval of normal menstruation (see Table 14-3). A thorough history will help determine what is a normal flow for the individual woman. However, determining what

TABLE 14-3 Common Definitions Referring to Menstrual Changes

Amenorrhea: Absence of any menses by age 16, or absence of menses in woman who has previously menstruated.
Menorrhagia (Hypermenorrhea): Normal menstrual intervals with excessive flow and/or duration.
Metrorrhagia: Menstruation occurring at irregular intervals, or incidences of spotting or bleeding between periods.
Menometrorrhagia: Excessive/prolonged menses at irregular intervals.
Polymenorrhea: Normal menses at more frequent intervals than normal (i.e., more frequent periods).
Oligomenorrhea: Normal menses at greater than normal intervals (i.e., fewer periods).
Hypomenorrhea: Scant bleeding at normal intervals.

is excessive bleeding can be a difficult task. A common perception has been that the saturation of three to four pads or tampons over a four-hour period at the time of menstruation is excessive [16]. Yet, for some women this can be part of their normal pattern, especially on the first two to three days of flow. Also, one individual's definition of a saturated pad or tampon can be quite different from that of another's [17]. The amount of blood loss considered normal during menses has been described as approximately 30 cc since research conducted in the 1960s, with anything greater than 80 cc deemed abnormal [5]. As pointed out by Engstrom and colleagues [18], this cutoff of 80 cc is the standard measure for defining menorrhagia, yet large numbers of women either overestimate or underestimate the amount of menstrual bleeding that occurs on a monthly basis. And with great diversity in pad/ tampon absorption rates and no standard way for women to determine what is meant by a "saturated" pad, translating monthly blood loss amounts into numbers of pads or tampons is virtually impossible. Newer, more accurate methods of measuring blood loss during menstruation, such as the alkaline hematin laboratory procedure that measures blood loss found on tampons or pads, and the Pictorial Blood Loss Assessment Chart (PBLAC), which estimates blood loss using diagramatic prompts, have been shown to be effective. However, due to cost, inconvenience, or lack of exposure, their use has been limited to research endeavors [18].

Perhaps the surest method of determining whether an individual's flow is potentially harmful is to obtain laboratory values of hemoglobin and hematocrit (H/H) to rule out anemia. The midwife needs to be aware that no matter what the physiological diagnosis turns out to be, if the woman believes that her blood loss is excessive, then the clinician must address this issue from a psychosocial perspective in order to promote the woman's well-being.

After garnering evidence to see if the woman's menstrual flow is excessive, the next step in treating menorrhagia is to discover the origin of the condition. Causes include hormonal changes along the HPO axis, uterine masses, systemic diseases, medication or herbal use, nutritional deficiencies (e.g., vitamin K), and inherited disorders, particularly those leading to bleeding problems (e.g., von Willebrand's disease) [19–21]. A thorough history is key to making a correct diagnosis. In addition to understanding, as much as possible, how much of a flow the woman is experiencing, the midwife should inquire about the menses' duration, color, and character, especially if clotting is involved. Any accompanying physical or psychosocial changes associated with the heavier menstrual flow need inquiry. This is especially true of potential contraceptive causes (IUD, OCs), psychosocial factors (stress, illicit drug use), sexual correlates (STIs, sexual practices), nutrition causes (obesity), and gynecological factors (past surgery, a history of unusual menstrual patterns). The clinician should inquire about the client's knowledge of any similar bleeding patterns or major gynecological conditions experienced by her mother or sisters. Finally the midwife should determine whether any close relatives have a history of hematological disorders, especially related to clotting.

Physical and pelvic examination must include assessment for signs of anemia and bleeding (e.g., bruising or petechiae). The vagina and cervix need to be assessed for masses, lesions, infections, or foreign bodies (e.g., IUD) that could contribute to heavier menses. If a Pap smear has not been performed within the past year, this sample should also be obtained. Bimanual examination includes assessing for ovarian or uterine masses or pain.

A pregnancy test may be appropriate, although the client presenting with a complaint of menorrhagia usually has had this symptom for several cycles, and typically will not describe signs or symptoms of pregnancy. Screens for sexually transmitted infections and chronic vaginitis or cervicitis should be considered. Although they are not part of a routine screen, if endometrial hyperplasia or cancer are suspected, endometrial curettage (also known as endometrial sampling or endometrial biopsy) should be performed (see Chapter 82). This brief, ambulatory care procedure allows for laboratory histological analysis of endometrial tissue without the risks or involvement necessary for the more traditional D&C. While diagnostic information is not immediately available during the procedure, the resulting laboratory report can offer assistance in discovering the source of the client's menorrhagia. Any nondefinitive or positive results should lead to a referral for follow-up testing (e.g., hysteroscopy) or treatment.

As stated previously, laboratory testing should include hemoglobin and hematocrit to gauge whether the bleeding that the woman is reporting is resulting in an anemic state. Obtaining a complete blood count (CBC) also allows for detection of an abnormally low platelet count (thrombocytopenia) accompanying a bleeding disorder (see Table 14-4). It should be noted, however, that several bleeding

TABLE 14-4 Possible Causes of Menorrhagia

Typically Presented As a Onetime Event

- Pregnancy
  - Intrauterine
  - Ectopic
  - Gestational trophoblastic neoplasm (e.g., hydatidiform mole)
- Infections (usually related to PID, use of IUD, or following instrument-based intrauterine procedure)
  - Endometritis
  - Salpingitis

Typically Presented As an Ongoing, Cyclic Pattern

- IUD use
- Neoplasia
  - Ovarian cysts
  - Uterine fibroids (myoma)
  - Adenomyosis (endometrial tissue located within the myometrium)
  - Endometrial hyperplasia
  - Polyps
  - Carcinoma
- Coagulation disorders
  - Inherited (e.g., von Willebrand's disease)
  - Acquired (e.g., idiopathic thrombocytopenic purpura [ITP])
  - Pharmacological (e.g., use of heparin, or even aspirin)
- Liver disorder (e.g., cirrhosis)
  - Impaired metabolism of estrogen
  - Decreased synthesis of fibrinogen and clotting factors
- Endocrine
  - Hypothyroidism

disorders (e.g., von Willebrand's disease) do not result in lowered platelet counts, and require additional laboratory testing. Other useful tests may include a thyroid-stimulating hormone (TSH) level to rule out thyroid disease; prothrombin time (PT) and partial thromboplastin time (PTT) to assess for certain bleeding disorders; and liver function tests (LFTs) to rule out liver disease. A urine HCG test will rule out pregnancy.

Pelvic ultrasound also can be an effective diagnostic tool. As listed in Table 14-4, a common cause of chronic heavy menstrual flow is the presence of uterine myomata (fibroids). While myomata may be palpated on PE, the least distinctive of these masses on bimanual exam—the submucosal fibroids—are those closest to the endometrium. These are the tumors considered most likely to cause menorrhagia [22]. Sonography will detect myomata as well as endometrial polyps (benign growths that can cause menorrhagia), and it will report on the "endometrial stripe," or thickness of the endometrium. Normally, during the follicular (preovulatory) phase of the menstrual cycle, the endometrium grows from a postmenstrual thickness of 1.0 to 2.0 millimeters to a preovulation thickness of 3.5 to 5.0 millimeters. Even though the endometrium can reach a normal thickness of 5.0 to 7.0 millimeters during the subsequent luteal (postovulatory) phase, any evidence of an endometrial stripe greater than 5.0 millimeters on ultrasound suggests the possibility of endometrial hyperplasia or carcinoma, and points to the need for endometrial curettage [5, 23, 24].

Treatment of menorrhagia necessitates first establishing a diagnosis. If excessive bleeding has been reported as a onetime, acute event and the likely diagnosis is either pregnancy or infection, then immediate action is generally required. Appropriate steps must be taken depending on the type of pregnancy (e.g., intrauterine versus ectopic) or infection and the desires of the woman. (Management of bleeding during pregnancy or of ectopic pregnancy is covered in Chapter 24; caring for the woman with endometritis or salpingitis is discussed in Chapters 15 and 44.)

If the menorrhagia is found to be chronic and cyclic, management still depends on the specific cause deemed responsible for the excessive bleeding. If an IUD is in place, the midwife should consider removal to see if the menorrhagia subsides. If the IUD is removed, an alternative form of birth control must be discussed with the client. It should be noted that the most recently FDA-approved IUD—the LNg 20 (Mirena)—is indicated not only for birth control but also for treatment of abnormal menstrual bleeding [25], and it may be considered by the midwife and client as a method of resolving menorrhagia while continuing with an intrauterine form of birth control.

Menorrhagia found to be caused by neoplasia, coagulation disorder, or liver disease requires referral to a specialist, who will usually first treat the woman pharmacologically, followed by surgery if drug therapy is not successful. Menorrhagia caused by endocrine dysfunction is manageable, at least initially, by the primary care practitioner, and usually begins with placing the woman on combined, low dose OCs. While the typical prescription calls for taking OCs in the same manner of women using the pills for birth control, recent evidence points to the success of a regimen in which active OCs are taken for 6 to 12 weeks before inert pills are used to facilitate the shedding of the uterine lining [18, 26].

Additional pharmacologic approaches to treating the woman with menorrhagia include the use of progestins, gonadotropin-releasing hormone (GnRH) agonists, NSAIDs, and Danazol, a synthetic steroid that suppresses HPO axis activity. Progestins can be helpful because they limit endometrial growth and simultaneously enrich any existing endometrial structure, resulting in reduced and less uneven menstrual flow [27]. The midwife can prescribe medroxyprogesterone acetate (e.g., Provera), 10 mg po, qd × 10 days or norethindrone (e.g., Aygestin), 5 mg po, bid × 10 days. With either drug, therapy should begin on day 15 or 16 of the woman's cycle. For individuals who have difficulty with a daily pill schedule, depot medroxyprogesterone acetate (DMPA) (e.g., DepoProvera), 150 mg IM can also be used to reduce menstrual flow, although irregular bleeding frequently occurs until the woman develops amenorrhea.

GnRH agonists (e.g., Lupron) affect the HPO axis, retarding the ovaries' ability to release hormones required for normal functioning of the menstrual cycle. Breaking up the activity required for cyclic menstruation causes the woman to enter a physiologic state most resembling menopause. Not only is menstrual blood loss slowed, but in many cases amenorrhea occurs. However, because of bone mass loss due to a drop in estrogen levels, this approach is limited to women for whom other therapies have been unsuccessful and is best managed by the practitioner specializing in gynecological disorders [27]. At minimum, any treatment using GnRH agonists requires monitoring the woman's bone density status.

Reduction in menorrhagia has also been demonstrated in women prescribed nonsteroidal anti-inflammatory drugs (NSAIDs) due to the ability of these medications to block the synthesis of prostaglandins necessary for cyclic endometrial sloughing [27]. Regimens are similar to those used for treating dysmenorrhea (see Table 14-2), and are used for the first three days of menstruation. Drugs that can be used include ibuprofen (e.g., Advil, Motrin, Nuprin), naproxen sodium (e.g., Aleve, Anaprox, Naprosyn), and mefenamic acid (e.g., Ponstel). However, NSAID therapy does not work for all clients, can cause gastrointestinal bleeding with long-term use, and for some individuals can result in an increase in vaginal bleeding due to inhibition of platelet aggregation and prolonging of bleeding time [18]. Women on OCs also may take NSAIDs at the time of menstruation and may benefit from the combination.

Danazol (e.g., Danocrine), a synthetic steroid, is used for treatment of endometriosis and has been successful in controlling some cases of menorrhagia. It requires daily dosage for 3 to 6 months, given as 100 mg po, bid, during which time a state of amenorrhea is likely to occur. The medication should then be discontinued for a period of time to assess whether the menorrhagia has returned. If so, therapy can be started again. Androgenic side effects, including weight gain, acne, and seborrhea, are common and have led to danazol not being the first choice of treatment for menorrhagia. As with GnRH agonists, this therapy is best managed by the practitioner specializing in gynecological disorders.

While there is some evidence for the treatment of menorrhagia with traditional Chinese medicines and acupuncture [28, 29], and several suggestions for the use of herbal, homeopathic, and aromatherapeutic remedies to help alleviate heavy menses [13, 30, 31], the body of evidence supporting these nonpharmaceutical methods is limited at this time. Based on evidence derived from actual clinical practice rather than scientific investigations, three herbs have been suggested to lessen menstrual bleeding: nettles, shepherd's purse, and yarrow [13]. Likewise, the homeopathic solutions of chamomilla, lachesis, and veratrum album are some of those recommended for relief of menstrual disorders, including heavy bleeding [31], and in the field of aromatherapy, rose oil has been recommended for menorrhagia relief [30]. As with all herbal, homeopathic, and aromatherapy suggestions, because there is usually limited scientific evidence to support their use, the midwife should consult first with a practitioner knowledgeable about amounts and contraindications before recommending any of these potential remedies to clients. Nutritionally, lack of vitamin K has been suspected of contributing systemically to menorrhagia. Improving vitamin K intake, through ingesting of green, leafy vegetables and cereals, could help reduce menorrhagia if this vitamin deficiency is the root cause of heavy bleeding [21]. Finally, it should be noted that the use of ergot derivatives, which are so helpful in controlling postpartum bleeding, appear to have little or no effect in alleviating menorrhagia [27].

In addition to, or in lieu of, the pharmacological and therapeutic remedies described above, surgery may be a necessity for a woman to obtain relief from menorrhagia. The surgeon to whom the woman is referred may first conduct a hysteroscopic examination in order to identify the source of excessive bleeding. Surgical interventions include

dilatation and curettage (D&C); endometrial ablation, using hysteroscopic visualization; and hysterectomy [5]. Of the procedures available, D&C is the one least likely to result in long-term resolution. Obviously, the midwife making a surgical referral should explain to the woman the possible solutions that may be proposed by the gynecologist and should encourage the client to express any anxieties or doubts about this possible step in managing menorrhagia.

Metrorrhagia

When menstruation occurs at irregular intervals, or there are incidences of spotting or bleeding between periods, the term metrorrhagia is used to describe these conditions. Of the various forms of abnormal bleeding patterns, this can be one of the most disconcerting because of the unpredictable timing at which spotting or bleeding occurs. Reestablishing a regular pattern of timing to a woman's menstruation can help her feel in a good state of health and avoid the inconvenience of an erratic menstrual flow.

Discovering the origin of metrorrhagia begins with a thorough history. An attempt should be made to have the woman describe, in as much detail as possible, how the bleeding she presents with is different from what has been normal menstruation for her. Does her experience better fit the description of menorrhagia or polymenorrhea? If the menstrual intervals are fluctuating, is the amount of flow consistent each time with a normal menses? If not, is the bleeding heavier, lighter, or as inconsistent as the timing? Are there any events or actions, such as sexual activity, that seem to accompany the timing of the abnormal bleeding? Have there been any changes in the individual's medical, emotional, or social history that have coincided with the menstrual changes? For example, has the client been diagnosed with a chronic illness? Is she taking any medications? Has she been experiencing any emotional distress lately? Has she had any major life changes recently? Ideally, the client will have kept a daily record, or log, of her bleeding, to establish whether or not there is a set pattern to the metrorrhagia. Usually, such a log comes at the suggestion of the midwife and is not typically available at the visit when the issue of metrorrhagia is first presented.

There are many possible causes of metrorrhagia (see Table 14-5). As with menorrhagia, the midwife should first consider the possibility of pregnancy as being the underlying state associated with the irregular bleeding. One incidence of spotting could have been caused by implantation bleeding in an early pregnancy, while an ongoing irregular pattern of spotting or bleeding suggests a threatened spontaneous abortion, an ectopic pregnancy, or a gestational trophoblastic neoplasm, such as a hydatidiform mole. Plans of action associated with any of these diagnoses are addressed in Chapter 24. If the client is not pregnant and states that the spotting typically occurs once monthly between her menses, the clinician should explore monthly ovulation as the underlying cause of the metrorrhagic state.

Once the diagnosis of pregnancy has been ruled out, the midwife should consider socially related causes. One is the possibility of sexually transmitted diseases (STDs) or other vaginal infections. A severe cervicitis or vaginitis, as well as an ascending infection such as pelvic inflammatory disease (PID), can

TABLE 14-5 Possible Causes of Metrorrhagia

- Pregnancy
  - Intrauterine
  - Ectopic
  - Gestational trophoblastic neoplasm (e.g. hydatidiform mole)
- Infections (usually related to PID, use of IUD, or following instrument-based intrauterine procedure)
  - Endometritis
  - Salpingitis
- IUD use
- Post–tubal ligation (controversial)
- Ovulation
- Hormonal Causes
  - OCPs, Depo, Norplant
  - HRT
  - Medications, herbs
  - Thyroid disorder
- Neoplasia
  - Ovarian cysts
  - Uterine myomata (fibroids)
  - Adenomyosis (endometrial tissue located within the myometrium)
  - Endometrial hyperplasia
  - Polyps
  - Carcinoma
- Coagulation disorders
  - Inherited (e.g., von Willebrand's disease)
  - Acquired (e.g., idiopathic thrombocytopenic purpura [ITP])
  - Pharmacological (e.g., use of heparin, or even aspirin)
- Organ disease
  - E.g., liver or renal failure

result in vaginal, cervical, or uterine bleeding related to the inflammation. Treatment with antibiotics will usually return the woman to a state of health in which the metrorrhagia will discontinue (see Chapter 15). In addition to infection, the clinician should rule out trauma to the genital region as a result of sexual activity or abuse. The former can usually be ascertained with a thorough sexual history and subsequently resolved with teaching the client healthy sexual practices. Abuse requires a much more extensive workup, and should involve consultation or referral to a community center or medical professional experienced in working with victims of assault (e.g., a rape crisis center or a sexual assault nurse examiner [SANE]) [32]. Depending on local laws governing such cases, the midwife may also need to contact a social worker or a law enforcement agent. Most importantly, the midwife should initiate safety and support mechanisms for the woman. Treatment of the abnormal bleeding will focus on ending the abusive situation but could involve referral to a gynecologist if any anatomical damage from the abuse, such as a laceration, appears to require surgery or extensive treatment.

Aside from pregnancy, infection, or trauma, the most likely causes of metrorrhagia are hormonal in nature (Table 14-5). These include the use of contraceptive pharmaceuticals or HRT, side effects of medications or herbal preparations, and HPO axis disorders. With regard to contraception, every individual reacts differently to the standardized doses contained in OCs, hormonal injections (Depo-Provera, Lunelle), contraceptive patches (Evra), vaginal rings (Nuvaring), levonorgestrel implants (Norplant), and progesterone intrauterine devices (i.e., Mirena IUD). (Note that the copper IUD, Para Gard, while containing a mineral rather than a hormone, can also contribute to metrorrhagia [33].) Likewise, in menopausal women on HRT, some spotting is possible. (An important cautionary note: As stated in the discussion of caring for menopausal women [Chapter 13], any postmenopausal genital bleeding, even if the individual is on HRT, requires the practitioner to assess for malignancies.) Finally, many prescriptive medications (e.g., the antibiotic ofloxacin) and herbs (e.g., ginseng) have metrorrhagia as a side effect. As with all health care assessments, it is vital to know what medications and substances the client regularly takes in order to accurately ascertain the cause of abnormal bleeding.

While any disease or interruption along the HPO axis can lead to bleeding disorders, most endocrine disruptions involving the hypothalamus or pituitary gland result in amenorrhea. (Hypothyroidism, which can lead to menorrhagia, is the exception to this [34].) Thus, the presentation of metrorrhagia should suggest to the clinician either organic causes found in the genital organs or bleeding disorders that also can cause menorrhagia (e.g., von Willebrand's disease). Organic causes include polycystic ovaries, cervical polyps or erosion, uterine myomas, adenomyosis, endometriosis, endometrial polyps, and cancer. The diagnostic process for many of these conditions has been described above in the discussion about menorrhagia, while screening for cancer is covered later in this chapter. In addition to a thorough history, a workup should include a complete physical and pelvic examination, with possible endometrial tissue sampling (see Chapter 82); laboratory studies (including a CBC, TSH, PT and PTT, LFTs, and possibly coagulation testing); and in many cases a pelvic ultrasound.

As with menorrhagia, treatment depends on diagnosis. Management of metrorrhagia due to pregnancy, infection, or abuse was discussed above. Metrorrhagia due to hormonal causes usually can be remedied with one of several possible plans. If the bleeding is caused by oral contraceptives, the midwife may change the pill to one with a different hormonal structure. It has been noted that menstrual irregularities, such as metrorrhagia, are the most frequently stated reasons by women for the discontinuation of OCs [35]. If the individual has recently initiated OC use, education usually can remedy the situation. The midwife should first check to see if the woman is taking the pill in the correct manner, since erratic use or missed pills will contribute to untimely spotting. If the pill is being taken correctly, irregular bleeding is most often resolved by the start of the fourth cycle [36]. If metrorrhagia continues, the most likely cause is inadequate endometrial support. Switching the woman to an OC offering greater stimulation and maintenance of the endometrium will resolve this hormone-induced metrorrhagia. The most efficient way in which to gauge and compare the endometrial support offered by the various OCs available is to utilize a clinical reference (e.g., Dickey [36]).

As with the management of menorrhagia, if an IUD is in place, and educating the woman about postinsertion bleeding patterns, and subsequently waiting for resolution, does not meet her needs, the midwife should consider removal of the IUD. As previously noted, continuation of IUD use while re-

solving abnormal bleeding patterns may be accomplished with the insertion of the LNg 20 (Mirena) IUD, recently approved by the FDA for use in the United States. Of course, if the woman decides against continued IUD use, the midwife needs to discuss with her an alternative form of birth control.

It is important to restate that any postmenopausal woman, whether on HRT or not, who experiences menstrual-like bleeding or spotting requires assessment for malignancy. At minimum, a Pap smear and an endometrial biopsy should be performed to rule out cervical and endometrial cancer. If any masses are noted on examination, a pelvic ultrasound to rule out uterine or ovarian tumors is warranted. Indeed, even when no obvious masses are noted on examination, sonography may still be required when no other source of bleeding can be found. For further discussion regarding management issues in a postmenopausal woman with genital bleeding, refer to Chapter 13.

Knowing what medications or herbal preparations an individual may be taking, especially on a routine basis, often can lead the clinician to discovering the source of, and remedying, the metrorrhagic state. Simple removal of a medication or herb is often the solution to the abnormal bleeding. However, this seemingly easy step may not be feasible, depending on the original reason for the woman's taking these medications. In that case, working in conjunction with the medical professional or herbalist who has been caring for the woman will usually lead to developing a plan in which the metrorrhagia is resolved and optimal health is maintained.

As with menorrhagia, if the cause of a client's metrorrhagia is thought to be a neoplasm, coagulation disorder, or chronic disease, referral to a specialist is necessary. While the specialist may initially treat the woman pharmacologically, surgery is also a possibility, depending on the etiology of the problem and the success of medical treatment. The woman should be informed of these possible treatments as preparation for her visit with the specialist.

If the etiology of the metrorrhagia is thought to be hormonal in nature, then exogenous hormones are usually the treatment of choice. Whether to initiate treatment with progestin, estrogen, or a combination of the two has historically depended on the type of bleeding with which the woman presents. In general, oligomenorrhea has been treated first with progestin, while metrorrhagia has been treated initially with estrogen [5]. However, in recent years it has been discovered that combination hormonal contraceptives are very effective in controlling a number of menstrual disorders, including oligomenorrhea and metrorrhagia. Thus, many clinicians use combined OCs as the first line of treatment, especially if the woman is interested in contraception.

To control continual, heavy bleeding, the midwife can prescribe a low dose combination monophasic OC pill, twice a day, for 5 to 7 days. Even if the bleeding stops or subsides within a day or two after initiation of therapy, the pills should still be taken for the remainder of the prescribed length of time [5]. If the bleeding does not end, and trauma has been ruled out, then the presence of pregnancy or a neoplasia should be reconsidered. If the bleeding does cease, then twice daily dose can be stopped after 5 to 7 days, but the woman must be warned that she will now have a heavy withdrawal bleed and strong cramping 2 to 4 days after taking the last twice-a-day dose. This is normal, and the bleeding will typically last at least 5 days. On the fifth day of flow, the woman should then be started on 3 months of routine OC use. With each monthly withdrawal cycle while on the OCs, the individual should experience decreasing amounts of bleeding and cramping.

At the end of the 3-month treatment, if the client desires birth control, the simple course of action is to leave her on the pill she has been using. If birth control is not necessary, or OCs are not her method of choice, then discontinuing OC use should result in the return of regular ovulation and the healthy build-up of endometrium by endogenous estrogen [5]. If spontaneous menses do not occur at this point, then an anovulatory state should be suspected. If pregnancy is ruled out as the cause, then the woman will need progestin therapy to help facilitate the shedding of estrogen-driven endometrial proliferation. This can be accomplished by prescribing medroxyprogesterone acetate (e.g., Provera) tablets, 10 mg po, once daily for 10 days, beginning approximately midcycle each month. Menstrual flow will occur anywhere from 2 to 7 days after the woman takes the last pill [5]. This therapy can be continued monthly to help maintain a cyclic balance between endometrial buildup and shedding. Each individual will need to be assessed for contraindications to exogenous hormone use before initiating this therapy (refer to the discussion of hormonal contraceptive methods in Chapter 20), especially with regard to the use of estrogen and its relation to cardiovascular risks.

If combined hormones or progestin therapy do not result in a regular menstrual flow, or metrorrhagia continues, referral for a more extensive workup must be considered.

For the woman whose complaint is unpredictable spotting during the month, the midwife should suspect low levels of cyclic endogenous estrogen, or greater amounts of progesterone than is normally required to balance with estrogen for a healthy menstrual cycle. This results in poor endometrial buildup that leads to less-than-optimal, intermittent shedding of tissue. While this can be found in a woman not using hormonal forms of birth control, the complaint of spotting also can be heard in individuals using injectable medroxyprogesterone acetate (e.g., DepoProvera), levonorgestrel implants (e.g., Norplant), or combined hormonal contraceptives. The spotting can normally be resolved with the use of estrogen therapy. For the woman not using a hormonal form of birth control, oral estrogen can be prescribed in the forms of conjugated estrogen (e.g., Premarin), 1.25 mg, or estradiol (e.g., Estrace or the pink tablet of Ortho-Prefest), 2.0 mg, given once daily for 7 to 10 days [5]. For the woman not taking any other form of hormonal medication, this course of estrogen will need to be followed with exogenous progesterone in order to initiate a withdrawal bleed. This is most often accomplished through the use of a combination OC, initiated at the same time as the estrogen therapy. Gynecological endocrinologists, such as Speroff and colleagues [5], then recommend continuing the individual on low-dose OC therapy.

As stated previously, when a new user of oral contraceptives is experiencing spotting even after 3 months of therapy, switching her to a pill with greater endometrial support will usually resolve the metrorrhagia. If the woman experiencing intermenstrual spotting has been on OCs for several months or more without bleeding side effects and has only recently experienced the spotting, then the clinician should consider switching her to an OC with greater estrogenic activity [36]. An alternative is to complement her monthly OC use with a therapy of either conjugated estrogen (e.g., Premarin), 1.25 mg, or estradiol (e.g., Estrace or the pink tablet of Ortho-Prefest), 2.0 mg, to be given monthly for 7 days along with the OCs. This same monthly distribution of estrogen can be given to users of injectable medroxyprogesterone acetate (e.g., DepoProvera) or levonorgestrel implants (e.g., Norplant) who are experiencing spotting. Keeping in mind concerns raised with regard to estrogen use and risks of cardiovascular disease and cancer, practitioners should be aware that these suggested estrogenic therapies should be considered short courses of action, not long-term therapy.

Discussions in the literature regarding other therapeutic approaches to metrorrhagia are limited. Most information about the use of traditional Chinese medicines, acupuncture, herbs, homeopathy, aromatherapy, and other modalities is related to menorrhagia and has been discussed earlier in this chapter. Their application to metrorrhagia is unclear, with further evidence needed before specific recommendations can be made. As stated previously regarding approaches to health care involving knowledge of modalities such as Chinese medicines, acupuncture, herbs, homeopathy, and aromatherapy, most of the evidence regarding safety and effectiveness of use is based on clinical practice, not on evidence-based scientific investigations. Thus the midwife should work with a practitioner knowledgeable in the particular modality being suggested to, or requested by, the client, and should keep abreast of the scientific literature regarding evidence-based studies that support or caution use of various modalities of health care.

Any continued bleeding after therapy has been tried, or any acute bleeding putting the individual at risk of systemic illness or compromise, requires referral to the appropriate specialist. Educating the woman as to what type of workup and possible treatment to expect from the specialist can do much to relieve her anxieties regarding the state of her health and possible solutions.

Oligomenorrhea

The term oligomenorrhea refers to infrequent or scanty menstrual flow. While some authors label only infrequent flow, or decreased number of periods, as oligomenorrhea, and refer to scanty but regular menses as hypomenorrhea [20], both conditions are worked-up similarly, and the term oligomenorrhea is frequently used clinically to refer to both forms of diminished menstrual flow. It is important to note that oligomenorrhea is often a reflection of normal development or physiological processes, and is not necessarily a sign of disease or pathology.

The most common times for the occurrence of oligomenorrhea are in the first few years following menarche and/or the decade before menopause. Scant bleeding during these two periods of time is part of normal development, seldom requiring intervention, except in the form of educating the

woman about the normalcy of what is occurring. The most likely cause is anovulation—for the adolescent because a regular pattern of ovulation has yet to occur, and for the perimenopausal woman because she is maturing toward a menopausal state, one in which ovulation no longer occurs. If the midwife is able to rule out other potential states, such as pregnancy or thyroid disease, then the key management tool is education. The adolescent needs to be made aware that a regular menstrual pattern should eventually develop, and if it does not, a thorough assessment will most likely lead to a definitive diagnosis. The perimenopausal woman benefits from understanding the normalcy of this time of her life. Options for long-term health maintenance will need to be reviewed, with a candid discussion required about lifestyle, diet, and the possibility of hormone replacement therapy or some other form of pharmaceutical or herbal regimen.

Another nonpathological cause of oligomenorrhea is the use of, or withdrawal from, hormonal contraception. Using combined hormonal contraceptives, DepoProvera, Norplant, or a hormone-based IUD often reduces the flow or timing of menstruation, and the discontinuation of one of these birth control methods can result in a delay in the return of a regular menstrual pattern. This is particularly true of DepoProvera: after stopping its use, normal menses may take close to a year to resume [37]. Also, if the midwife is caring for a woman who has recently come to the United States from a foreign country, the clinician must inquire about the client's possible use of a hormonal contraceptive that may not be available in this country and that may have influenced her menstrual pattern. In general, there is no harm associated with these cases of oligomenorrhea, and the clinician must simply educate the client as to the safety of this reduced flow. (Obviously, if underlying pathology is suspected, an appropriate assessment workup is warranted.) Even though oligomenorrhea is often not a sign of ill health, the woman's fears and anxieties must still be acknowledged, and she must be supported in adjusting to any physical and lifestyle changes. Finally, for the woman who is experiencing oligomenorrhea after discontinuing hormonal contraception, she may believe that reduced menstrual flow is an indication that she cannot become pregnant. This is not the case, and birth control options must be discussed with the client unless pregnancy is desired.

Other factors can contribute to oligomenorrhea. These include anxiety and stress, chronic disease, certain medications, occupational and environmental hazards, disease states, poor nutrition, strenuous exercise, and significant weight loss. In addition, any malfunction along the HPO axis can result in decreased menstrual flow. Potential diseases and conditions of this regulatory axis include hyperprolactinemia, Cushing's syndrome, and polycystic ovarian syndrome (PCOS). Also, beyond HPO axis problems, disruptions of thyroid or adrenal function can result in oligomenorrhea.

The clinical evaluation required to find the cause of oligomenorrhea resembles those actions taken to discover the reasons for amenorrhea (see above). As with the evaluation of amenorrhea, the initial step in assessing oligomenorrhea is to rule out pregnancy. Depending on timing of the visit in relation to the last normal menses, a urine HCG test usually will allow the clinician to make this diagnosis.

If the woman is not pregnant, the midwife should ask the client about her overall health, nutritional and exercise status, use of medicines and/or herbs, and emotional state. Complementing these questions with a complete physical will enable the clinician to rule out most chronic illnesses, anorexia nervosa, bulimia, crash dieting, obesity, strenuous exercise, physically demanding activities, medicinal/herbal side effects, and overall emotional stress as potential causes of the individual's decreased or scant flow [5]. Typically, resolving an underlying illness or condition will result in more regular menses and flow.

Once pregnancy, normal developmental changes, general ill health, or nutritional, physical, medicinal/herbal, and emotional problems have been ruled out, the next step is to measure levels of TSH and prolactin. Again, as with the assessment of amenorrhea, the midwife is attempting to rule out hypothyroidism, hyperthyroidism, hyperprolactinemia, and galactorrhea, the specific treatments of which should contribute to the resumption of regular menstrual flow. An elevated TSH level suggests primary hypothyroidism and is an indication for treatment with a synthetic thyroid hormone preparation. Levels of TSH below normal could indicate secondary hypothyroidism or hyperthyroidism (e.g., Graves' disease), and will require further testing that typically indicates the need for consult or referral with an endocrinology practitioner. Treatment of any of these potential thyroid conditions should contribute to alleviation of the oligomenorrheic state.

Elevated prolactin levels are an indication of hyperprolactinemia and galactorrhea, the causes of

which are usually prolactinomas, secretory tumors of the pituitary. While the cause may also be idiopathic, the treatment is the same for either etiology [5]. Bromocriptine (e.g., Parlodel) or a dopamine agonist can be prescribed, resulting in more consistent ovulation and subsequent menses. It should be noted that individuals on drug therapy for pituitary problems require close monitoring of prolactin levels and pituitary status, thus suggesting that this care be handled by an endocrine specialist, either directly or through consultation. Also, medications aimed at remedying pituitary deviations from normal often cause a rise in the person's libido and sexual response. Women should be counseled of this possibility before initiating medication.

If hypothyroidism, hyperthyroidism, hyperprolactinemia, and/or galactorrhea are ruled out as underlying causes of oligomenorrhea, then the clinician will follow the same steps followed in the diagnosis of amenorrhea, beginning with a progesterone challenge (refer to section on amenorrhea found earlier in this chapter). Since the individual with oligomenorrhea has already demonstrated that menses does occur, assessing for a patent genital outflow tract is not required. As with the workup of the amenorrheic individual, a progestin challenge is used to assess for the presence of endogenous estrogen needed for the routine monthly buildup of endometrial tissue. If the challenge results in menstrual bleeding within a week of discontinuing the progestin, then the presence of endogenous estrogen is established, and the focus of the workup then becomes anovulation. At this point, abnormal functioning of either the ovaries, pituitary, or CNS is suspected. The assessment of these three areas for healthy functioning follows the same steps used in the workup of amenorrhea. As with amenorrhea, treatment for the woman often involves hormone therapy. Combination OCs can be taken continuously to regulate the timing and amount of menstrual flow, with the added benefit of offering birth control, if so desired. If the individual does not desire birth control, then the woman can take medroxyprogesterone acetate, 10 mg po for 10 days each month, after which she can anticipate withdrawal bleeding.

As with the evaluation of any menstrual irregularity, the midwife must offer the woman knowledge and support throughout the process. Depending on her age and desired fertility, a number of potentially anxiety-provoking issues need to be addressed, such as fears about infertility or cancer. Good communication between the clinician and the woman's other health care providers and/or specialists can do much to support her during the assessment and treatment phases of the oligomenorrheic workup.

Premenstrual Syndrome

One of the more difficult deviations from a healthy state to accurately identify in a woman is the collection of symptoms known as premenstrual syndrome (PMS). Physical, psychological, and behavioral cyclic changes (e.g., bloating, mood changes, appetite changes) that mirror the timing of the menstrual cycle occur in almost all women at some time between menarche and menopause [38]. Attempting to discern when these symptoms collectively form a syndrome, particularly one that necessitates intervention, can be a challenge to the midwife, since there exists no single physical finding or laboratory test that enables one to diagnose PMS. Thus a careful history from the woman regarding her reported symptoms and the timing of them is vital to understanding any complaints from her that seem to be related to her menstrual cycle. This history will aid the woman and her midwife in distinguishing between (1) normal, nonpathological monthly changes, (2) PMS, and (3) the more severe premenstrual dysphoric disorder (PMDD), a state of depression defined in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as occurring in a pattern reflecting the menstrual cycle [39].

While it is safe to assume that the symptoms of PMS have been experienced by women throughout the evolutionary process, it was not until the middle of the twentieth century that PMS came to be formally defined [40]. Over the last 50 years the definition has varied, but in general, PMS refers to a cluster of physical, psychological, and behavioral symptoms that occur during the late luteal phase of the menstrual cycle and end with the onset of menstruation [41]. It has been estimated that up to 75 percent of women will experience symptoms of PMS at some time in their adult life [39], and that 20 to 40 percent will seek medical help for PMS. The most severe cases generally occur in women ranging in ages from their late 20s until their mid-30s [41]. Well over 100 symptoms have been attributed to PMS, and most are listed in Table 14-6.

PMDD is a condition in which the symptoms of PMS are more severe and cause significant functional impairment [39, 42]. It has been estimated that anywhere from 3 to 9 percent of women suffer from this disorder at some point in their postmenarche, premenopause adult life [41, 43]. As with PMS, this disorder can be difficult to accu-

TABLE 14-6 Symptoms of Premenstrual Syndrome (PMS)

Abdominal bloating	Cystitis	Hostility	Rage
Abdominal cramps	Decreased concentration, efficiency, motivation	Hunger pangs	Rhinitis
Accident proneness		Hypersomnia	Runny eyes
Acne	Depression	Indecision	Sadness
Aggression	Diarrhea	Insomnia	Salt/sweet cravings
Agitation	Dry hair	Irritability	Seizures
Alcohol intolerance	Edema	Joint and muscle pain	Self-inflicted injury
Anger	Epilepsy	Lethargy	Sensitivity to rejection
Anorexia	Exhaustion	Libido changes	Skin rash
Anxiety	Eye problems	Migraines	Social isolation
Assault	Fainting spells	Mood swings	Sore throat
Asthma	Fatigue	Muscle cramps	Stiffness
Backache/pain	Food binges	Nausea	Suicidal ideation
Blackness around eyes	Food cravings	Noise sensitivity	Sweating
Blurred vision	Frequent urination	Oily skin	Tension
Boils	Frustration	Oliguria	Tonsillitis
Breast engorgement	Greasy hair	"Out-of-control" feelings	Tremors
Breast tenderness	Headaches	Palpitations	Urethritis
Bronchitis	Herpes attacks	Panic attacks	Vertigo
Bruising	Hirsutism	Paranoia	Weeping spells
Child abuse	Hives	Paresthesia	Weight gain

Confusion			

rately diagnose. Diagnosis involves distinguishing between PMS and PMDD, as well as differentiating PMDD from a concurring state of depression, which exists in over 50 percent of women believed to have PMDD [41]. The American Psychiatric Association [39] offers the definition of PMDD presented in Table 14-7. While PMDD can be viewed as a severe form of PMS, it is important to note that

TABLE 14-7 Criteria for Premenstrual Dysphoric Disorder (PMDD) in the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*

In order to make a diagnosis of Premenstrual Dysphoric Disorder (PMDD), at least 5 of the following 11 symptoms are required.

- At least one of the following:
  Feeling sad, hopeless, or self-deprecating
  Feeling tense, anxious, or "on edge"
  Marked lability of mood interspersed with frequent tearfulness
  Persistent irritability, anger, and increased interpersonal conflicts
- And 1 to 4 of the following additional symptoms:
  Decreased interest in usual activities, possibly associated with withdrawal from social relationships
  Difficulty concentrating
  Fatigue, lethargy, or lack of energy
  Marked changes in appetite, possibly associated with binge eating or craving certain foods
  Hypersomnia or insomnia
  Feeling of being overwhelmed or out of control
  Physical symptoms, such as breast tenderness or swelling, headaches, sensations of bloating or weight gain, and possibly joint or muscle pain

Any collection of these symptoms may be accompanied by thoughts of suicide.

In order to apply the diagnosis of PMDD, these cyclic symptoms must have occurred "most months" [not clearly defined in the *DSM-IV*] over the last 12 months, and disappear shortly after the onset of menses each month. Typically, the symptoms last from the week prior to menses until mid-menses, and are always absent during the week after menses.

PMDD focuses on matters of psychological and emotional nature, and that PMS can also encompass physical deviations from normal without the psychological sequelae. Thus a woman could have cyclic physical symptoms (e.g., diarrhea, hirsutism, or skin rash) that are not psychological in nature yet can be quite restrictive in terms of performing the activities of daily living (ADL). This individual would not be diagnosed technically with PMDD, yet could be suffering just as much interruption in ADL as the woman with PMDD. To date, there is no title to attach to this extreme form of "physical PMS," nor is there evidence as to how many individuals actually suffer from this malady.

The etiology of PMS is unknown. Theories originally emphasized psychological factors, but have since ranged from those with a biological emphasis to those suggesting a combination of biological, psychological, and social factors. The hormones estrogen and progesterone have been theorized to play a role in PMS, mainly because of their fluctuating patterns that occur during the menstrual cycle. In addition, estrogen's ability to affect serotonergic neurological function has led some reseachers and clinicians to postulate that PMS involves problems with the serotonin system. While past treatment regimens involving the use of progesterone have not proved effective, there has been recent clinical evidence to support the use of selective serotonin reuptake inhibitors (SSRIs) as treatment for moderate to severe PMS or PMDD [44, 45]. In fact, fluoxetine (Sarafem, Prozac) is an FDA-approved agent for use in treating PMDD [41]. However, SSRI treatment does not work for many women with PMS or PMDD [46], and midwives are cautioned to recognize that simply prescribing an SSRI without looking at all of the symptoms reported by a client is categorizing PMS or PMDD as a biological condition and may lead to overlooking the psychological or social contributing factors that also require attention.

In evaluating a woman who appears to have PMS, the first step is to obtain a thorough history regarding the symptoms. The timing of the symptoms is vital to diagnosing this condition. Because there are so many factors related to PMS (see Table 14-6), the midwife must be sure that the woman does not have a separate condition, with similar symptoms, that is not dependent on her menstrual cycle. For example, hypothyroidism and clinical depression have many of the same symptoms found in PMS. While the symptoms in these other conditions may vary in intensity, they do not do so in a cyclic manner consistent with the timing of the menstrual cycle. Most importantly, the symptoms of PMS consistently disappear with the onset on menses, while the symptoms of other conditions either wane sporadically or do not disappear at all.

The most effective manner in which to obtain a history of symptoms is to do so prospectively. Encouraging a woman to keep a daily log of symptoms along with a charting of her menstrual cycle will give the midwife a more accurate depiction of what is occurring than will asking the woman to attempt to recall the timing of symptoms based on prior experience [46]. Typically, a three-month log should include a daily recording of the menstrual cycle status, any physical or emotional symptoms, any alterations in the individual's ADL, and the woman's diet and exercise routine. This prospective recording will afford the midwife and the woman a significant amount of information for use in ruling out PMS. The information will also be vital in working toward a possible solution.

A physical and pelvic examination will assist in diagnosing PMS because it will help the midwife to rule out other possible causes of the symptoms that the woman is experiencing. For example, a thyroid disorder, a cardiac abnormality, or a pelvic mass could be the source of symptoms thought to be related to PMS and could be discovered on examination. It is important to note, however, that even if a physical cause for a woman's symptoms is found and subsequently treated or controlled, the individual could still be suffering from PMS and may require additional treatment and therapy related to this latter condition.

While laboratory procedures can be useful in ruling out differential causes of symptoms related to PMS, there are no current standard or routine assessment procedures recommended for diagnosing this condition.

If a diagnosis of PMS or PMDD is made, treatment can take various forms, and must be individualized for each client. Management of these conditions starts with an understanding, caring approach that acknowledges the reality of what is happening to the woman who is suffering. It serves the midwife well to know the historical perspective of Western medicine and traditional cultural beliefs regarding premenstrual symptoms. Prior to the mid-twentieth century, symptoms of PMS were not recognized as occurring specifically during the late luteal phase. They were more broadly described as being related to the general process of menstruation and were more closely linked to the actual bleeding

of menses. The symptoms experienced by women were attributed to causes ranging from the work of the devil to psychotic breakdown unique to the female psyche, and women suffering from PMS-like symptoms were considered, as late as the mid-twentieth century, to be "invalids" [40, 42, 47]. With the recognition over the last 50 years of PMS and its accompanying symptoms as a unique disorder, the various stigmas attached to menstrual-related symptoms began to break down. However, from a cultural standpoint, these historical perspectives do not disappear with ease, and even today women with PMS have been reported to view their bodies in a negative light, with feelings of failure and shame having been expressed [48]. Thus the midwife must begin any management of PMS or PMDD with an expression of empathy and support toward the woman, so as to acknowledge not only the symptoms she is experiencing but also the possible cultural stigma that she may be bearing or trying to avoid.

Most of the available scientific literature regarding treatment of PMS and PMDD focuses on the latter. A number of studies have been conducted over the last decade exploring pharmaceutical means of treating PMDD, but little research has been conducted that examines other approaches, such as lifestyle changes, for managing PMDD, and there are no reports in the literature of clinical trials currently testing methods of treating PMS.

There are, however, a number of medical textbooks, self-help publications, and Web-based "PMS" sites that generally promote the same consistent approach to treating PMS [49–51]. This approach involves a multifaceted change in an individual's lifestyle, including diet, daily activity, and reduction in stress. Goals of treatment should include building self-esteem and self-control, stress relief, tempering or eliminating symptoms, and facilitating the body's natural, healthy processes to increase feelings of well-being. Helping a woman to feel in control is critical for a PMS sufferer. Knowing that she has PMS provides a name and a reason for the feelings that may be causing her to feel out of control. Discussion with family and friends and participation in PMS support groups enables the individual to develop ways of coping and to establish channels of communication with close family members for understanding and help during premenstrual days.

Looking for causes of stress and seeking ways of reducing them serve the double function of diminishing the stress actually being experienced by the woman while increasing her feelings of control. Programs of exercise and nutrition specifically designed for the individual woman will help to promote physical and psychological well-being. Nutritionally, the woman should benefit by reducing her premenstrual intake of salt, refined sugars, caffeine (coffee, tea, sodas, and chocolate), and alcohol. She should try to maintain balanced nutritional intake, regular eating times, and increased intake of water (a natural diuretic) throughout her daily life, but especially prior to her menstrual period.

It is important for both the woman and the midwife to recognize that these suggestions are likely to represent a major adjustment to the woman's daily life. Success in treatment of PMS is not likely to occur if all suggested changes are attempted to be made at once. It is best to begin alterations in ADL by learning where the woman is currently with regard to such matters as diet and exercise, and then building slowly from there. Recommendations for change should begin with the most immediate and essential factors contributing to PMS symptoms; when these alterations are ingrained, add other recommendations one at a time. For example, in nutrition, start by having the woman reduce her use of sugars, caffeine, and alcohol; later add complex carbohydrates; and then reduce fats. With exercise, if the woman is sedentary, encouraging a daily short walk at her own pace will be far more likely to bring results than starting her with a more rigorous regimen that requires warm-ups, wind-downs, and calculations of pulse rate. These helpful techniques can be added later, but the first goal should be initiating some form of exercise. Even basic stretching exercises can be useful in promoting a general feeling of well-being and reducing stress. If the individual can afford to hire a personal trainer, or can encourage a friend or family member to assume this role, there is much to be gained by having a personal "coach" encourage the woman to make the changes needed to reduce the symptoms of PMS.

If the symptoms of PMS are severe or if the woman is diagnosed with PMDD, adding psychological therapy and/or medication to the diet and exercise changes mentioned above may be required elements of treatment. There is evidence that cognitive-behavioral therapy can help control the symptoms of PMDD, and that the effect is long lasting [52, 53]. However, most research in the medical literature explores the use of medications for the treatment of PMDD. While GnRH agonists, oral

contraceptives, and benzodiazepines are some of the pharmaceuticals that have been tested, the efficacy of these elements has been mixed at best. The class of medications that has shown the most promise in treating PMDD has been the SSRIs, including fluoxetine, sertraline, paroxetine, and citalopram [41]. Of these, the most effective in clinical trials has been fluoxetine (Sarafem, Prozac) [38, 44, 45]. Of several regimens tested, it is the most effective at the lowest possible dose: 20 mg taken daily, either on an ongoing, continuous basis or for the 14 days of the luteal phase each month, ending with the onset of menses. Because of side effects inherent to the taking of SSRIs, it is recommended that the woman begin with the 14-day per month regimen, and increase to the ongoing, continuous regimen only if little or no relief of symptoms is achieved with the intermittent approach.

While the use of fluoxetine has been tested with subjects diagnosed as having PMDD, the medication has been used clinically with clients suffering from moderate to severe forms of PMS. However, the midwife must use this, and any medication, with caution when managing the care of an individual with PMS. As mentioned previously, SSRI treatment, even with fluoxetine, does not work for a substantial number of women with PMS or PMDD [46]. Midwives must thus avoid the temptation to seek an "easy fix" to this complex problem. Prescribing an SSRI should not keep the midwife from addressing additional factors, such as physical conditions or social situations that contribute to the PMS symptoms and that will receive no relief with the action of an SSRI.

In addition to medications, multiple vitamins, minerals (especially calcium), and a number of complementary therapies have been recommended for use in treating PMS [54–57]. Yet, the availability of research evidence supporting these recommendations is limited. Many of the individual symptoms of PMS have been reported by practitioners of various modalities to be treatable using such techniques as aromatherapy, chiropractic, homeopathy, hypnotherapy, magnet therapy, massage, reflexology, Reiki, and yoga [58]. However, a review of randomized clinical trials, each of which had examined the use of individual complementary modalities specifically addressing the treatment of PMS, led to the conclusion by the reviewers that no current evidence exists for the treatment of PMS using these modalities [59]. The specific techniques examined in these clinical trials included the use of herbal elements (chaste tree, gingko, and evening primrose oil), homeopathy (specific element not mentioned), reflexology, chiropractic, massage, biofeedback, relaxation techniques, and nutritional supplements. The reviewers stated that they were unable to find any randomized clinical trials for the modalities of acupuncture, aromatherapy, Chinese herbs, hypnosis, meditation, therapeutic touch, or yoga. However, an examination of the current literature reveals a number of authors who promote the use of several of the aforementioned modalities and who present evidence to support their recommendations [54, 56, 60, 61]. Thus the midwife is presented with a confusing collection of evidence regarding treatment of PMS using any one of a variety of complementary modalities. The most that the clinician can do is to review with each individual client what potential treatments of PMS exist, explain what evidence, if any, supports each of the treatment modalities, and assist the woman in making a decision about which route of care she desires taking. Again, despite the current confusion in the treatment of PMS, simply having acknowledged to the woman that she indeed does have real symptoms that require addressing is a large first step the midwife can make in helping to improve the client's health and well-being.

Abdominal and Pelvic Pain

Overview

Complaints of abdominal and pelvic pain are common motivations for seeking gynecological care and comprise a significant portion of the energies of women's health care providers. Entire volumes are dedicated to the evaluation and treatment of pelvic pain and interested midwives will find many opportunities to expand their skills in this area. This section will address the most important issues in the evaluation of pelvic pain and the most common causes of the pain.

Many women present for an annual check-up, and upon taking a careful history the midwife discovers that the issue of chronic pain is the underlying reason for the visit. Pain has a significant impact on a woman's quality of life, producing fatigue, tension, or depression, yet she may be reluctant to discuss this for a variety of reasons. Previous providers may have overtly or inadvertently discounted her pain, or she may have been uncomfortable discussing her pain completely. Pelvic pain often rep-

resents or triggers many emotions centered on her sense of self as a woman, her ability to conceive and bear children, or feelings pertaining to her sexuality.

On the other hand, a woman may present with abdominal or pelvic pain complaints after having been seen by one, or many other practitioners who have reached the limits of their skills and have recommended a gynecologic consult. This woman, and perhaps her family members as well, are often angry and frustrated, and they have ever-mounting concerns regarding the source of her pain.

Acute abdominal or pelvic pain also commonly presents as a problem visit in the office or on the phone. Careful screening must accompany the evaluation of acute pain to ensure appropriate management.

One or more visits are often needed for this assessment and at times require a great deal of time and provider energy, both of which may be in short supply in a busy practice [62]. The current emphasis in some practices is on short, focused visits and this may seem incompatible with a high quality, comprehensive approach to a problem; however, as with the assessment of many ambulatory problems, the midwife must be able to adapt visit structure and time to allow for flexibility in the appropriation of office time and resources.

The approach to assessing pain must recognize both the physical and psychological realities of the person experiencing the pain. In order to establish a trusting, mutually satisfying clinical relationship, the midwife must validate the woman's experience and communicate a commitment to a comprehensive exploration of the problem as perceived by the woman [63, 64]. The midwife should also at some point during the visit, explain to the woman that the cause of her pain may have both a physical and a psychological component and that the cause may be elusive and not lend itself to a simple explanation or solution. It is useful to mention that relief often results from dietary changes, activity changes, or a variety of other approaches to her life and lifestyle [65, 66].

When beginning to explore pelvic pain with a woman, the midwife must carefully sort out the often unspoken knowledge that each woman holds as her own reference point for "normal"—her own social, cultural or religious influences on her sense of self as a woman and her unique perception of the various aspects of reproductive function. Her beliefs with regard to what is normal or not will have an inevitable impact on her interpretation of her menstrual cycle, vaginal secretions, and emotional response to any perceived variation in function including pain or discomfort.

Finally, it is important to remember that historically, women have been told that many gynecologically based problems were "all in your head." Some women interpret the suggestion that pain might have a psychological component as an example of this dated and misogynist behavior by the provider. She might also react negatively to the notion that there may be an emotional issue contributing to her physical distress. Despite current advances in the public's understanding and acceptance of mental illness, the stigma is still prevalent and the midwife must proceed sensitively in any discussion of potential referral to mental health treatment or support groups, when they are appropriate. The midwife must often overtly reinforce that the body and the mind are not independent entities, and that comprehensively addressing a problem in one "system" often necessitates a multifaceted approach.

Types of Abdominal/Pelvic Pain

Acute Pain The ability to recognize and accurately manage acute abdominal pain is an important skill in women's health. The midwife must be able to recognize and appropriately evaluate a potential abdominal emergency. The ability to safely care for clients experiencing such an emergency necessitates the existence of a preexisting relationship with surgical and nongynecologic referral systems and providers. It is often the case that in women of childbearing age, an ectopic pregnancy or other serious gynecological problem must be ruled out in order for her to be cared for by the right medical or surgical providers. Consequently, the ability to recognize the signs of an ectopic pregnancy is of primary importance to the midwife. Other causes of acute pain that necessitate prompt diagnosis include appendicitis, pelvic inflammatory disease (PID), and ovarian torsion. Each of these will be addressed individually.

In an emergency situation the midwife may need to enlist support services at her institution in order to address a lack of health insurance, childcare needs, or other issues. If a diagnosis of pregnancy has been made, one must consider issues of confidentiality and the impact this information might have on other persons in this woman's life. The fact that she has been sexually active, or sexually active outside of an acknowledged relationship, may have the potential for devastating consequences and must be handled carefully.

Chronic Pain The woman with chronic pelvic pain may present as a person who has had a long series of encounters with health care providers. She, and the significant others in her life, may have found their contacts with providers less than satisfying or are seeking care from several different providers in search of a particular diagnosis or treatment. The inability of the woman's system of care to meet her perceived needs may lead to inappropriate or overuse of health care resources, including diagnostics and treatment interventions [67, 68]. It is crucial to know if the client has indeed had such an experience so as to be clear about her motivations for this visit and her expectations for your involvement in her care. The woman's history of her previous care is just as important as the history of her pain. On the other hand, the client may have chronic pain that has never been fully articulated or fully explored with a care provider. She has presented for multiple problem visits with vague complaints but has never had her concerns adequately or comprehensively addressed.

Evaluating Pelvic Pain

Midwives are familiar with the use of a systematic and thorough approach to the evaluation of a problem. The collection of data in the evaluation of pain must be particularly thorough in order to reach an accurate conclusion. A helpful tool in the evaluation of any complaint, including pain, is the "OLD CART" system (see Table 14-8). The use of this simple review guides the midwife through a comprehensive evaluation of the problem from the woman's point of view. The system is useful with the modification of several lines of inquiry. In the midwife's exploration of the woman's complaint of pelvic pain the following information must be obtained:

Onset: When did the pain begin? Can the woman identify a particular event or point in time related to the initial recognition of the pain?

Location: Many women refer to any pain below the umbilicus as "abdominal" pain. Assist her in specifically identifying the location of her pain. Many women have an inaccurate perception of where their pelvic organs actually are and may, for instance, think that the uterus is commonly located above the pubic bone. The midwife needs to ascertain if the pain moves or radiates or has a different quality in varying locations.

Duration: Is the pain cyclic or noncyclic? Is it related to her menstrual cycle? Is it related to her bowel function or to sexual activity? Is the onset of the pain related to her diet or diet changes? Is it related to work or athletic activities? Is it related to her emotional state of being or to the onset of emotional stress?

Character: Try to assist the woman in describing her pain if she cannot do so spontaneously. Give her a wide variety of descriptors used for pain such as *sharp/dull*, *gnawing*, *burning*, *achy*.

TABLE 14-8 The "OLD CART" Method of Obtaining a History About Reported Pain

Onset	When did the pain begin? Can the individual identify a particular event or point in time related to the initial recognition of the pain?
Location	Specifically identify the location of the pain. Does the pain move or radiate or have a different quality in varying locations?
Duration	Is the pain cyclic or noncyclic? Is it related to other health factors (e.g., bowel function, physical activity, sexual activity, menstrual cycle)? Is the onset of the pain related to diet or diet changes? Is it related to work activities? Is it related to the individual's emotional state of being or to the onset of emotional stress? How long does the pain last once it begins?
Character	Ask the individual to describe the pain. Offer a wide variety of descriptors used for pain, such as *sharp/dull*, *gnawing*, *burning*, *achy*.
Aggravating factors	What makes the pain worse (e.g., exercise, diet, constipation, diarrhea, urination, physical activity, sexual activity, menses)?
Relieving factors	What relieves the pain (e.g., rest, diet change, bowel movement), and to what degree?
Treatment used	What treatments has the individual used to help alleviate the pain? Were they recommended by other providers or suggested by a family member, friend, book, or Web site? Were medications used, either over-the-counter or prescription, or both? Were any "alternative" treatment modalities used? What was the success or failure of any treatments that were used?

Aggravating factors: Elicit any information regarding what may make the pain worse, such as exercise, sexual activity, constipation, diarrhea, menses, urination, diet.

Relieving factors: Elicit what relieves the pain, and to what degree.

Treatment: Assess what the woman has done to try and relieve the pain and to what degree each intervention was successful. Specifically inquire as to the treatments suggested by other providers and any "alternative" treatment modalities used.

Several questionnaires are available for use in the evaluation of chronic pain [63]. Should the midwife be in a practice where caring for women with chronic pain is common, the use of such data collection instruments is advisable. Many women will answer these questionnaires in detail and provide a wealth of information; however, others who have not considered their pain in any comprehensive manner may need to return for a future visit with a pain diary or history. Finally, it is always important not to forget to ask perhaps the most obvious question: What does the woman think the problem is?

History A thorough history, including menstrual cycle characteristics and sexual activities, will be of use in this evaluation. The midwife should include the woman's assessment of how her pain has affected her quality of life. She may have adapted many of her daily activities, including her work, school, athletics, and sexual activities in response to her pain. The impact of her pain may extend far beyond her physical sensations. If her pain has had an impact on her quality of life, her relationships with her coworkers, family, and friends may have suffered as well. This will have inevitable negative consequences on her emotional well-being. In the case of long-standing pain, evaluation and treatment by a mental health professional may be productive.

In the event that further screening or diagnostic studies or referral for treatment is indicated, it is useful to know whether the woman's ability to obtain further care may be influenced by her socioeconomic or health insurance status. While it is always important for the midwife to be judicious in the choice of testing or treatment, lack of insurance coverage makes these choices even more challenging. A midwife should be familiar with the payment options and eligibility criteria of her referring institutions and laboratories, such as a sliding payment scale based on income, or waived payment for care, often referred to as "charity care." Additionally, many low-income women may be eligible for free or low-cost gynecologic cancer screening or treatment via government or institutionally sponsored programs. Because some women may be reluctant to disclose that they are unable to pay for testing or treatment, the midwife should be cognizant of a woman's insurance coverage status or resources to pay for care. An exploration of the ability of the woman to proceed with the testing or treatment is much more useful at the time when the plan is made rather than at some later time when the midwife realizes that the woman did not return for care and may be at increased risk for disease or disease progression.

Examination Examination of a woman presenting with abdominal or pelvic pain may require a complete exam or may be quite focused depending on the level of previous care and the acuity of the pain. A woman with acute pain, especially when accompanied by fever, tachycardia, significant change in blood pressure, signs of shock, vomiting, or evidence of significant blood loss, must be evaluated for the possibility of immediate referral or consultation. Efficient evaluation, documentation of findings, and consultation are in order. A diagnosis of ectopic pregnancy, appendicitis, bowel obstruction, sepsis, or ovarian torsion all dictate the need for immediate physician consultation and referral for care.

In the absence of an acute presentation, the midwife should perform a complete examination. The woman's demeanor and presentation should be included in the evaluation. Is she relaxed or tense in her stance or posture? Is her stance or posture asymmetrical indicating the guarding of an area or long-term discomfort? Vital signs may be helpful in assessing for an underlying condition related to the pain. Evaluation of the back and lower extremities are often useful to rule out a musculoskeletal injury, such as a muscle strain or stress fracture.

Abdominal Examination A standard abdominal exam should be performed, including observation, auscultation, percussion, and palpation. The goal in palpation is not only to palpate for organ enlargement or displacement, or to identify a mass or enlarged lymph nodes, but also to see if the pain can be reproduced. It is often useful to first ask the woman if she herself can reproduce the pain. If not, proceed with care and respect, with attention to the unaffected side or area first. For instance, if the woman reports right lower quadrant pain, examine

the left side first to encourage relaxation and improve her ability to tolerate the entire examination. Communicating your findings and letting her know what is next throughout your examination is usually helpful and maintains an atmosphere of trust and caring. Pay special attention to any area of tension or guarding. Knowledge of patterns of referred pain points is useful as well.

Pelvic Examination As noted in Chapter 56, pelvic examinations must always be performed with respect and care. This is especially important in the presence of pelvic pain. The ability to perform a thorough examination can be severely limited by a lack of trust or inordinate discomfort on the part of the woman.

On visual inspection, check for any signs of swelling, lesions, trauma, or other skin changes. The woman's tolerance of the insertion of the speculum is often an important observation, especially if she reports pain with sexual activity. After insertion, check for the presence of physiologic or abnormal vaginal secretions, collect a sample of any secretions for a wet mount examination, and perform STD testing as indicated. Visual inspection of the cervix may reveal a protruding IUD, color change indicative of pregnancy, or the presence of a polyp or other mass. After the speculum has been withdrawn, prepare the patient for the bimanual portion of the examination. If she anticipates discomfort, pause for enough time to allow her to regroup and relax. Proceed carefully, noting whether any discomfort is at the introitus versus deep in the vagina. Note any cervical, adnexal, or uterine motion tenderness. Palpate for organ dislocation or the inability to completely palpate the uterus or adnexa indicating dislocation. Palpate carefully for any masses, uterine fibroids (myomata), or uterine or adnexal enlargement indicative of pregnancy. Note the muscle tone and the presence of any cystocele or rectocele or of uterine prolapse. Confirm any findings with a rectal exam and check for constipation, polyps, or masses. A fecal occult blood test (FOBT) may be useful as a preventive health measure or to aid in the management of any abdominal mass.

The midwife should always share physical examination findings appropriately with the client and allay as many fears as possible. The ability to communicate the finding of a mass or enlarged organ—to the woman or to any potential consultant—must include the size, shape, location, mobility and relation of the mass to other organs. In addition, one must proceed gently with the physical examination so as not to incur undue pain; but if pain is elicited, the midwife must be able to describe the intensity and location of the pain, especially as it compares with the woman's perception of the pain.

Laboratory/Screening/Diagnostic Tests Judicious selection of screening and diagnostic tests is necessary in the contemporary evaluation of pain. Women often encourage their providers to test for "everything" based on fear, especially with regard to malignancies. It is important for midwives to resist this request and proceed based on the need for test results that will directly inform management plans. Clearly a pregnancy test is indicated if there is any suspicion of pregnancy, missed menses, or other unexplained vaginal bleeding in a woman who is heterosexually active. A complete blood count (CBC) is often ordered as a standard test—although in the absence of an infectious process or concerns with regard to anemia, a CBC may not be particularly useful. If concerns exist that the cause of the pain is urologic in nature, a urinalysis or urine culture may be useful. Tests for STDs or a wet mount for vaginitis may be useful if indicated by history and examination.

A pelvic or abdominal ultrasound (U/S) is a common test to aid in the diagnosis of uterine or adnexal abnormalities. If an ultrasound is ordered, a vaginal probe may be part of the examination. For women who have never had vaginal penetration or who have cultural prohibitions with regard to pelvic procedures, this part of the test may be distressing. Prepare your client for this portion of the examination, explain its purpose and if necessary, note on your order form that this is an initial pelvic ultrasound for this particular client. This may alert the technician that a little extra patience and time may be required in this instance.

Consultation and referral for further physician evaluation may be indicated upon diagnosis of a condition requiring treatment or management beyond the midwife's scope of practice. If this is indicated, the woman should be provided with as much information as possible, and a report of her care by another practitioner should be requested.

If the evaluation results in an inability to diagnose the cause of the woman's pain, a variety of plans might be made. If the woman wishes to continue investigation of her pain with the midwife, a more detailed "history" of her pain should be suggested. This might include the use of anatomical drawings to locate her pain; the use of a pain diary

with a pain severity scale; the use of a journal to additionally chart her pain in relation to her daily activities, menstrual cycle, bowel habits, sexual activity, and diet.

The midwife may also wish to review with the woman normal anatomy and physical sensations related to gynecologic and menstrual function, including the wide range of normal variations. If nothing abnormal is found on examination, reinforcing the normalcy of the woman's anatomy and organs is vital, as this may be what she is seeking after all. Education and support may provide her with a new perspective on her relationship to her "gynecologic self." The social, religious, and cultural forces in her life may have shaped her view of her physicality, and the clinician may be able to provide an additional, previously unknown perspective on this "self." This might include viewing both positive and negative aspects of the woman's menstrual cycle, her sexuality, and her fertility. The midwife's office can continue to serve not only as an ongoing source of primary health care or gynecologic care but also as a safe space for education and exploration.

Referrals to specialists may be appropriate, including mental health specialists, if it is felt that an exploration of the woman's psychological well-being might be useful. Many support groups also exist for women who experience a variety of conditions, such as endometriosis, as well as those who have been abused or sexually traumatized.

Causes of Acute Abdominal/Pelvic Pain

Ectopic Pregnancy Ectopic, or tubal, pregnancy is any pregnancy implanted outside the endometrial cavity. In the past, tubal pregnancies were considered to be emergency situations that necessitated surgical intervention and loss of the affected Fallopian tube. While still considered an emergency, ectopic pregnancy may currently be treated using a medical approach (e.g., Methotrexate), and in the event of surgical intervention efforts are usually made to preserve the integrity of the tube. No matter what the treatment, ectopic pregnancy must still be looked upon as a life-threatening condition and promptly diagnosed and treated. The classic ectopic presentation is a triad of abdominal pain, irregular vaginal bleeding, and amenorrhea [69]. Any combination of these symptoms must always trigger an evaluation for an ectopic pregnancy in a woman who is heterosexually active. Additionally, women who present with any of the above and with fever, tachycardia, or low blood pressure must be evaluated for shock and emergency referral, even in the absence of vaginal bleeding. Adnexal enlargement or tenderness on pelvic examination, a pregnancy test, and ultrasound may confirm the diagnosis of ectopic pregnancy. Sharing the diagnosis of an ectopic pregnancy with the woman must be done in a manner that conveys the serious nature of the problem and the need for referral to a provider capable of a potential surgical intervention. It is important to note that the client may have not suspected a pregnancy at this time and may be required to integrate a great deal of information at a very stressful moment. (For more detailed information, refer to Chapter 24.)

Appendicitis Another common abdominal emergency is appendicitis. The classic symptoms of right lower quadrant pain accompanied by a fever and an elevated white blood count (WBC) may not always be present. Appendicitis may present with left lower quadrant pain, fever may be not present, and changes in the WBC do not always initially occur. The variety in the presentation of appendicitis may include right-sided pain, bilateral pain, nausea, vomiting, diarrhea, constipation, referred shoulder pain, fever, and a loss of appetite.

Any suspicion of appendicitis necessitates consultation and referral to a surgical provider. The management of appendicitis includes a variety of management options currently. These include surgery as well as inpatient and outpatient observation. (Refer to Chapter 7 for a complete discussion of appendicitis.)

Ovarian Torsion An uncommon cause of acute pelvic pain is ovarian torsion [70]. Causes of torsion include previous adnexal surgical manipulation, especially tubal ligation, ovarian enlargement, adnexal structural anomaly, or pregnancy. The client may present with point specific pain or more generalized unilateral pelvic or flank pain, nausea, and vomiting. This diagnosis may be confused with gastrointestinal disorders.

The treatment is surgical intervention during which the ovary is replaced and fixed in place or removed depending on the cause, if evident, and any presence of tissue damage or necrosis. It is not uncommon on surgical examination to discover a false positive diagnosis of ovarian torsion. Instead, the pain may be due to endometriosis, ovarian enlargement, or unknown causes not apparent to the surgeon.

Causes of Chronic Abdominal/Pelvic Pain

Urologic Urinary tract infections (UTIs) or pyelonephritis may present as lower abdominal pain or achiness in addition to, or in place of, the better known symptoms of dysuria, urinary frequency, and changes in the appearance or odor of the urine. Either of these infections may present with increasingly intense pain, fever, and a feeling of malaise. Pyelonephritis may also present with back or flank pain and tenderness at the costovertebral angle. Management of urologic infections is discussed in Chapter 7.

Pelvic Inflammatory Disease/Salpingitis Pelvic inflammatory disease (PID) may present as either chronic or acute pelvic pain. Diagnosis and management of PID are discussed in Chapter 15.

Interstitial Cystitis Interstitial cystitis (IC) is a chronic urinary irritation that presents as a chronic pain or achiness in the pelvis [71, 72]. The woman may experience urinary frequency, urgency, nocturia (urination more than two to three times in a night), and relief upon emptying her bladder. Dysuria is not a typical symptom. Since any of these symptoms are common with urinary tract infections, many women are treated initially with a variety of antibiotics with little or no relief. Women with a long history of UTIs or unsuccessfully treated UTIs may benefit from an evaluation for IC. The urine culture of clients with IC is negative with the exception of the presence of small to numerous WBCs. The physical examination of a woman with IC is not particularly remarkable, although in some cases she may have pelvic floor pain. The diagnosis is essentially one of exclusion.

Spicy foods, alcohol, stress, or sexual activity may aggravate the IC symptoms, and vaginal penetrative sexual activity may be so painful as to be impossible. The cause of IC has not yet been identified successfully and a wide variety of pharmacological and surgical treatments exist, with varying degrees of success. Women with IC may experience relief from a change in diet, bladder training exercises, or long-term pain medication.

Dyspareunia and Vulvar Pain The woman with vulvar pain or pain associated with sexual activity may have some difficulty in articulating her discomfort. This may be due to embarrassment, a lack of anatomical information, or a reluctance to discuss sexual activity [73]. The use of anatomical drawings may be useful in obtaining an accurate history of her pain. Additionally, the midwife must validate that this is an appropriate opportunity for the discussion of this type of pain and that discomfort during sex is not uncommon. The midwife should reinforce the notion that attaining sexual pleasure is a healthy state and that sexual well-being is deserving of the woman seeking a health care provider's assessment and advice. A frank discussion of the woman's sexual activities and habits is important, including the use of douches, tampons and pads, "sex toys," lubricants, and contraceptives.

Fear of pain, as well as pain during sexual activity, can produce a distressing cycle of sexual frustration and tension in relationships. The woman's partner may be present during a visit intended to discuss these problems, and may be a support or a hindrance during the history and examination portions of the visit. The midwife may request to see the woman without her partner or offer this option to her. Common causes of tension resulting in painful or difficult sex include a fear of pregnancy, a history of infertility, a lack of trust in the contraceptive method used, a latex allergy if latex condoms are used, or a lack of vaginal lubrication due to age, medications, sexual arousal, or a lack of partner patience. A disinterest in sex or an interest that does not match that of her partner may also be at the root of a woman's pain. Each of these must be discussed frankly prior to seeking a physical cause of the pain.

Physical causes for vulvar pain irrespective of its presence during sexual activity include herpes simplex virus (HSV) lesions; vaginal tears or scarring due to tears as a result of trauma, surgery, or childbirth; vaginitis; Skene's or Bartholin's gland infections; or vulvadynia. Pain relief should follow the treatment of HSV lesions, vaginitis, or any other infections that are present. Vaginal trauma must be permitted to heal prior to any further vaginal sexual activity. An inquiry into and appropriate follow up of the source of the trauma is required. Vaginal scarring may be somewhat more difficult to treat. Additional lubrication during sex and partner patience may assist the healing process. If the woman fails to attain relief, a referral to a gynecologic surgeon may be required.

Vulvodynia Vulvodynia is defined by the International Society for the Study of Vulvar Disease as "chronic vulvar discomfort, especially that characterized by the patient's complaint of stinging, irritation or discomfort" [73]. The cause of vulvodynia is not yet well understood and consequently the ex-

pectations for treatment must be realistic. The presentation of vulvodynia may include vulvar complaints that are chronic and unrelenting, cyclic or related to some aggravating activity such as vaginal penetrative sex or prolonged sitting or bike riding.

The evaluation for vulvodynia includes an extensive history of the onset and duration of symptoms, aggravating activities, sexual activities, use of topical preparations, a history of vaginitis or other STDs, use of contraceptives comprised of latex including condoms, diaphragms, cervical caps, and any treatments used. A woman experiencing vulvar pain has frequently tried numerous over-the-counter treatments including antifungal medications and topical steroid preparations. These treatments in themselves may have caused a dermatitis that must be minimized before further evaluation can occur [74].

Examination of the vulva includes evaluation of skin changes, vaginal secretions, presence of lesions and changes in the vulvar architecture [75]. It is useful to perform an evaluation of point specific pain and sensitivity using a cotton swab and gently proceeding in a clockwise fashion on the vulva. Particular areas of sensitivity may be noted, especially at the 11 to 1 o'clock points and the 5 to 7 o'clock points [73, 76].

Treatment may be based on physical findings of dermatologic conditions such as lichens sclerosus or lichens planus and focus on topical steroids. Treatment may also focus on the diagnosis of a chronic yeast infection. A diet high in oxalates (e.g., tea, coffee, cocoa) may contribute to vulvadynia. Other relief measures include the use of white unscented toilet tissue, loose cotton clothing, unscented soaps, taking showers instead of baths, and avoiding the use of latex products. Some clinicians are making efforts to associate particular points of pain with a variety of specific nerve pathways or nerve injuries and suggest surgical treatment [77, 78]. Antidepressants have also been used in the treatment of this condition, as they appear to have value in the relief of some pelvic neuropathies [78]. A variety of alternative modalities have been used for the treatment of vulvadynia including herbal therapies, the use of traditional Chinese medicines, and homeopathy [71]. As previously noted in this chapter, clear evidence of benefit is not always readily available with regard to nonallopathic treatments. However, due to the complex nature of this problem, the midwife and her client may wish to explore a wide variety of relief options.

The woman with vulvar pain presents a special challenge to the clinician. This client is well served by the patience and sensitivity of midwifery care and the ability to incorporate a variety of approaches and consultation options in her treatment.

Endometriosis Endometriosis is the presence of endometrial tissue outside of the uterine cavity. It is believed that endometriosis exists in 5 to 20 percent of women and the degree of symptoms ranges from none to severe pelvic pain or infertility [79, 80]. The cause of endometriosis is unknown; however the presence of endometriosis is rare before menarche and after menopause and is most commonly diagnosed between the ages of 20 and 30 [79].

The presentation of women symptomatic for endometriosis is quite typical and includes three symptom clusters: (1) pelvic pain, (2) dyspareunia, and (3) infertility. Conversely, surgeons may discover endometriosis in a significant number of asymptomatic women during the course of some other pelvic surgery or procedure. The pelvic or lower abdominal pain due to endometriosis may be related to the menstrual cycle and present as pain at or following ovulation. The pain may be present intermittently from ovulation to menses or may continue through the menses as dysmenorrhea. This pain may also occur in patterns unrelated to the menstrual cycle. Pain related to sexual activity occurs during or after sex and may be so severe as to preclude sexual activities. Women with endometriosis may present for an infertility evaluation with any of the above symptoms or with infertility alone. In the evaluation of any pelvic pain, it is important to keep in mind that endometriosis may confuse a diagnosis of appendicitis or ectopic pregnancy as each of these conditions may present with the acute onset of severe, unilateral, pelvic pain.

Findings on physical examination may be normal, with no significant tenderness associated with organ palpation or movement. However, there may be significant cervical motion tenderness, bilateral or unilateral adnexal tenderness, ovarian enlargement, or a fixed, retroverted uterus. Definitive diagnosis is only possible by visualization during laparoscopy. Biopsies are typically taken to confirm the diagnosis and assist in future treatment. The use of imaging such as that possible by MRI may provide further information, but ultrasound is not particularly useful.

It is useful to note that the CA-125 marker test commonly used during the treatment of ovarian cancer may be positive in women with endometrio-

sis. As with its use in ovarian cancer, the CA-125 is not a definitive diagnostic tool as it may be elevated in women who have PID, are pregnant, or have fibroids, but it may be used to evaluate ongoing treatment.

The treatment for endometriosis remains variable in success owing to a lack of understanding of the etiology of the disease. The treatment may include pain relief measures such as the use of NSAIDs, medications that suppress hormonal stimulation of the endometrial tissue such as combined or progestin-only hormonal contraceptives, surgical removal of the lesions, a combination of medical and surgical means or complete surgical removal including hysterectomy and oophorectomy [81, 82]. The treatment employed remains dependent on the wishes of the client, her age, the degree of pain and impact on her quality of life, her desire for future childbearing, and the degree to which her fertility is impaired.

Medical treatment for endometriosis centers on the premise that pain and lesion growth and stimulation will be diminished by altering the ovulatory cycle and inducing a hypoestrogenic state [79, 80]. Current attempts to do so include a variety of medications. The most common approach is that of inducing anovulation with the use of danocrine (Danazol). Danazol reduces the LH and FSH surge of ovulation and at most doses produces amenorrhea. The androgenic side effects of Danazol are significant and may include a deepening of the voice, weight gain, and lowering of HDL. Though Danazol has been the treatment of choice for endometriosis for many years, recent reviews have shown that it is no more or less effective than other medical approaches [83]. Various progestins and antiprogestins such as depot medroxyprogesterone acetate and mifepristone (Mifeprex, RU-486) have also been employed. Common side effects of these medications include irregular vaginal bleeding. Combination oral contraceptives (both high- and low-dose formulations) are common options as well [84]. The usual side effects of oral contraceptives must be discussed with the woman. If relief is not adequate with routine OC use, a continuous regimen (i.e., omitting the use of the inert pills in the OC pack and taking the hormone-containing pills continuously) may be employed to produce amenorrhea. Gonadotropin-releasing hormone agonists (GnRH) may be used to reduce ovarian stimulation and produce a pseudomenopause [85]. The GnRH agonists, as might be expected, may produce a variety of side effects not unlike that of menopause, including hot flashes, irregular vaginal bleeding, vaginal dryness, decreased libido, breast tenderness, depression, and insomnia. Additionally, the GnRH agonists may have an impact on bone mineral density. This effect must be closely monitored and treated by a hormonal "add back" (i.e., the concurrent use of an estrogen and/or progestin concurrent with the GnRH use) typically employing combination OCs [86, 87]. Medical treatment of endometriosis is typically managed by a physician or by the midwife in close consultation with a physician.

The goals of surgical treatment for endometriosis may include the restoration of normal reproductive function and a decrease in pain by removing the lesions. A combination of medical and surgical treatment is a common approach with women experiencing infertility. Definitive surgical treatment, removal of the uterus, and depending on the age of the woman, her ovaries as well, are clearly management options of last resort.

Pelvic Masses

Fibroids

Fibroids, also known as leiomyomas or fibromyomas, are the most common gynecologic mass found. Estimations of occurrence range from 12 to 80 percent of the female population [88, 89]. Fibroids are also known to have a higher prevalence in some racial and ethnic groups, such as among African American women [90]. Fibroids are solid masses and are comprised of uterine smooth muscle tissue. Fibroid growth may respond to changes in circulating levels of estrogen and progesterone. Situationally, fibroid growth may be stimulated by pregnancy, while fibroids may degenerate during or after the menopause.

There are three types of fibroids based on their location: (1) subserous, (2) intramural, and (3) submucosal (see Figure 14-1). Subserous fibroids are just under the uterine serosa and are located outside of the uterus. They are attached to the uterus by a large or small base and may be easily palpated on abdominal exam. Intramural fibroids are located within the uterine myometrium and may give the uterus an irregular contour. Submucosal fibroids are located in the uterine endometrium and are usually palpable only as an enlarged uterus. On examination one can often differentiate an enlarged uterus due to fibroids from an enlarged uterus due to pregnancy by the more firm character of the fibroids and by the irregularity of the uterine shape.

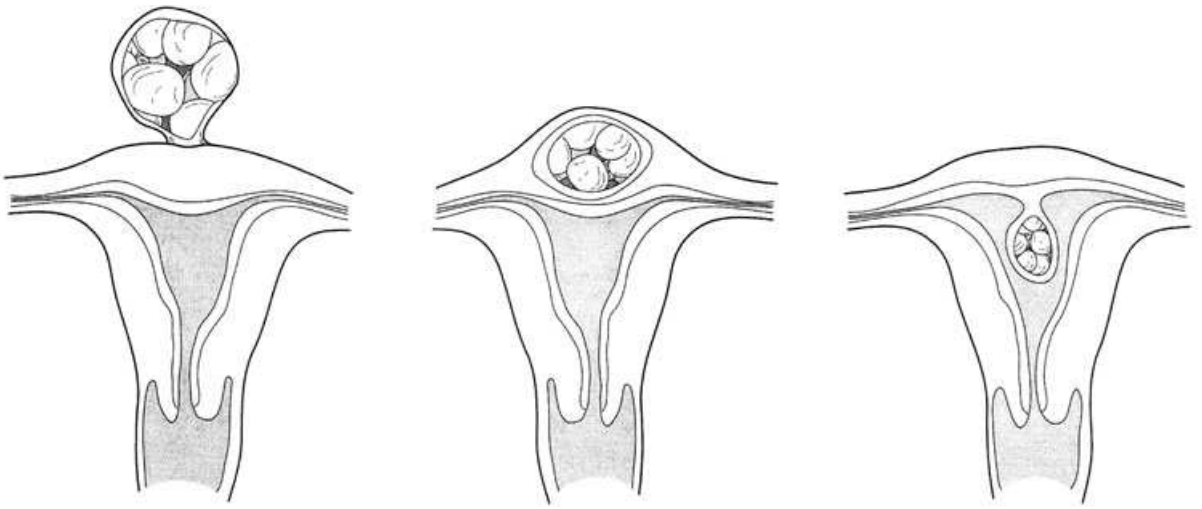

FIGURE 14-1 Classification of fibroids (leimyomas) by location in relation to the uterus.

Upon noting a fibroid during an examination, the midwife should share this information with the woman and discuss any appropriate follow-up or pertinent information.

Women with fibroids may be asymptomatic or present with chronic pelvic pain or "pressure." The fibroids may cause urinary frequency, rectal pressure, or interference with sexual activity. Depending on their location, fibroids may also interfere with pregnancy and may cause infertility, miscarriage, premature labor, malpresentation of a fetus during pregnancy or labor, or a dysfunctional labor pattern [91]. Women with large bulky fibroids may have gradually grown accustomed to the feelings of pelvic fullness and report few symptoms or little pain. Fibroids that have grown to a significant size may cause pain during pregnancy. Fibroids may also be implicated in dysfunctional uterine bleeding, especially in the perimenopause. This bleeding may be significant enough to cause anemia with resultant fatigue and headaches. Some women may not recognize the degree to which this blood loss may be a contributing factor to their overall feeling of ill health or lack of energy.

Changes in abdominal girth or shape may cause a woman to seek evaluation. She must be reassured that fibroids are always benign but may necessitate medical or surgical intervention. Fibroids can be well visualized on ultrasound, a frequent aid in assessing size, location, and growth changes [92].

Fibroids in women without physical symptoms may be observed until such time as the fibroids change significantly in size, begin to cause discomfort or a change in urinary or bowel function, or obstruct an adequate pelvic examination. In asymptomatic women, careful documentation of fibroid size and shape at each annual examination, along with a careful history of any change in symptoms, is an acceptable management plan.

Hysterectomy remains the most common nonpregnancy-related surgical procedure in this country [93]. Fibroids remain the most common diagnosis associated with hysterectomy and comprise a significant portion of cost for women's health care procedures [63, 93]. Controversy regarding the use of hysterectomy surfaced in the latter years of the twentieth century; however little has changed in the rate at which the surgery is performed. Research on the most appropriate approach to the treatment of fibroids lacks definitive answers but inquiry is proceeding into the spontaneous regression of fibroids if left untreated [94].

The most recent trend with regard to the treatment of fibroids is the exploration of alternative approaches to the management of problematic fibroids and reinforcment of the concept that all fibroids do not necessitate surgery. A variety of intrauterine procedures, including uterine artery embolization, are being employed to provide an intervention with fewer side effects and with preservation of the uterus [95, 96]. Many women welcome these organ-preserving procedures, as losing one's uterus is often feared and considered undesirable for a variety of social and psychological reasons, aside from those of fertility [97]. As with many other common gynecologic problems, re-

searchers are exploring a variety of alternative therapies for the treatment of uterine fibroids, including the use of acupuncture, bodywork, imagery and traditional Chinese medicine [98].

If surgical intervention is deemed appropriate, prior to the removal of fibroids (myomectomy), a GnRH agonist may be used to shrink the fibroids. Smaller fibroids are much easier to remove and shrinkage may give the surgeon the option of a vaginal versus an abdominal surgery [99]. In the case of large fibroids, hysterectomy is a common treatment option depending on the woman's age and childbearing plans.

Benign Ovarian Cysts

A variety of benign ovarian masses may present to the midwife either on pelvic examination or as a result of ultrasonic examination. Except for dermoid cysts or large cysts causing acute pain, most do not require intervention and may be managed by careful observation for changes in size or in the client's perception of pain or discomfort. It is vital to reassure clients that most ovarian cysts are not associated with malignancy and that watchful waiting is preferable to the risks of surgery.

On examination ovarian cysts may or may not be palpable, depending on their size and location. Due to their commonly asymptomatic nature, most ovarian cysts will only be found due to a ultrasound examination for some other reason. Cysts of significant size cause adnexal motion tenderness or pelvic pain and may grow to such a size that they cause ovarian torsion. Adolescent girls, in particular, may experience acute abdominal pain due to benign ovarian cysts [100]. The differential diagnosis of the pelvic pain in these women may be difficult since adnexal motion tenderness results from PID, ectopic pregnancy, endometriosis, or adhesions from prior surgical procedures.

Follicular Cysts If a normal ovarian follicle does not rupture or an immature follicle does not undergo normal atresia, a follicular cyst may form. Follicular cysts, the most common kind of ovarian mass, are generally asymptomatic and may be discovered due to an ultrasound examination or on pelvic examination. The most common management plan is to follow the size and probable regression of the cyst. Oral contraceptives may hasten this resolution [70, 101]. If the cyst increases in size, further evaluation must be made to rule out an ovarian neoplasm or other mass.

Corpus Luteum A corpus luteum cyst results from hemorrhage of the corpus luteum, most often from day 20 to day 26 of the menstrual cycle. Ultrasound may confirm the diagnosis and in the absence of a large amount of continued bleeding, no intervention is necessary as the cyst will regress spontaneously. In the event of significant bleeding or acute pain secondary to the bleeding, a negative pregnancy test may assist the midwife in differentiating the ruptured corpus luteum cyst from an ectopic pregnancy. If continued bleeding occurs, surgical intervention may become necessary.

Dermoid Cyst/Cystic Teratoma Dermoid cysts or cystic teratomas are generally asymptomatic, unilateral ovarian tumors that can develop to the point of being malignant. The mass arises from all three germ cell layers (ectoderm, endoderm, and mesoderm) and therefore may contain skin, bone, hair and teeth. Dermoid cysts are generally found on pelvic examination or ultrasound. Because dermoid cysts do not regress and have a 1 to 3 percent chance of becoming malignant, the treatment is surgical removal [70]. At the time of surgery, a thorough examination of the ovary, surrounding tissues, and the other ovary for any signs of abnormality or cancer is indicated.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common condition affecting approximately 5 percent of women [102]. PCOS is the most common diagnosis implicated in ovarian dysfunction related to infertility [103]. In fact, PCOS is more correctly termed hyperandrogenism and is characterized by a complex of occurrences such as menstrual irregularities of either amenorrhea, or heavy irregular and infrequent menses (oligomenorrhea), chronic anovulation, and infertility. Physical characteristics of women with PCOS may include obesity, acne, alopecia, and hirsutism. Women with PCOS are often insulin resistant and may exhibit signs of diabetes, including Acanthosis nigricans, a brown velvety appearance to the skin in various folds, such as the back of the neck, in the axillae, under the breasts or in the groin [104]. The cause of PCOS is unknown.

The diagnosis of PCOS may be made coincidentally during infertility surgery, during routine pelvic examination, or by laboratory studies that reveal elevated levels of serum androgens. On ultrasound, one or both ovaries may be significantly en-

larged and contain multiple follicles. The enlarged, polycystic, ovary is actually a consequence of the anovulatory state, not a cause of anovulation. The expression of the hyperandrogenic state may range from complete amenorrhea to an apparently normally functioning endocrine system. Ovulation and conception may occur spontaneously and result in normal pregnancies. Due to the associated obesity in some women with PCOS, enlarged ovaries may not be detected on pelvic examination. Laboratory studies include serum levels of LH, testosterone, estrogens, and 17-OHP.

Treatment of PCOS varies and is dependent on the degree of infertility and desire for conception. PCOS in obese women has been treated with weight loss programs alone. Obese women who experience weight loss have been observed to resume more normal ovulatory and menstrual patterns and have conceived spontaneously [104, 105]. If conception is not immediately desired, ovarian function (and continued physical enlargement) may be suppressed with the use of combination hormonal contraceptives. This temporary ovarian suppression hopefully results in the initiation of normal ovarian function upon discontinuation of the contraceptives. A variety of other medications, such as GnRH agonists and spironolactone, have also been employed as antiandrogens. Induction of ovulation, with the use of clomiphene, is a common strategy for the prompt treatment of infertility in women with PCOS [103]. The antihyperglycemic agent metformin (e.g., Glucophage) has also been observed to result in spontaneous ovulation in women with diabetes and/or PCOS [106, 107] specifically for the treatment of anovulation [103].

As continued research is conducted on PCOS, two important theories have emerged pertaining to the long-term health of women with PCOS. The first is grounded in the knowledge that women with PCOS, even those who are not obese, may be significantly insulin resistant and thus at a higher lifetime risk for the development of Type II diabetes and also for cardiovascular disease [107–110]. The second is that due to the potential for the development of the above-mentioned diseases and the potential for a decreased quality of life due to infertility, obesity, and hirsutism it is especially important to diagnose and treat PCOS in adolescent girls presenting with amenorrhea, irregular menses, obesity, or hirsutism [108, 110–113]. This information has offered greater support for the continued examination of the use of metformin, because in addition to its antihyperglycemic action, the medication also increases insulin sensitivity [106, 107].

In the context of PCOS it is also important to consider the presentation of women with hirsutism, especially accompanied by obesity or any other signs of diabetes. Idiopathic hirsutism may represent a racial or ethnic variation and may occur in women with normal menstrual cycles and ovulatory patterns. However, it is important to thoroughly evaluate women with significant hirsutism, as the hirsutism may indeed be a sign of PCOS in a woman with normal menses and a normal BMI. Early diagnosis and intervention with respect to hyperglycemia and abnormal cholesterol and lipid profile may indeed prove to be lifesaving. It is important to note here that a dramatic short-term increase in hirsutism is not likely to be the result of PCOS but of a rapidly progressing adrenal tumor, which must be ruled out and warrants referral to a physician.

Congenital Uterine Anomalies

Congenital uterine anomalies are often undiagnosed until a woman presents for evaluation due to infertility, recurrent miscarriages, pelvic pain, difficulty with vaginal penetrative sexual activity, or ectopic pregnancy [114–116]. The diagnosis may be made by bimanual examination or ultrasound, or during a surgical procedure. The anomalies range from a failure of the uterus to develop (agenesis) resulting in primary amenorrhea to structural abnormalities of the uterus in an otherwise asymptomatic woman. Therefore, the actual incidence of anomalies is unclear [117–119].

The anomalies most commonly encountered by midwives in the office setting will most likely be those due to fusion defects resulting in an abnormally shaped uterus (see Figure 14-2) [120]. The midwife may be able to appreciate a uterus with one horn, (unicornuate), or with a V-shape (didelphys), or a heart shape (bicornuate). A woman may also have a heart-shaped uterus that is otherwise normal (arcuatus), in which case the aberrant shape is of little consequence. Women with uterine anomalies have a higher incidence of renal anomalies and should be screened accordingly.

The unicornuate uterus has one horn with its associated fallopian tube and uterus and one cervix. The opposite side of the uterus may be absent or underdeveloped. The didelphys uterus has two sep-

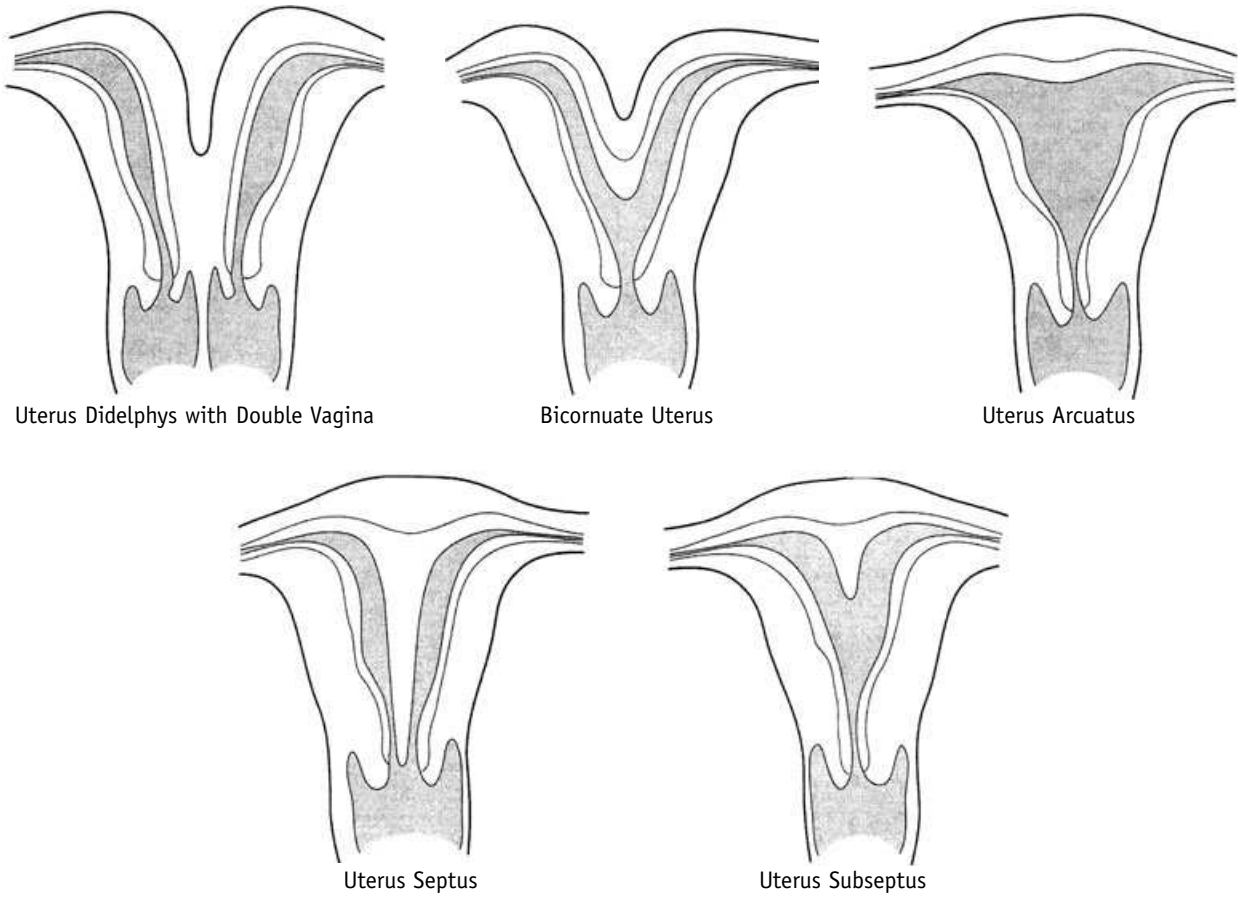

FIGURE 14-2 Types of uterine anomalies.

arate cavities, each with its own cervix. The uterus itself may have a V-shape. Upon diagnosis, it is important to remember that any future or current screening or diagnostic procedure must be performed on each cervix, for instance, two separate Pap smears; or two endometrial biopsies, one from each endometrial cavity. A pregnancy may occur in either or both cavities. The bicornuate uterus has a heart shape owing to two separate uterine cavities separated by myometrial tissue and one cervix. The septate uterus is essentially a normal uterus with a septum running down its midline. The septum may be complete (uterus septus) or partial (uterus subseptus). The septate uterus has two cavities separated by avascular tissue and one cervix. The contraceptive choices of a woman with an anomalous uterus may be somewhat complicated. If the woman does not desire to become pregnant, the most effective choices might involve hormonal methods or condoms as opposed to barrier methods or an IUD.

The diagnosis of an anomalous uterus must be shared in a gentle and supportive manner. Concerns related to fertility and childbearing may be uppermost in the mind of the woman of childbearing age and must be addressed promptly. Regardless of her age or childbearing plans, information pertaining to an organ anomaly, especially one so closely associated with one's "womanhood," may have a significant emotional impact. Continued support and referral to any local resources are essential.

Pelvic Floor

Midwives have always had a particular interest in the preservation of the integrity of the vagina and perineum during childbirth. The ability to allow for the safe birth of an infant in a manner that is nontraumatic to both the mother and the infant has long been a skill held in high esteem and meticulously taught in midwifery education. Although we

now know that a birth that occurs in the absence of episiotomy incurs less long-term harm to the woman's pelvic floor and vaginal health, even the most nontraumatic birth may result in a degree of loss of muscle tone from pregnancy alone [121–125].

Attention must be given to the loss of pelvic floor muscle tone, as well as organ prolapse into the vagina, in every woman during gynecologic exams [121]. Loss of pelvic floor integrity may be due to childbirth, the presence of abdominal or pelvic masses, previous surgical procedures or simply aging coupled with gravity. As a result, *cystocele* (bladder descent into the vagina), *rectocele* (protrusion of the rectum into the vagina), or *uterine prolapse* (descent of the uterus into the vagina) may occur. Each of these conditions, or a combination of them, may be of particular distress to the women and may interfere with normal bladder or rectum functions or with pleasurable sexual activity [126]. Either urinary or rectal incontinence may have a severe impact on a woman's quality of life as it may limit her ability to travel away from her home, her participation in various activities, or her ability to maintain good hygiene and avoid skin irritation or breakdown.

The evaluation of pelvic muscle strength is an important assessment during every routine examination. This examination may be performed by requesting that the woman tighten her vaginal muscles during the bimanual portion of the examination, otherwise known as a Kegel exercise [127]. Additionally, while observing the vulva, the midwife may request that the woman perform a Kegel or Valsalva maneuver. This may allow the midwife to assess the muscle integrity or the degree of organ prolapse visually. Uterine prolapse may also be observed with the woman in an upright position, since in significant prolapse the cervix may protrude through the vulva.

In the absence of pelvic masses, treatment for pelvic floor relaxation may include the initiation of a regimen of Kegel exercises. Women often require specific instruction and feedback during a vaginal examination to learn how to perform this exercise correctly. Additional therapies that have proved useful in efforts to improve pelvic floor muscle tone are the use of vaginal cones, biofeedback, and vaginal electrical stimulation [128].

A variety of support devices or pessaries have been employed in the case of significant uterine prolapse [129]. The choice of size and type of pessary is determined by a midwife or physician. After the choice of the appropriate pessary, the woman often returns for a follow-up visit in one week to assess comfort and normal urinary function. The woman then returns in one month and annually thereafter. The vagina of a woman with a pessary in place must be visually inspected at least annually to assess for any lesions or bleeding due to tissue erosion from the pessary. The pessary should be removed and cleaned monthly. This removal may be done by the woman herself or by her midwife. A woman with a pessary in place should be cautioned to report any vaginal bleeding promptly as this may be a sign of tissue damage or may be intrauterine bleeding indicative of the growth of a malignancy, especially in a postmenopausal woman.

Surgeons have employed a multitude of surgical procedures in attempts to repair or restore lost muscle tone. Despite these efforts, the long-term success rate of surgery is variable and may result in complications such as urinary incontinence [130, 131]. Obviously, the risk of taking a surgical approach to restoring pelvic floor integrity comes with a clear possibility of physical, emotional, and financial cost to the woman. It is important for the woman to discuss the risks and benefits of this approach with her providers prior to making a decision.

Urinary Incontinence

Urinary incontinence—the involuntary loss of urine—is a stressful condition that is unreported for a variety of reasons, including embarrassment, denial, and the prevailing notion that the only treatment option is surgical [132]. In assessing the potential for incontinence, it is important to appreciate that this often represents not only a physical condition but also a significant diminishment of a woman's quality of life [133]. A woman not only often begins to limit her activities or social contact, but she also experiences a significantly disturbed sleep pattern, with the consequence of an adverse effect on her emotional health and functionality. The impact of her incontinence may lead to a dramatic change in a woman's lifestyle and overall well-being.

The causes of incontinence are varied and require a detailed history and thorough workup by a primary care provider or urologist [134]. Incontinence may be temporary or transient if it is the result of a medication side effect, change in

mental status, or change in mobility. Structural abnormalities may result in incontinence, such as a small bladder capacity or a urethral abnormality (e.g., urethral diverticulum). A woman's lifestyle may result in incontinence, such as a change in the amount of fluids she is ingesting or the use of diuretics, either prescription, over-the-counter, or herbal. Certain disease states have the effect of increased urination and incontinence, such as diabetes, a urinary tract infection (UTI) or other renal disease, a bladder mass, or a pelvic mass such as fibroids or ovarian cancer. Neuropathies may result in a variety of incontinent presentations. A change in muscle tone, a side effect of various medications, may result in incontinence. Surgery, childbirth, or pelvic trauma also commonly result in some degree of involuntary loss of urine.

Stress incontinence is the most common type of urinary incontinence. It is the result of the inability of the urethral sphincter to maintain normal function. This may be due to the physical stress of childbirth, surgery, the presence of a mass, obesity, a UTI, or a chronic cough. Stress incontinence occurs when one laughs, sneezes, coughs, lifts an object or a child, or exercises. It is important to remember that nulliparous women also experience stress incontinence, and that incontinence is not entirely related to childbirth [135]. It is not uncommon for stress incontinence to occur with a detrusor instability—the involuntary and inappropriate contraction of the detrusor muscle in the absence of an urge to void. A less common type of incontinence is urge incontinence. Urge incontinence occurs when a woman experiences the "urge" to urinate and cannot tighten the urethral sphincter to inhibit voiding. Urge incontinence may be due to a variety of neuropathies. The combination of stress and urge incontinence is termed "mixed incontinence."

Due to the myriad causes of incontinence and varieties of clinical presentation, it is necessary to take a detailed history of physical, medical, or life event changes if a report of incontinence is made. A careful assessment must be made of a woman's voiding habits and pattern of incontinence, as well has her intake of fluids. It is important to reassure women that getting up to void once or twice in a night is not indicative of urinary dysfunction, or that an occasional episode of "leaking urine" does not meet the criteria for incontinence treatment. She may, however, benefit from an evaluation of her fluid intake and schedule of voiding. Many women resist the urge to void for long periods of time during the course of their waking hours, and over time believe that the eventual inability to "make it to the bathroom" is a sign of bladder dysfunction. Women must be reminded that to retain bladder health, a regular schedule of bladder emptying is needed. Women also restrict their fluid intake in a desire to eliminate the need to take the time to go to the bathroom. They must be reminded of the need for adequate fluids, especially water, for all body systems to function normally. A "diary" of fluid intake, number of voids, and number of incontinent episodes may be a useful teaching tool.

In the absence of a urinary tract infection, a pelvic mass, or some other extrinsic cause of incontinence, the diagnosis of incontinence is refined and the identification of the dysfunction is accomplished using a combination of the woman's history and a variety of urinary function tests. These tests include evaluating the woman's bladder pressure, the rate of urine flow, and the degree of incontinence [134, 136, 137]. Treatment for urinary incontinence is prescribed depending on the type and degree of incontinence identified. A variety of surgical procedures have been employed to correct anatomical defects or dysfunctions resulting in incontinence. It has been well acknowledged that these surgeries may have limited success and undesired surgical consequences, such as adhesion formation and a greater loss of urinary function [138]. Consequently, medical or behavioral therapies are commonly employed as a first line of treatment [139]. Behavioral therapies include pelvic floor exercises, bladder training exercises, the use of vaginal cones, and biofeedback. Pessaries have also been used to assist as mechanical bladder support. Stress incontinence is treated with either behavioral methods or surgery. Detrusor instability is treated with behavioral, medical, or surgical methods. Urge incontinence is most often treated medically.

As previously stated, at any point in the evaluation of a report of incontinence, it is vital to assess a woman's efforts at self-treatment by limiting her intake of fluids and to strongly advise against this practice. The role of the midwife in assessing and treating urinary incontinence is most often accomplished in consultation with physicians or other colleagues who specialize in this area.

Effects of DES Use

Diethylstilbestrol (DES) is a nonsteroidal estrogen that was widely used from 1948 to 1971 to prevent

a number of the complications of pregnancy. Initially used as a treatment of threatened abortion, DES came to be used to prevent recurrent miscarriage and third-trimester complications. Thus a woman might be on the medication for most of her pregnancy. An estimated 1 to 2 million women received the drug. In 1971 the FDA withdrew approval of the use of DES in pregnancy, as reports started to surface of women with clear cell adenocarcinoma who had been exposed to DES in utero. Since then a number of structural and functional abnormalities have also been identified as effects of in-utero exposure to DES:

1. Vaginal epithelial changes including adenosis and squamous metaplasia, most commonly observed on the anterior and posterior vaginal walls with extension into the lateral fornices.
2. Cervical collars (hoods), cockscombs, pseudopolyps, abnormal or absent fornix, fusion of cervix to vagina, and hypoplastic (immature) cervix.
3. Incomplete transverse or longitudinal septum of the vagina.
4. T-shaped or hypoplastic uteri.
5. Constricting bands in the endometrial cavity.
6. Infertility.
7. Poor pregnancy outcomes (preterm delivery, ectopic pregnancy).

Most clear cell adenocarcinomas in DES-exposed women have occurred before the age of 30. However, as this cohort of women is now approaching the age of higher risk and incidence of other reproductive cancers, it is vital to continue close monitoring [140]. Those women identified with in-utero DES exposure (also known as DES daughters) should have their first Pap smear at the onset of menses, at age 14, or after initiation of sexual intercourse, whichever comes first. A baseline colposcopy should be considered. Both vaginal and cervical Pap smears should be done every 6 to 12 months until the woman is 30 years old; after age 30 she should receive annual vaginal and cervical Pap smears. Any abnormal spotting or bleeding should arouse suspicion, and a colposcopy should be performed at that time.

Recent research has also begun to address a possible increased risk of reproductive cancer among women who took DES themselves (DES mothers) [141, 142]. This research has shown DES mothers to be at a somewhat higher risk for breast cancer. A relationship between the in-utero exposure of sons of pregnant women taking DES and testicular cancer remains under investigation [141]. Finally, there now exists the opportunity to follow the children of DES exposed daughters. The "third generation" effect remains unclear, although there is some evidence of an increased incidence of hypospadias in sons of DES daughters [143].

Due to the time lapse that has occurred between the discovery of the effects of DES on the offspring of women who took it and the present time, a knowledge gap may exist in the current population of women seeking gynecological care [144]. Information regarding a woman's mother or grandmother and DES exposure may be unknown. Women who took DES themselves may be unaware of continuing research into the long-term effects of exposure. Therefore, it remains important to continue to include this inquiry in one's health history-taking and adapt the question as indicated given the age of the woman. If she is a member of a family that includes DES mothers, daughters, sons or grandchildren, it is vital to share the most current information and courses of research.

Special Considerations in Gynecologic Care

For all of the above problem assessments the midwife should be cognizant of several key factors that can influence the manifestation of the woman's condition, as well as the follow-up care required. These special conditions include: age, culture, fertility status, sexual well-being, and past history of any possible sexual abuse.

Age

Children Children experiencing gynecological problems, including pelvic pain, present a unique challenge. Pediatric providers typically assume the care for children with gynecological issues. However, in the absence of pediatric gynecologists, the midwife may be called upon to consult with the pediatrician. The use of pictures or dolls may be useful in obtaining an accurate description or history of a problem. One must always evaluate the index of suspicion of abuse in children presenting with pelvic pain and proceed according to the protocols of your practice or institution. The pelvic examination of children must obviously be done sensitively and with a great deal of care, and demands the use of appropriate-sized specula.

Adolescents The treatment of teenagers for gynecologic problems present special issues as well. The need for confidentiality must always be balanced with the legal requirements for parental notification and involvement in care. In cases when the parent and teen have a conflicting view of management, it is important to try and sort out the best course of action for both the girl and her family. The midwife must respect the autonomy of the teenager and her ability to make safe decisions, as well as the teen's unique perspective on her health and her life choices. Issues that might present conflict for a midwife should be discussed with his or her professional colleagues. One must be cognizant of the legal ramifications of providing care to a teenager in the absence of her parents, and the relevant state or local laws pertaining to the care of minors. For example, in some states, teens are "emancipated" for the purposes of seeking care for pregnancy, family planning, or treatment for sexually transmitted infections. Such issues in the evaluation of pelvic pain, pelvic masses, or menstrual cycle dysfunction include sexual activity, previous or current pregnancy, past or current sexually transmitted diseases, the nature of the teen's sexual activities, past or current abuse, eating disorders, and the use of drugs or alcohol.

Teenage girls also present for gynecological evaluation based on their perceptions and possible misinformation regarding normal menstrual function and sensations and normal gastrointestinal function [100, 145]. Body image often has a direct impact on how a young woman perceives her physical sensations and developmental changes. An altered body image or eating disorder might color a young girl's view of her gynecologic health. A desire for control of one's bodily functions might also lead her to seek care. Misuse of laxatives or a restricted diet might lead to gastrointestinal distress or constipation, each of which might be interpreted to be a gynecologic problem. The activity level of teens, especially young athletes, might also contribute to a musculoskeletal injury presenting as pelvic pain. Any contact with teens provides a special opportunity to evaluate her need for information regarding sexual well-being, contraceptives, and substance abuse including cigarette smoking and diet. Performing the initial pelvic examination that a young woman receives also affords the midwife a unique opportunity to introduce the teen to nontraumatic, respectful, empowering care.

Aging Women As women progress through and beyond menopause, gynecological concerns take on a new context. Issues regarding childbearing, contraception, and menstrual cycle control fade and new priorities emerge. Postmenopausal concerns encompass disease prevention, disease detection, and preservation of function. Consequently, the role of the midwife must expand to address these health issues and address them in a comprehensive fashion. The midwife must take care to continue to address relationship issues and family demands, as the care of children may have been replaced by the care of aged parents or ill partners. Education must include anticipatory guidance with regard to potential physiologic changes related to aging (e.g., relief measures for vaginal dryness) in addition to preventive and screening measures for disease. Fear of cancer or other terminal illness diagnosis may often cause a woman to delay medical evaluation. Diagnosis of masses, abnormal bleeding, or organ dysfunction must be conducted sensitively and in a nonjudgmental fashion. The clinician must also continue to direct efforts to assess safety in the home with regard to both domestic partner violence as well as violence stemming from other family members, especially if the woman is frail and requires assistance with personal needs. Unexplained bruising or issues with regard to incontinence must be examined within the context of each woman's personal circumstances.

Culture

The evaluation of gynecologic complaints or concerns must address the issue of the role of culture in a woman's view of her body and her ability to address her health needs in an autonomous fashion. Trained medical interpreters are especially crucial in the evaluation and treatment of any gynecologic issue. Using family members, especially children, is never appropriate when dealing with sensitive and potentially embarrassing information. A woman may feel more comfortable with a female relative or friend present during her visit. Permission to limit the presence of her partner or male relative might be a difficult but important negotiation for the midwife to accomplish.

The ability to learn what the woman believes about her body and her identified problem are of primary importance. Additionally, the woman's beliefs and influences with regard to sexual activities, fertility, and pain are crucial. Pertinent questions might also include the following:

> What is this pain/problem called in your community? What is the meaning of this pain/problem?

Do other family members or friends experience this also? What do they do about it?

How is this treated? How have you treated it so far?

Are there other family or community members who must be consulted before treatment in this medical system can occur?

Fertility

The desire for or fear of pregnancy may have an enormous impact on how a woman interprets pelvic pain or sensations. Other family members may have an influence in this as well. Feelings following a birth, an abortion, a miscarriage, or hysterectomy may have an impact on how a woman perceives pelvic pain or menstrual irregularity. Feelings of depression, sadness, or worry about gynecologic function may contribute to or manifest as physical pain. An exploration of the nature of these events and their significance for the individual woman often prove useful. When caring for teenagers, it is important to recognize that pregnancy is not always undesired. The ability to conceive and bear children may be culturally or socially desirable to a young woman and being unable to do so may be the source of considerable distress. The midwife's responsibility includes offering information concerning the menstrual cycle, achieving and/or avoiding pregnancy, and the risks of pregnancy at an early age.

Sexual Well-Being

Despite the fact that all humans are sexual beings, it remains difficult for many women and their midwives to articulate sexual concerns or to perceive sexual health as an important element of general health care. Overtly encouraging an atmosphere of safety and acceptance often results in the disclosure of significant concern regarding pain with, or as a result of, sexual activity. Further exploration may reveal that the emotional overlay of guilt or fear of sexual activity has exacerbated any physical problem that might exist [97]. A nonjudgmental atmosphere established by the midwife will enable the woman to honestly discuss her sexual activities and concerns.

Sexual Abuse and Assault

Clearly, the woman who has experienced past or current sexual abuse presents with a very particular perspective on her gynecological needs, especially that of pelvic pain. It must be the primary goal of her gynecologic provider not only to address her medical needs but to do so in a manner that does not add to her pain, either physical or emotional. An honest explanation of the nature of the exam and a discussion of the cycle of "tension-fear-pain" might be of use in these circumstances. Midwives often have particular patience and skills in encouraging relaxation. This is a perfect opportunity to use those skills. The nature of the gynecologic examination may be particularly prone to retraumatizing the woman if her abuser and health care provider are of the same gender. If abuse is known to the midwife or revealed during the visit, the midwife should offer the presence of another staff member or a support person for the examination. Give control of the exam to the woman and proceed only with her consent. She must be given permission to stop the exam at any time, and you must comply at that time. If it is difficult for the woman to proceed with an exam, the visit may be broken up into smaller steps and encounters unless there is an acute, emergent problem apparent. If the problem appears to be acute, the midwife should assess what type of examination other providers (e.g., Sexual Assault Nurse Examiners [SANE]) may need to do and limit the current examination to only those elements that are absolutely necessary for consultation or referral.

Regardless of the reason for the visit, the midwife must acknowledge the woman's experience and offer the office as a safe haven for exploration and healing. As with all women, but especially with women who have been assaulted or abused, it is crucial to stress the normalcy of their anatomy, and to the extent that it exists, their gynecologic health and well-being. Similarly, any diagnosis of an abnormality might have a heightened meaning to women who have been abused and must be clearly discussed, especially as the problem may or may not relate to the abuse.

Cancer Screening/Diagnoses

"Cancer" is a word that arouses anxiety in most individuals, in part because almost everyone has known someone who was diagnosed with cancer; has cared for a family member or friend who lived, and possibly died, with cancer; or has experienced cancer themselves. In 1999, over 500,000 people in the United States died from cancer [146]. For women in this country, malignant neoplasms are

the primary cause of death between the ages of 35 and 75 [147]. Clearly, cancer is a major health problem demanding the attention of any clinician, especially those offering primary care. To this day, screening for cancer remains the best defense against this potentially lethal disease.

Because many people have a strong fear of cancer, screening for any health problems related to a cancerous process can become a challenge for midwives. Helping clients to understand the importance of monthly self-breast examinations, annual Pap smears, or routine stool occult blood testing without raising excessive fears of cancer requires skilled communication. Most people do *not* die of cancer in this country. Overall, heart disease remains the largest cause of mortality and is responsible for 40 percent more deaths annually than cancer [146]. Yet the potential suffering associated with cancer, and the success demonstrated with preventing cancer mortality through early detection, warrant every midwife incorporating cancer screening into general practice. The routine annual visit offers several opportunities to assess for signs or symptoms of a cancerous or precancerous process, through history-taking, physical examination, and possible follow-up laboratory work. Office visits also present the chance to teach individuals about screening that can be accomplished at home, as well as preventive measures for reducing the risks of ever experiencing cancer.

Although cancer can occur in a number of body sites, including the lungs and the circulatory system, the focus here will be on those areas most closely associated with gynecological health. These include the breasts, cervix, endometrium/uterus, ovaries, vulva, and vagina.

Breasts

Breast cancer has long been the second leading cause of cancer mortality in women in the United States, second only to lung cancer [148]. Due to an increased awareness of the prevalence of this illness, coupled with strong political pressure asserted over the past decade for greater governmental and societal funding to combat this almost exclusively female disease, there has been a greater understanding by clinicians and clients of the causes of breast cancer and the methods for averting it. However, confusion and large gaps in scientific knowledge about the illness continue.

For example, a statistic often heard in the media and printed in scientific journals is that a woman has a lifetime risk of 1 in 8 of contracting breast cancer. However, few are able to articulate exactly what this means. This figure assumes that the woman lives to be at least 85 years of age. If that is the case, then over her lifetime she has a 1 in 8 chance of developing breast cancer. So, for every eight women who are currently 30 years old and who live to be 85, 1 of them will develop breast cancer. The other seven will not [149]. Certainly, this lifetime figure is an important tool for helping to educate women as to the importance of breast cancer screening, but the midwife must be cautious not to use the statistic without accompanying explanation, and avoid running the risk of frightening individual clients into thinking that breast cancer is inevitable.

Similar to this confusion is the continued gap in knowledge about the origins and risks of breast cancer. Risk factors for this disease exist, and they include age, country of birth, prior history of breast cancer in one breast, and a family history of two first-degree relatives diagnosed with breast cancer at an early age (see Table 14-9). However, only 20 to 30 percent of women diagnosed with breast cancer have associated risk factors. Early excitement about the discovery of mutated BRCA1 and BRCA2 genes associated with breast cancer has been tempered somewhat by evidence that less than 10 percent of breast cancer cases are actually due to heredity, and only approximately 5 percent are related to mutated BRCA1 or BRCA2 genes [150, 151]. The majority of women diagnosed with

TABLE 14-9 Risk Factors Associated with Breast Cancer

- Older age (risk increases with each year of aging, especially after the age of 40)
- Early age at menarche (<12 years)
- History of never giving birth, or later age of giving first birth (≥30 years)
- No prior history of breastfeeding
- Caucasian American, African American
- Prior history of breast cancer
- Strong family history of breast cancer, especially in two or more first-degree relatives
- History of proliferative benign breast disease
- Prior history of having received thoracic radiation, especially prior to age 30
- History of nodular densities on postmenopausal mammograms
- Oophorectomy before age 35
- History of hormonal contraceptive or hormone replacement therapy use
- Alcohol use

breast cancer have no risk factors at all. While this may be a frightening fact for women to hear, it should serve no better purpose than to justify the need for careful and systematic screening.

Screening The three major aspects of screening for breast cancer include (1) client self-evaluation, (2) the physical examination, and (3) the use of radiology in the form of a mammogram. While all three are well known to clinicians, their effectiveness as screening tools and recommendations for their routine use remain open to discussion.

Self-Breast Examination (SBE). Most women past menarche, and especially from the age of 20 years on, are instructed by clinicians and advised to conduct monthly self-breast examinations (SBE) (see Chapter 52). The purpose of this recommendation is to encourage women to become familiar with their own breast tissue and to report any deviations from the norm, especially with regard to the presence or growth of any unfamiliar mass. Such a finding will lead, in theory, to further screening by a woman's clinician, and should result in early diagnosis of any cancerous tumor, thus facilitating treatment and recovery to optimal health. But does SBE actually accomplish this? The response is controversial, and far from being definitive.

In one of the larger recent reviews of the effectiveness of SBE in screening for breast cancer, an analysis of 35 years of research revealed that there is *not* sufficient evidence to support SBE as a method for detecting cancer [152]. Yet this advice goes against long-standing suggestions by health care providers that all women be taught and encouraged to conduct SBE. A review of current gynecology and advanced practice nursing textbooks reveals that it remains the standard of practice to encourage SBE with clients. Thus the decision of any individual midwife to educate clients about SBE currently cannot be supported definitively one way or the other [153]. It behooves practicing midwives to keep informed of the latest scientific literature exploring this issue and adjust clinical practice accordingly. It should be noted that whether or not SBE has a direct link to adequate cancer screening, familiarity of any individual with her own body is a positive health practice and should not be discouraged. While SBE alone may not be relied on as a sensitive screening tool for breast cancer, it still will lead to some women discovering tumors and will subsequently result in early treatment for cancer.

Clinical Breast Examination (CBE). The routine visualization and palpation of a woman's breasts during physical examination as a screen for breast cancer is another practice that has long been a part, like SBE, of the recommended trio of activities thought necessary for adequate breast cancer screening. As with SBE, there has been controversy as to whether there is actual evidence to support the belief that routine CBE reduces mortality related to breast cancer [148]. A review of the findings from over 750,000 CBEs show that while this practice is helpful in screening for breast cancer, the overall effect is modest at best [154]. Despite this lukewarm evidence, clinical texts in midwifery, obstetrics, and primary care continue to urge CBE as a routine method for breast cancer screening. The U.S. Preventive Services Task Force (USPSTF), a health care practices review board of the U.S. Public Health Service, recently examined the evidence for recommended breast cancer screening techniques. The USPSTF report stated that there is not enough evidence for or against CBE to recommend its continued use as a screening tool for breast cancer [153]. As with SBE, the decision to use CBE as a part of routine clinical practice remains an open question, given this lack of clear, definitive recommendations. CBE certainly increases the likelihood of discovering a breast mass when compared to not performing the examination at all. Of course, the risk of a false-positive finding always exists, and in part contributes to the lack of a definitive recommendation for CBE from such organizations as USPSTF. However, unless evidence is found pointing to greater harm being caused by CBE than by not performing CBE, it behooves the midwife and her client to continue incorporating this breast assessment tool into the larger screening physical examination. Plus, it is a good opportunity to teach the woman about breast health care and SBE.

Nationally, a number of health care organizations continue to recommend routine CBEs, including the American Cancer Society (ACS) and the American College of Obstetricians and Gynecologists (ACOG). Again, each midwife and her clients will probably realize greater benefit from continuing CBE than by discontinuing this routine practice. In the meantime, each midwife will need to stay current in the ever-expanding knowledge of the effectiveness of various breast cancer screening tools. It appears clear that *combining* CBE with mammography screening (see below), and/or with SBE, enhances to some degree the opportunity to discover a neoplasm before it metastasizes, and thus contin-

ues to be worth the effort until more efficient screening methods are devised.

Mammography. The use of routine radiologic examination to screen for breast cancer has become standard practice in the United States. Although the use of ionized radiation to image breast tissue was first performed in 1913, it was not until the mid-1960s that mammography was formally promoted as a means of screening for breast tumors [155, 156]. Widespread use of mammography gradually occurred but was only moderately effective in screening for cancer because of a lack of standardization of equipment, technicians, and interpreters of results. In 1992, the U.S. Congress passed the Mammography Quality Standards Act that mandated certification of mammographic facilities by the Food and Drug Administration (FDA). This standardization process, along with ever-improving technology, has advanced considerably the ability of mammography to accurately detect breast masses before they are palpable through SBE or CBE (approximately 1 to 10 millimeters in size) [157, 158]. Mammography today is the most common imaging examination that results in the reduction of mortality from disease [156]. Yet the timing and frequency of using this screening tool continue to be a matter of debate.

As recently as 1997, the National Cancer Institute (NCI) recommended that mammography screening begin at age 50. Because there was not enough evidence to support the effectiveness of screening before this age, the NCI had stated that any decision to have a screening mammogram prior to age 50 should be an individual choice made by the woman. The ACS disagreed and has long promoted annual screening beginning at age 40 [157]. The USPSTF, under the U.S. Department of Health and Human Services (HHS), recently called for screening mammography, with or without clinical breast examination, every one to two years for women age 40 and over [159]. It should be noted that for women with risk factors (see Table 14-9), there is consensus that initial mammography screening should occur between the ages of 35 and 40 and should be repeated annually thereafter.

Interestingly, there is conflicting evidence over the value of yearly mammography screening between the ages of 70 and 75, and no evidence of screening benefit for women over the age of 75 [157]. Traditionally, organizations such as the NCI and ACS have not placed upper age limits on recommendations for when to stop promoting yearly mammograms. Yet there is evidence that clinicians themselves stop ordering mammograms for women over a certain biological age [160]. Even if an older woman is experiencing a chronic illness, mammography should still be considered because advanced breast cancer can be very painful and can be avoided with early detection.

Additional Screening Tools. Other screening methods have been suggested but to date are not recommended by NCI, ACS, or the USPSTF. These proposed methods include the use of screening sonography and magnetic resonance imaging (MRI). While these types of examination have been helpful in diagnosing breast lesions once they have been discovered, the lack of specificity and high cost remain prohibitive in their use with the general population [161–163].

In summarizing breast cancer screening suggestions, it is clear that consensus does not exist as to whether all three of the traditional methods should be used and when. Additionally, new techniques exist for genetic screening, such as blood testing for mutated BRCA1 and BRCA2 genes, but these are not without controversy. Until more definitive evidence is available, individual midwives will need to discuss screening methods with clients and make decisions accordingly. Continuing routine use of SBE, CBE, and mammography is supported by NCI, ACS, and the USPSTF. Currently, genetic blood testing is only suggested for people at risk for inheriting mutated genes (see Table 14-9), but even the screening of these individuals raises difficult medical and ethical questions. For example, if someone is found to have a mutated BRCA gene, should prophylactic mastectomy be performed? And can this individual be denied insurance coverage for what could be viewed as a preexisting condition or for being too great a health risk for the insurer? These types of questions are not unique to the area of breast health care, but certainly do play a role in the quest to prevent breast cancer.

Diagnosis While the role of most midwives in addressing breast cancer is to screen for this potential illness, and then refer if necessary, some initial diagnostic steps can be performed if a neoplasm is suspected. *Any* suspicious or unidentifiable mass requires follow-up assessment and possible treatment. When referring a woman to a breast clinic or a surgeon, the midwife can initiate the diagnostic process by ordering a diagnostic mammogram or ultrasound. The former includes more views than a

screening mammogram, and its focus is on the region of concern, although additional bilateral screening can be ordered at the time if thought necessary. More specific information about a suspicious mass can be obtained with an ultrasound, which will distinguish between a fluid-filled cyst and the more worrisome solid mass. Depending on the findings of the ultrasound, the breast specialist will proceed with a fine needle aspiration, a lumpectomy, or a plan for monitoring the potential growth of the mass in question without current intervention. This plan will often involve collaborative practice between the specialist and the midwife to ensure the health of the woman.

Cervix

One of the greatest success stories in American public health in the twentieth century was the vast decrease in cervical cancer mortality. This success was due mostly to the invention and promotion of the cervical cytology smear, or Pap smear, by George Papanicolaou in the 1940s. Enhanced by more recently improved technologies, the Pap smear has reduced death by cervical cancer in the United States by over 70 percent [164], and has begun to have similar effects worldwide. It continues today to be the first-line screening tool for detecting cervical cancer [165, 166].

Despite the notable decrease in cervical cancer mortality, the quest for improved and less costly screening techniques continues, and for good reason. Each year, over 4000 women in the United States die from cervical cancer, and 13,000 new cases are diagnosed [167]. As with most terminal cases resulting from gynecological cancer, the circumstances of death are usually prolonged and painful [168]. Thus any efforts to discover signs of carcinoma early in the disease process will assist in decreasing further the mortality related to cervical cancer.

Screening

Pap Smear. As with breast cancer screening, guidelines for routine cervical cancer screening have never been absolute and can vary from one agency to the next. The NCI recommends Pap smear testing on a regular basis after the onset of sexual activity or at the age of 18, whichever comes first [164]. While these guidelines are not specific about what is meant by "sexual activity," it cannot be assumed that this refers to heterosexual intercourse, since recent evidence has shown that the risk of sexual practices associated with later development of cervical cancer can involve more than just exposure of the cervix to the male penis [169, 170]. Indeed, there is evidence that human papillomavirus (HPV), increasingly implicated as the primary cause of cervical cancer, can be contracted even without any history of sexual contact [171, 172]. Thus, the midwife should take a thorough approach to screening and resist any temptation to avoid doing a Pap test based on presumptive lifestyle factors (e.g., a lesbian woman or a nonsexually active individual).

More specific than the NCI guidelines, the ACS recommends *yearly* Pap screening beginning with onset of sexual activity or at the age of 21. Once an individual reaches the age of 30, and she also has had three consecutive negative Pap results, then the ACS suggestion is for this person to have Pap screening less frequently, usually once every two to three years. However, more frequent screening should occur if the woman has certain risk factors for cervical cancer, such as HIV or other immune system problems. The ACS also is currently recommending that women age 70 or older need not have Pap smear testing done if they have had three normal results and no abnormal findings over the last ten years (173).

On the other hand, the USPSTF recommends routine screening only after sexual activity has been initiated, and only once at least every three years. Like the ACS, USPSTF addresses testing later in a woman's life, stating that if an individual has had normal Pap results throughout her life, it may be possible to discontinue regular testing after the age of 65 if no risk factors for cervical cancer are present [174]. Thus, as with breast cancer screening guidelines, suggestions from organizations and agencies are varied. The midwife should practice according to those guidelines that best suit the population with which she is working, and she should offer each client appropriate education and choice regarding the interval timing of routine Pap testing.

The technique of collecting a Pap smear is discussed in Chapter 57. There has been discussion in recent years over the best data collection method to use when performing a Pap smear [165, 166]. Developments in gathering specimens and preparing them for transport to a laboratory have led to continual changes in how Pap smears are collected. Gathering Pap samples has involved the use of Ayre spatulas and cotton swabs, extended tip wooden spatulas, the cytobrush, the Cervex brush, and various combinations of these tools. No matter what technique is used, the primary goal of collecting a

Pap sample has always been to obtain cells from the endocervical region of the cervix. Current evidence, as reviewed in the literature by Mashburn [165], indicates that combining the use of an extended tip spatula and a cytobrush is the most efficient technique for accomplishing this goal. And, despite the increased amount of bleeding caused by using these two devices in combination, this is still the recommended Pap smear collection method for both nonpregnant *and* pregnant women.

In addition to ongoing discussion about the most efficient method of collecting Pap samples, there is continual dialogue about the most effective manner in which to prepare the specimen for transport to the cytopathology laboratory. Traditionally, smears have been prepared by swiping the collected cells onto a dry slide, followed by transfixing the specimen with a chemical spray. In recent years this technique has been increasingly replaced by the use of a liquid medium in which the cells are directly placed after collection, and then subsequently transported to a laboratory. At the laboratory, the cells are then prepared on a slide for evaluation. Evidence has shown that the latter method, commonly referred to as the thin-layered prep technique (e.g., ThinPrep or AutoCyte Prep), is better than the traditional transport method in reducing the number of ambiguous report findings that often require clinical follow-up [175, 176] (see below). Yet, the cost of the thin-layered prep method remains higher than the transfixing technique, and consumer advocates have raised concerns about the heavy influence of health care industry manufacturers on government officials who have promoted the use of thin-layered prep methods of cervical screening over the traditional Pap smear technique, especially without convincing evidence of the newer technology's benefit [166].

Interpretation of findings, as usually reported by a properly accredited external laboratory, is accomplished best by using the internationally accepted Bethesda Classification System of cervical cytological reporting [177] (see Table 14-10). Follow-up actions based on report findings can vary from one clinical site to the next. In general, if the test result reflects the presence of atypical squamous cells of undetermined significance (ASC-US) or a high-grade squamous intraepithelial lesion (HSIL), a colposcopic evaluation is warranted. If a low-grade squamous intraepithelial lesion (LSIL) is found, and the woman has no history of prior abnormal Pap results, then expectant management of repeat Pap smears every four to six months can occur. If three consecutive Pap smears are then negative, the woman may return to annual testing. If any of the three follow-up smears revealed ASC-US or SIL of any degree, then colposcopic testing should be initiated.

The presence of abnormal glandular cells (AGC) requires follow-up colposcopic testing that may be accompanied by a cervical biopsy, endocervical curettage, endometrial biopsy, and/or a pelvic ultrasound, since the origin of these atypical cells is difficult to discover and can be located at any point along the reproductive tract, including as high as the ovaries [165]. The role of the midwife in this testing can range anywhere from immediate referral to the actual performance of these tests, depending on the individual practitioner's experience and skill level. If the results of a Pap smear involve any finding of advanced disease, such as squamous cell carcinoma or adenocarcinoma, immediate referral to a specialist working with gynecological carcinomas is necessary.

Colposcopy. A second step in screening for cervical cancer involves the use of colposcopy. This technique of illuminating and magnifying the cervix to search for premalignant or cancerous cells was first used in Germany in the 1920s, but did not receive widespread use in the United States until the 1980s [166]. There has been debate in recent years about the potential use of colposcopy as a screening mechanism rather than just a diagnostic tool [165]. When compared to the Pap smear, the colposcopic examination is more specific and more sensitive in diagnosing abnormal cervical cells, yet the cost is much greater [178, 179]. While the specificity and sensitivity of Pap screening improve with serial testing, as is the current recommendation, the question that needs answering from both ethical and economic perspectives is at what point the cost of routine colposcopic screening becomes less than the cost of treating cancer left undetected by the use of the less costly Pap smear.

Diagnostic and/or follow-up indications for a colposcopy are shown in Table 14-11. For a woman the experience is similar to that of Pap smear, in that a speculum examination is performed (see Chapter 56). However, clients need to be made aware that the procedure lasts considerably longer than a Pap smear does, and pain or discomfort, as well as post-examination bleeding, can result from any biopsy procedures accompanying a colposcopy.

If any lesions of the cervix are found during the magnified inspection of the colposcopic procedure,

TABLE 14-10 The 2001 Bethesda System (Abridged) (177)

Pap smear reports using the Bethesda Classification System will reflect the following language:

[Note that confusion remains a problem with interpreting results because the alternative terminology of the three category "CIN (cervical intraepithelial neoplasia)" reporting system or the descriptive "dysplasia" system still may be used by some laboratories, either as a substitute for the Bethesda terminology or as additional descriptors.]

Specimen Adequacy

- Satisfactory for evaluation (presence/absence of endocervical/transformation zone component noted)
- Unsatisfactory for evaluation (reason specified)
- Specimen rejected/not processed (reason specified)
- Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (reason specified)

General Categorization (optional)

- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality
- Other

Interpretation/Result

Negative for Intraepithelial Lesion or Malignancy

- Organisms:
  - *Trichomonas vaginalis*
  - Fungal organisms morphologically consistent with *Candida* species
  - Shift in flora suggestive of bacterial vaginosis
  - Bacteria morphologically consistent with *Actinomyces* species
  - Cellular changes consistent with herpes simplex virus
- Other non-neoplastic findings (optional to report)
  - Reactive cellular changes associated with:
    - Inflammation (includes typical repair)
    - Radiation
    - Intrauterine contraceptive device
  - Glandular cells status posthysterectomy
  - Atrophy

Epithelial Cell Abnormalities

- Squamous cell
  - Atypical squamous cells (ASC)
    - of undetermined significance (ASC-US)
    - cannot exclude HSIL (ASC-H)
    - [All ASC is considered to be suggestive of SIL. Accordingly, the category of "ASCUS, favor reactive" has been eliminated. Also, when a report of "ASC" is given, it has been suggested by the American Society for Colposcopy and Cervical Pathology (ASCCP) that laboratory personnel conduct HPV DNA typing for high-risk viruses, if the clinician had requested "reflex to HPV hybrid capture" on the original laboratory request form. If "reflex" was not specifically requested by the clinican, some laboratories' staff will inquire on the written report if the clinician desires follow-up typing. However, it is important to note that reflex HPV DNA typing is only available if cervical cells were collected originally using liquid-based cytology.]
  - Low-grade squamous intraepithelial lesion (LSIL)
    - [encompassing old terminology of human papillomavirus/mild dysplasia/cervical intraepithelial neoplasia (CIN) 1]
  - High-grade squamous intraepithelial lesion (HSIL)
    - [encompassing old terminology of moderate and severe dysplasia, carcinoma in situ; CIN 2 and CIN 3]
  - Squamous cell carcinoma
- Glandular cell
  - Atypical glandular cells (AGC) (endocervical or endometrial or not otherwise specified)—*formerly known as AGUS (atypical glandular cells of undetermined significance)*
  - Atypical glandular cells, favor neoplastic (endocervical or not otherwise specified)
  - Endocervical adenocarcinoma in situ (AIS)
  - Adenocarcinoma

TABLE 14-10 The 2001 Bethesda System (Abridged) (177) (*continued*)

Other (list not comprehensive)

Endometrial cells in a woman ≥40 years of age

[Note that cervical cytology is primarily a screening test for squamous epithelial lesions and squamous cancer. It is unreliable for the detection of endometrial lesions and should not be used to evaluate suspected endometrial abnormalities.]

Automated Review and Ancillary Testing (included as appropriate)

For example, if a slide has been scanned by an automated computer system, the instrumentation used and the automated review result should be included in the cervical cytology report.

Educational Notes and Suggestions (optional)

Although not required, there has been evidence reported in the literature that laboratory staff suggestions included on a Pap report regarding further evaluation improves the likelihood that appropriate follow-up actually will occur.

TABLE 14-11 Indications for Colposcopy

- An abnormal-appearing cervix on physical examination
- Pap smear consistent with HPV infection, dysplasia, or cancer
- Pap smear with ASC or repeated ASC
- Pap smear with ASG (possibly with other tests)
- Pap smear with multiple unexplained inflammation
- Patients with a history of intrauterine diethylstilbestrol (DES) exposure

sampling of the region is required. This is accomplished through the use of punch biopsies, endocervical curettage, and/or cone biopsy. The purpose is to rule out cancer or precancerous lesions, and subsequently treat the individual. Depending on the clinician's level of experience and preference, treatment can occur during an initial colposcopic examination, prior to laboratory confirmation of diagnosis, if any lesion is found to be suspicious of cancer. This avoids the need for follow-up surgery and a delay in treatment, yet runs the risk of unnecessary surgery being performed based on visual inspection without laboratory confirmation. As with any procedure, the possible actions to be taken during a colposcopy need to be discussed with the client *before* the examination begins. No matter what procedures were performed during the initial colposcopic examination, positive results on any tissue analysis require follow-up with a practitioner experienced in the treatment of cervical cancer, usually a gynecological oncologist.

Cervicography. A less expensive technique than colposcopy for screening and/or diagnosing abnormal cervical cells has been cervicography, also known as a cervigram. Introduced in the United States in the 1980s, this method involves the use of low magnification photographs of the cervix which are then read by a cytopathologist, either simultaneously at another location via real-time broadcast, or at a later time after transport of the images from the clinical site to the cytopathologist's laboratory. As with colposcopy, the use of this technique requires training and access to a practitioner skilled in interpreting the photographic images. Despite efforts to improve the sensitivity and specificity of cervicography, colposcopy remains a more effective technique [180]. For this reason, cervicography has not reached the level of use that colposcopy has. However, there is sufficient evidence to show that this technique can serve an important role in cervical cancer screening, especially in locations where access and cost are issues with which to contend [181].

HPV Molecular Testing. Another development in cervical cancer screening has been the ability to identify HPV according to type. Because most cervical cancers are related to at least one type of HPV, of which over 100 have been identified [172], it seems logical that screening for cancer would involve identifying the type of any HPV lesion discovered on Pap smear. Indeed, as many as 13 HPV types have been linked to the development of cervical cancer, with types 16 and 18 having been related to a majority of carcinoma cases [182].

While there is optimism that typing of HPV found on the cervix will lead to more specific iden-

tification and possible treatment of individuals at risk for cervical cancer, the use of HPV testing as a population-based screening tool remains not recommended [164, 165]. In fact, the cost of testing also curtails the use of HPV testing as a secondary level of screening following an abnormal Pap result but prior to colposcopic examination. In studies utilizing this three-step method, almost all individuals with an abnormal Pap were triaged to colposcopy based on HPV tests. Thus the HPV testing had become for most of the women an extra layer of testing, with time and cost involved, that resulted in the need for a colposcopy anyway [164]. There exists optimism that with new, less expensive techniques for HPV typing and with the quantification of the viral load, or amount, of particular HPV types, clinicians will someday be able to screen and treat in a more efficient and timely manner those women at greatest risk of developing cervical cancer.

Diagnosis

Pap Smear. The primary purpose of the Bethesda system for reporting Pap smear findings (see Table 14-10) is to categorize and describe epithelial cell abnormalities. However, refinement of clinical collection and data analysis techniques has also led to the reporting of positive findings listed as "negative for intraepithelial lesion or malignancy," but then followed with a description suggesting the presence of a specific organism on the cervix (e.g., "*Trichomonas vaginalis*," "Fungal organisms morphologically consistent with *Candida* species," or "Cellular changes consistent with herpes simplex virus"). This raises the question of the clinical significance of these laboratory findings, especially in the absence of any symptoms or signs of vaginal or cervical infection.

According to Policar [157], clinical action for Pap report findings that indicate the presence of an organism depends on the organism named. The Pap smear has been found to be a highly specific test for *Trichomonas* [183], meaning that if "trich" is found on a Pap slide, the woman almost certainly has the organism present in her vagina and thus should be treated. However, the Pap test is not a very sensitive mechanism for diagnosing *Trichomonas*. Only about half of women with this parasite will have it detected by a Pap smear. Therefore, diagnosis is still best accomplished using a wet mount microscopic examination.

Candida found on a Pap smear does not necessarily require treatment. All women have *Candida* colonized intravaginally as a part of normal flora. Its presence on a Pap report gives no indication of the amount of *Candida* present. When a woman's Pap smear findings mention *Candida*, two actions should be taken. The first is to decide if treatment was already accomplished by reviewing the chart, or establish if treatment is now required by contacting the individual to see if symptoms of *Candida* overgrowth are present. The second action is to assess the recommendation of the cytopathologist regarding the degree to which the Pap smear could be interpreted given the presence of the *Candida*. If inflammation due to the organism was sufficient enough to impede assessment of the cervical cells on the Pap slide, then repeating the Pap smear after treatment of the *Candida* infection is warranted.

As with *Trichomonas* findings on a Pap smear, the test is highly specific with regard to herpes simplex virus (HSV), yet not very sensitive. Thus, a Pap smear should not be used to screen for or diagnose HSV on the cervix. Obtaining HSV cultures remains the most accurate method of identifying this organism. However, if a Pap result indicates the presence of HSV, the woman needs to be notified of this. Treatment at the time would only be required if the individual is symptomatic (see Chapter 15).

Many laboratories still report a predominance of coccobacilli when greater numbers of these organisms are present than is normally found in vaginal flora. Originally, this potential finding was entered onto laboratory reports as a method of indicating possible bacterial vaginosis (BV). However, the Pap smear is neither sensitive nor specific in diagnosing BV, and some cytopathologists do not report specific information regarding the presence or amount of coccobacilli found in a sample. According to Policar [157], when a report of coccobacilli is given, there remains disagreement over what action, if any, to take. Some clinicians believe that no action is necessary, and that a routine Pap schedule should be maintained. Others will contact the woman and offer a clinical evaluation for BV infection. This especially is the case if the woman is pregnant because of the risk of preterm labor related to the presence of BV.

One final organism report on Pap should be acknowledged. If the findings from a Pap smear indicate the presence of "bacteria morphologically consistent with *Actinomyces spp*," the clinician needs to follow up with the woman if she has an IUD in place. *Actinomyces israelii* is a bacterium

found to cause pelvic inflammatory disease (PID) in women with IUDs. The woman needs to be examined for any signs and symptoms of pelvic infection. If infection is likely, the IUD should be removed and antibiotics initiated. If the woman is asymptomatic, Policar [157] has suggested removing the IUD, repeating the Pap smear in three months, and then inserting a new IUD if the follow-up Pap report indicates the lack of presence of *Actinomyces*. Alternative forms of birth control need to be discussed after removing the IUD or if the presence of *Actinomyces* persists.

To summarize the use of the Pap smear as a diagnostic tool, its main purpose is to categorize and describe epithelial cell abnormalities. In this capacity, the Pap smear is primarily a screening mechanism. Certainly, if the clinician discovers an unusual lesion or mass on the cervix, a Pap test will be performed. However, a colposcopy will be the main diagnostic tool used in this situation (see below).

If a Pap report indicates the presence of certain organisms, clinicians should act upon these results in accordance with the guidelines by which they practice. However, as indicated previously, the Pap test should not be used as a diagnostic tool due to the less-than-optimal sensitivity of this test in identifying organism-based vaginal or cervical infections.

Colposcopy. As mentioned above, the main purpose of colposcopy is as a diagnostic tool. Because colposcopy is more specific and more sensitive in diagnosing abnormal cervical cells than the Pap smear, it is the logical follow-up diagnostic tool to use when an abnormal Pap smear is reported. To date, its cost in terms of time and money still prevent the colposcopic examination from becoming the first line of screening for cervical cancer.

Table 14-11 indicates the reasons for utilizing a colposcopic examination. As with all techniques of assessment or management, the degree to which the midwife uses the colposcope for diagnosing suspicious cervical lesions depends on expertise, experience, and availability. When discussing the potential use of colposcopsy as a screening tool, follow-up of abnormal Pap reports will be dictated by an individual's practice guidelines; recommendations from organizations such as NCI, ACS, and the USPSTF; and the most recent evidence-based practice research findings published in health care literature. It is important in screening for, and treating, cervical cancer that midwives are clear about which recommended screening schedule (e.g., NCI, ACS, or USPSTF) they will follow in their practice, and are diligent in following-up with referrals and care as indicated.

Endometrium

Three times more women are diagnosed each year with endometrial cancer than with cervical cancer [167, 184]. While there are a variety of carcinomas that can be found in the uterus, including sarcomas and gestational trophoblastic tumors (e.g., hydatidiform mole), the endometrium is the source of 90 to 95 percent of cancers involving the corpus of the uterus [185]. One positive note is that the cure rate for endometrial cancer, when detected early in the disease process, is approximately 90 percent [186] because tumors tend to be localized and well-defined. However, the high incidence of this form of cancer still results in over 6500 deaths per year [167].

Screening The primary *diagnostic* tool for endometrial cancer today is the endometrial curettage or biopsy (EMB) (see Chapter 82). First proposed as a *screening* tool in the 1920s, EMB has undergone a series of proposals and analyses for being used to screen for endometrial cancer, especially as newer and less expensive techniques for performing EMB have been devised over time [187]. For many years, the standard of care in diagnosing endometrial hyperplasia, an overgrowth of the endometrium that often leads to the development of cancer, had been the use of the dilatation and curettage (D&C) [185]. However, this invasive procedure has always been considered too involved and costly to justify its use as a screening tool for endometrial cancer, and indeed is no longer the standard technique for diagnosing this disease.

Other tools that have been proposed as possible mechanisms for routine screening of endometrial cancer have been the Pap test, endometrial aspiration, and more recently, transvaginal ultrasound. However, a review of the literature on the effectiveness of all of these methods have led to the conclusion that routine screening of women for endometrial cancer, no matter which method is used, is currently of no proven benefit [184]. The primary use of these tools is in *diagnosing* women who are at high risk for endometrial cancer (see Table 14-12), or who display signs of endometrial hyperplasia or cancer.

Diagnosis Endometrial hyperplasia, and the possible subsequent development of endometrial cancer, occurs most often in women over the age of 50,

TABLE 14-12 Risk Factors Associated with Endometrial Cancer

- Age >50 years
- Early menarche or late menopause
- Polycystic ovary syndrome
- Obesity
- Nulliparity, infertility
- Family history
- Caucasian race
- European or North American country
- Use of unopposed exogenous estrogen (estrogen replacement therapy [ERT])
- Estrogen secreting tumors
- Diabetes
- Gallbladder disease
- Hypertension
- Prior history of pelvic radiotherapy
- History of breast cancer
- Use of tamoxifen for treatment of breast cancer

with the average age of diagnosis being approximately 60 years [185, 186]. However, other risk factors besides age exist (see Table 14-12), and the midwife should not make a decision to assess for endometrial cancer based on age alone. In fact, the length of time an individual has had unopposed stimulation of the endometrium by estrogen should be the principal factor guiding when to consider testing for endometrial cancer [188].

Clinically, the most significant sign of endometrial cancer is bleeding. In postmenopausal women, *any* bleeding, except that experienced in a regular pattern while on HRT, is considered to be a sign of potential cancer. Prior to menopause, irregular bleeding could be a sign of cancer. However, since most endometrial cancers occur in postmenopausal women, any irregular bleeding prior to menopause should be assessed in the manner described previously in this chapter with regard to abnormal uterine bleeding. Other signs or symptoms of endometrial cancer, such as pain, usually only occur during late stage disease, when the cancer spreads beyond the uterus.

Endometrial Biopsy. Today, endometrial biopsy (EMB) is the most frequently used method for diagnosing disorders of the endometrium. The procedure has been reported to be safe and cost-effective, and can easily be performed during an ambulatory setting visit [187, 188] (see Chapter 82). However, the rather wide range of evidence regarding EMB sensitivity and specificity for diagnosing endometrial abnormalities has raised objections to this test being the sole diagnostic tool used to assess for carcinoma [184]. Obviously, EMB serves an important role in evaluating the cause of abnormal uterine bleeding, and it is considered to be an important part of diagnosing endometrial cancer when used in conjunction with other assessment tools. Thus the midwife should consider the use of EMB in ruling out endometrial hyperplasia or cancer, but not rely only on that information ascertained from EMB.

It also needs to be mentioned that some clinicians who prescribe HRT to postmenopausal women will use EMB prior to initiation of hormone therapy as an assessment tool to establish a healthy endometrium. However, there is no clinical evidence that this invasive practice is necessary nor that it reduces the number of endometrial cancers that develop [184].

Transvaginal Ultrasound. Often accompanying EMB as an assessment of endometrial abnormality is the transvaginal ultrasound, which, in addition to detecting possible intrauterine masses, measures the thickness of the endometrium (the "endometrial stripe") as a gauge of intrauterine health. (Depending on the study reviewed, a thickness of greater than anywhere from 4 to 6 millimeters is thought to be associated with pathology [189].) As ultrasonographic technology has improved, this technique has increased in popularity for evaluating endometrial abnormalities. While not yet sophisticated or cost-effective enough to be used as a screening tool for endometrial cancer, transvaginal ultrasound has proved to be highly sensitive (96 percent) and fairly specific (61 percent) in detecting cancer [189, 190]. When combined with EMB, transvaginal ultrasound is quite effective in helping to rule out carcinoma of the endometrium.

Dilatation and Curettage (D&C). The traditional method for ruling out suspected endometrial cancer had been the use of dilatation and curettage (D&C). Not only did this procedure give the practitioner a more-than-adequate sample of endometrial tissue for analysis, it also initiated treatment of any anomalies by removing potentially harmful tissue. However, in the 1980s the value of this diagnostic procedure, which involved considerable time and money, began to be questioned, especially since its sensitivity and specificity in ruling out endometrial cancer were unclear. Attention turned toward EMB as being the most efficient method for directly assessing endometrial bleeding. Today, a D&C is rec-

ommended only for those women in whom the endometrial stripe is found to be thicker than normal, yet is resistant to sampling using other, less costly data-gathering tools. Also, when less invasive diagnostic measures have been unable to identify a cause of suspected bleeding, a D&C can be a useful tool for reaching a diagnosis [189].

Pap Smear. The success of the Pap smear in assessing for cervical cancer does not transfer to success in ruling out endometrial cancer. The collection technique for the Pap smear does not include any attempt to obtain intrauterine endometrial tissue samples. Thus, one should not anticipate that Pap results can assist the midwife in ruling out endometrial cancer. It should be noted, however, that in postmenopausal women who are not on HRT, a routine Pap result that shows the presence of endometrial cells requires follow-up assessment and possible treatment for endometrial hyperplasia that has extended into the cervical canal.

Other Techniques. The diagnosis of endometrial cancer can involve more technological mechanisms than those already discussed. As with transvaginal ultrasound, endometrial biopsy, and D&C, these are not techniques learned in basic midwifery education, but they should be understood by any midwife referring a woman for further uterine assessment so that preparatory teaching can be offered.

The two most common advanced assessment tools are hysteroscopy and sonohysterography. The former involves direct visualization of the uterine cavity using an endoscope that is inserted through the cervix. During the examination visible masses (e.g., polyps) or suspicious areas of endometrial lining can be biopsied or completely removed, depending on the type of endoscope equipment used. Due to this ability to directly visualize the endometrium, the hysteroscopy is quite effective in discovering the source of uterine bleeding. Although considered by some to be the new "gold standard" of endometrial assessment, replacing the traditional D&C, hysteroscopy is thought to be best used only if the less costly and invasive EMB and transvaginal ultrasound are used initially and are unable to reveal any evidence of cancer or cause of abnormal bleeding [189].

Sonohysterography involves inserting sterile saline into the uterine cavity through the cervix, and then imaging the uterus with a transvaginal ultrasound. This technique separates the two walls of the endometrium, allowing for a more detailed examination of endometrial thickness and possible polyp growths. In addition, submucosal myomas are more readily visible in sonohysterography than they are in transvaginal ultrasound, allowing for a better assessment of their site and size. As with hysteroscopy, sonohysterography is a more invasive procedure than other endometrial assessment tools described previously. Sonohysterography is used for diagnosis only, and any sampling of endometrium or removal of polyps requires additional interventions [189]. As with all medical procedures, it is important that the woman undergoing sonohysterography be aware of these advantages and disadvantages, and make an informed choice about having this procedure performed.

In summary, there are several mechanisms for *diagnosing* endometrial cancer when this pathology is suspected, usually as a result of abnormal uterine bleeding, especially in a postmenopausal woman. However, an accurate and cost-effective *screening* method for endometrial cancer remains elusive. Midwives are encouraged to keep abreast of new developments in endometrial assessment techniques; seek training in advanced, postgraduate skills so that clients can be offered a variety of assessment procedures without need for seeing additional practitioners; and inform and support clients in their choices regarding the ruling out of endometrial cancer.

Additional Uterine Cancers

Although endometrial cancer is by far the most common form of uterine cancer, two additional forms of abnormal growth bear mentioning: gestational trophoblastic tumors (e.g., hydatidiform mole) and uterine sarcoma. The former are masses composed of products of conception that are located in the uterus. The most common of these tumors is the hydatidiform mole, which in its beginning stages is a benign growth whose elements are those of placental tissue. The woman presents with a positive pregnancy test, usually with excessively elevated human chorionic gonadotropin (HCG) levels, and abnormal bleeding. Her uterus will be larger than expected given her gestational age, and confirmation of diagnosis is accomplished through ultrasonography. Treatment usually involves the use of D&C with the goal of preventing the development of metastatic disease. (More information on hydatidiform moles can be found in Chapter 24.)

Uterine sarcomas are a rare form of gynecologic cancer (less than 1 percent), and comprise

only 2 to 5 percent of all uterine carcinomas [191]. Generally occurring after menopause, these anomalies originate in the uterine muscle or the endometrial epithelium. The only known etiology, found in close to 25 percent of these cases, is prior therapeutic radiation to the pelvic region used to curtail benign uterine bleeding that occurred earlier in the individual's life. There is no recommended form of routine screening, other than the assessment of uterine size and shape that occurs with annual examination. The presenting symptom/sign of this form of cancer is abnormal uterine bleeding. Initial diagnosis involves a bimanual examination to discover any unusual growth or shape to the uterus. While sarcomas cannot be easily distinguished on physical examination from benign leiomyomas, it is important to remember that sarcomas usually are found postmenopause, whereas leiomyomas more commonly manifest themselves prior to menopause, and begin to reduce in size postmenopause when estrogen stimulation diminishes.

If sarcoma is suspected after a careful history and thorough physical examination, further assessment involves the possible use of endometrial biopsy, ultrasonography, D&C, and laparoscopy. In general, the midwife will refer the woman in whom uterine sarcoma is suspected to an appropriate specialist. As with most cancers, prognosis is dependent on the extent of the disease when diagnosis is made. If the cancer is confined to the uterine corpus upon discovery, the five-year survival rate is 50 percent. The survival rate at five years for metastatic sarcoma ranges, unfortunately, from 0 to 20 percent [191]. Therefore, early discovery is vital to curtailing the spread of this disease. As with efforts to successfully diagnose endometrial cancer in beginning stages, it is important to stress the significance of uterine bleeding in postmenopausal women.

Ovaries

Perhaps the most troubling of gynecological cancers faced by both women and midwives is that which affects the ovaries. Ovarian cancer represents an estimated 30 percent of new cases of genital forms of cancer diagnosed each year, yet constitutes over one-half of the deaths to women who suffer from carcinoma of the genital organs [167]. These statistics do not imply that a diagnosis of ovarian cancer constitutes automatic mortality. In fact, approximately 50 percent of the women afflicted with this disease will survive past five years from the time of diagnosis, thus effectively surviving the disease [167, 192]. However, by modern standards of diagnosing and treating individuals suffering from cancer, this rate of mortality is high.

Due to the almost total absence of signs and symptoms for the earlier stages of ovarian cancer, its presence often goes undetected until the disease is advanced, thus accounting in part for the high rate of mortality. Also adding to the perplexing nature of this disease is the fact that there is no single form of ovarian cancer. In fact, there exist at least three categories of malignant neoplasms of the ovary (epithelial, germ cell, and sex cord-stromal tumors), depending on the tissue types of origin [193]. The incidence of ovarian cancer increases with age, with the median age at diagnosis being 63. However, the disease can occur at any time during the reproductive or postmenopausal years [194]. The mystery that surrounds ovarian cancer is also due in part to the fact that its etiology is poorly understood. Increased parity, use of oral contraceptives, and breastfeeding are all associated with a decreased risk of having this form of cancer. On the other hand, a family history of ovarian cancer and a history of infertility drug use are associated with increased risk [194], as is use of estrogen replacement therapy [195] (see Table 14-13). Factors such as age at menarche, age at menopause, or age at first birth appear to be unrelated to ovarian cancer risk.

TABLE 14-13 Risk Factors Associated with Ovarian Cancer

- Age: ≥50 years
- Strong family history of ovarian cancer (first-degree relative [e.g., mother or sister] or multiple second-degree relatives)
- Evidence of mutations in the BRCA1 or BRCA2 genes
- More than 40 years of active ovulation (e.g., nulliparous never-user of oral contraceptives)
- Nulliparity
- Infertility
- Caucasian race
- Use of estrogen replacement therapy (ERT)
- Endometriosis
- High-fat, low-fiber diet deficient in multiple vitamins, including vitamins A, E, and beta-carotene
- Smoking
- Prolonged exposure to asbestos or talcum powder (the latter is controversial)

Note: Conflicting evidence regarding the above risk factors can be found in the literature, and strongly definitive risk factors for ovarian cancer have yet to be identified. Clinicians are encouraged to remain updated with the literature as more evidence becomes available.

Researchers investigating the etiology and risks of ovarian cancer have mentioned other possible associated factors. The use of talcum powder has been suggested by some to be related to ovarian cancer, yet the evidence remains conflicting [194]. Earlier investigations demonstrating increased levels of the CA-125 tumor antigen in serum samples of women with ovarian cancer led to optimism that this factor could identify nonaffected women at risk for later developing this form of cancer. However, more recent studies have tempered this optimism, with evidence showing that even individuals already in early stages of ovarian cancer have normal serum levels of CA-125 [196], and levels of CA-125 in healthy women vary considerably according to a number of biological and social factors [197]. Similarly, links between ovarian cancer and mutations in the BRCA1 and BRCA2 genes, more commonly known to be associated with certain familial strands of breast cancer, have been proposed, but conflicting evidence to date also renders this potential link inconclusive [198].

Screening The lack of evidence regarding the etiology of ovarian cancer, definitive risk factors, and means of early detection make screening for this disease difficult for both women and practitioners. Currently, there are no effective routine screening tools for detecting ovarian cancer. Potential methods include thorough anticipatory teaching, bimanual examination, transvaginal or abdominal ultrasound, measures of the CA-125 antigen, and assessment for mutations of the BRCA1 and BRCA2 genes.

Routinely instructing women about the signs and symptoms of ovarian cancer will potentially aid in detecting this carcinoma. These signs and symptoms include abdominal bloating, flatulence, and other persistent GI disturbances; abdominal or pelvic pain; fatigue; urinary complaints; and irregular vaginal bleeding [199]. For the woman whose review of systems includes such current symptoms, it is essential that the possibility of ovarian cancer be considered by the midwife as she performs the woman's clinical examination. However, the fact that a majority of individuals afflicted with this anomaly do not become symptomatic until late in the disease process renders the sensitivity of screening through education and history-taking low. Bimanual examinations during routine well-woman visits have long been the only ovarian cancer screening tool not dependent on self-report. However, there is no evidence as to the sensitivity or specificity of these examinations with regard to detecting ovarian cancer. When a finding leading to a diagnosis of ovarian neoplasm is initially reported, the disease usually has already advanced to a later stage in the process.

There is evidence that either transvaginal or abdominal ultrasounds are reliable in detecting small ovarian masses. However, the specificity of these screening tools for cancer is low. In research to date, the percentage of ovarian masses discovered on routine screening ultrasound that have been demonstrated to be cancer has ranged from 3 percent in asymptomatic women to 10 percent in individuals with a family history of ovarian cancer [194]. The financial and emotional costs that would be involved in routinely screening all women, or even those individuals with a strong family history, followed by performing surgery on those with positive ultrasound findings, are very high when weighed against the number of ovarian cancer cases that would actually be discovered.

While the detection of the tumor-associated antigen CA-125 in women diagnosed with ovarian cancer has led to a call for using this serum marker as a method for screening all women to discover those at risk for the disease, the sensitivity of this screening approach has proven to be too low to justify mass screening. What makes this approach especially difficult is that CA-125 is not specific to ovarian cancer. Elevated levels have been found in women with nongynecological cancers, with endometriosis, and even in the first trimester of pregnancy [194]. Even less specific than CA-125 in screening for ovarian cancer is the presence of mutations of the BRCA1 and BRCA2 genes. Originally linked to breast cancer, these mutations have also been discovered in some women found to have ovarian cancer and have led to hope that screening for the BRCA1 and BRCA2 mutations, especially in families with a history of ovarian cancer, would aid in the early diagnosis of this disease. However, only 20 percent of women diagnosed with ovarian cancer have a family history of this disease, and less than 10 percent actually carry a BRCA1 or BRCA2 mutation [200]. Thus the notion of screening the general female population for these mutations in order to screen for the potential subclinical presence of ovarian cancer is not currently recommended.

Diagnosis Because early ovarian cancer is essentially asymptomatic, and no effective widespread screening method is currently available, diagnosis

of this disease often occurs during later stages of the pathology. As stated previously, once the diagnosis of ovarian cancer has been made, the five-year survival rate is approximately only 50 percent. However, it should be noted that not all news about ovarian cancer is grim. While the causes and related factors remain a mystery, simply increasing the public's awareness of this form of cancer, coupled with some improvements in treatment, has raised the five-year survival rate over the last decade from 39 to 52 percent [167, 201]. Thus steps are being made to improve outcomes, and increasing greater awareness by midwives as to possible signs of the disease can only add to this improvement.

Although they are not very sensitive in diagnosing ovarian cancer, the earliest symptoms reported by women later discovered to have this disease tend to be gastrointestinal. Abdominal bloating and flatulence are two of the more common complaints expressed by those afflicted with this disease. Because many individuals attempt to treat these symptoms at home for some time before seeking medical care, and because practitioners often assess these complaints initially as originating in the gastrointestinal system, delay in diagnosing ovarian cancer can occur [202]. There is no evidence that screening *any* woman with these GI complaints will improve the rate of discovery of ovarian cancer, or improve overall outcomes. Yet it behooves the midwife who hears of these complaints from an individual with risk factors for ovarian cancer (see Table 14-13) to proceed toward diagnosing this disease.

Late stage ovarian cancer is associated with persistent GI disturbances; possible enlargement of the abdomen with ascites; abdominal or pelvic pain; fatigue; urinary complaints; and vaginal bleeding [199]. The presence of these symptoms in any woman should lead to the midwife to consider ovarian cancer in the differential diagnosis. The initial step in ruling out this disease is to conduct a thorough history, including family history and social history, with an emphasis on revealing exposure to environmental factors associated with the disease (see Table 14-13). A history is followed by a physical examination, with emphasis on the bimanual pelvic examination to explore for a possible mass. Even if no distinct mass is palpated, a transvaginal ultrasound should be ordered if the midwife suspects ovarian tumors. As noted above in the discussion of screening for ovarian cancer, this is a helpful tool in discovering ovarian masses, but it is not completely sensitive or specific [203]. Recommendations for more extensive evaluation also include the possible use of abdominal ultrasonography or magnetic resonance imaging (MRI). However, the use of these additional technologies are usually initiated by an oncology specialist to whom a woman has been referred.

Drawing blood to establish the possible presence and level of the CA-125 tumor antigen may be an additional task conducted by the midwife. This information will help to identify an individual at increased risk for ovarian cancer, although no matter what the findings, the results of this test are not definitive in making a diagnosis.

To date, the only manner in which to clearly diagnose ovarian cancer is through surgery, usually involving laparoscopy with appropriate biopsy. The midwife's role toward this regard is the initial referral to an appropriate specialist, along with an explanation to the woman regarding what to anticipate. Follow-up with the woman will depend on diagnostic findings and any subsequent treatment that may occur. Certainly, if the individual does have ovarian cancer followed by successful treatment, midwifery care would then include assisting the woman in reducing risky behaviors as well as encouraging her to educate her female relatives about the possible familial link involved with ovarian cancer.

Vulva and Vagina

The forms of genital cancer that are the least frequent in occurrence and in resulting mortality are those involving the vulva and the vagina. It is estimated that in 2002 there will be 5800 new cases of these forms of cancer, with vulvar incidences being almost double those of the vagina, and approximately 1600 deaths as a result of these cancers [167]. If the diseases are discovered prior to nodal involvement, the five-year survival rate is 90 percent for vulvar cancer and even greater for vaginal cancer [204, 205]. The majority of both forms of cancer are squamous cell in type, and most cases are found in women over the age of 50. However, a rarer form of vaginal cancer, found primarily in daughters of women who took diethylstilbestrol (DES) during pregnancy, is clear cell adenocarcinoma, which occurs in late adolescence and the early twenties [205].

Screening and diagnosis of these cancers involve any history of vulvar or vaginal growth noted by the client, followed by pelvic examination, with visualization and palpation playing major roles. Both forms of cancer are associated with the human

papillomavirus (HPV), which is thought to be a causative agent of these diseases. Thus anyone with a history of having had contracted HPV should be considered at risk for vulvar or vaginal cancer. The most common site of vulvar involvement is the labia majora, while the most common location of vaginal cancer is the upper third of the vaginal wall [206]. Early symptoms for vulvar cancer may be persistent pruritis and the presence of condylomata [207], whereas vaginal disease may be accompanied with bleeding, heavy discharge, and pelvic discomfort. Depending on the extent of the latter disease process, pelvic examination can reveal a mass at the site of involvement, and possible lymphadenopathy [208]. Any suspicious lesion could be sampled for a Pap smear, although typical diagnostic procedure involves a colposcopy and/or biopsy. Definitive laboratory findings or the inability to rule out a carcinogenic process necessitates referring the woman to a specialist, often a gynecologic oncologist. As stated previously, early detection, as is the case with most cancers, results in a high rate of survival.

Nongynecologic Cancer Screening and Teaching

As is the case with all primary care practitioners, midwives routinely screen for additional forms of cancer beyond those involving gynecologic organs. At each annual visit, history-taking and physical examination assist in assessing for cancer of the skin, thyroid, lungs, and abdominal organs. In addition, for women 50 years or older or at risk for GI disease, screening for GI cancer occurs through rectal examination followed by testing stool for occult blood. Any positive or suspicious findings as a result of physical assessment will lead the midwife to initiate follow-up testing, consult with an appropriate specialist, or refer the client for necessary care.

Accompanying the assessment that occurs during annual examination is teaching regarding healthy habits and lifestyle that help to thwart the development of cancer. There is sufficient evidence to demonstrate that, although heredity plays a role in the development of cancer, a majority of related factors involve behavior or activities that can be altered by the individual [167]. Research to date highlights the importance of people following certain dietary patterns, avoiding specific risky behaviors, and remaining physically active throughout life. Every individual type of cancer, both gynecologic and nongynecologic, has specific components of diet associated with prevention that are worth exploration by midwives and other practitioners who regularly counsel women. In general, the most common themes in the evidence presented about diet and cancer prevention are that the consumption of whole foods and mostly plant-based items is the healthiest approach to avoiding cancer. Processed and high fat foods are best avoided, and maintaining appropriate weight for age and height is optimal for staying healthy.

In addition to teaching about a healthy diet, midwives can promote cancer prevention by encouraging a physically active lifestyle. Moderate activity for 30 minutes or more a day for five days in a week has been shown to reduce the incidence of cancer. The reasons for this vary depending on the type of cancer. (For example, with regard to breast cancer, physical activity is thought to improve energy metabolism, which subsequently aids in reducing circulating concentrations of physiologic growth factors that may have a role in tumor growth. Also, physical activity helps to limit the presence of excessive body fat cells, in which is found additional endogenous estrogen that has been related to breast cancer development [167].) Accompanying the promotion of a physically active lifestyle should be discussion regarding the possible limiting of alcoholic consumption, which has been associated, for example, with increased risk of breast cancer, and the elimination of tobacco use. Certainly, individual and cultural differences need to be acknowledged when counseling women about cancer prevention. Knowledgeable recommendations to women depend on the midwife keeping apprised of the latest medical literature, as well as each individual's health and cultural background, and then assisting her in making optimal choices for preventing cancer and the ill health that accompanies it.

Conclusion

Certainly, the ACNM motto "With women, for a lifetime" speaks well to the role of the midwife. Both from a historical and a current perspective, the care offered by midwives has included the diagnosing and management of gynecological health and diseases. This chapter has summarized the most common gynecological problems and the diagnostic/management steps associated with them. As with all midwifery care, the essential element of practice involved with all of these situations is to listen to the client and what she has to say about her condition and the effect it has on her life. Not only will

this approach to care validate what the woman is feeling and experiencing, but it will offer the most essential information needed for making an accurate diagnosis and subsequent plan of care. As stated at the beginning of this chapter, the majority of most women's physical well-being over the lifespan involves gynecological health. It is thus paramount that midwifery practice offers optimal care that includes the knowledge presented here regarding the diagnosis and management of common gynecological problems as well as screening for more complicated conditions.

CHAPTER

15

Infections of the Genital Tract

Vulvovaginal/Cervical Infections and Sexually Transmitted Diseases

Vulvovaginal/cervical infections and sexually transmitted diseases (STDs) not only cause intense physical discomfort, pain, and mental anguish but STDs may be devastating to a woman's reproductive health and even to life [1]. The acquisition of the STD is usually so distant from any resulting mortality that the association is not made. Examples include mortality from ectopic pregnancy (associated with PID) and cervical cancer (associated with HPV) [1, 2].

Women are especially vulnerable to the acquisition of STDs and thus to STD-related morbidity and mortality. There are several reasons for this vulnerability in women compared to men:

1. more biologically susceptible to STDs [1, 3]
2. more apt to acquire an STD from a man than vice versa [1, 4, 5]
3. more apt to be asymptomatic with an STD, with resulting delay in diagnosis and treatment [1, 6]
4. STD complications are more severe [4]
5. powerlessness in situations of sexual abuse and rape
6. the practice of douching [7]

The Committee on Prevention and Control of Sexually Transmitted Diseases of the Institute of Medicine published a report in 1997 entitled *The Hidden Epidemic: Confronting Sexually Transmitted Diseases* [4]. The report details a number of conclusions and recommendations made by the committee in the areas of education, population groups, and clinical practice. The clinical practice recommendations fall into two categories: (1) prevention and (2) management and treatment of STDs in accord with CDC guidelines [8]. Prevention encompasses risk assessment, counseling, and promotion of sexual health [9]; partner notification and treatment; and incorporation of STD-related services into primary care.

Risk assessment involves obtaining a history that will reveal practices that put a woman at risk for STDs (see Table 15-1). Preface your history taking with an expression of your understanding that these questions are highly personal but that you need to ask them in order to provide her with the best possible care. The woman's answers then become the basis

TABLE 15-1 STD Risk Assessment History

At what age did you start having sex?
How often do you have sex now?
Are you having sex with more than one partner?
How many partners have you had sex with in the last six months?
Do you have sex with men, women, or both?
What sex is your current partner?
Does your partner have other partners? Are they the same sex as your partner or the opposite sex?
Do you and your partner have sex while using alcohol or recreational drugs?
Do either you or your partner use intravenous drugs? Do you or your partner share needles?
Do you have anal intercourse?
What percentage of the number of times you have sex do you use a condom or dental dam?
Do you have a history of a previous sexually transmitted disease? Which one(s)? When? Treatment? Cure?
Do you douche?
What is your occupation?

Source: Used with permission from Washington State Department of Health STD/TB Program Training Center, and Cindy Fennell, MS, MT, ASCP.

for your counseling as you individualize the information and make it pertinent to her. Be careful not to make assumptions about the woman and in the process either alienate or deprive her from health care she needs. It helps to remember that age makes no difference and that counseling needs to be sensitive, nonjudgmental, and in accord with the woman's sexual orientation, sexual practices, frequency, number of partners, associated use of alcohol or drugs, contraceptive method, frequency of use of condoms, practice of douching, and occupation. The primary health care of every woman, regardless of age, should include essential STD-related services as enumerated in Table 15-2 [1].

A cardinal rule in diagnosing and making a differential diagnosis among the possible vulvovaginal/cervical infections is to never make the diagnosis on the basis of what you see on speculum examination (i.e., characteristics of the discharge; condition of the cervix, vaginal walls, and vulva). Although these findings are helpful in distinguishing among the different possible vulvovaginal/cervical infections, "eyeballing" is fraught with error. The discharge caused by one infection sometimes looks like the discharge caused by another; excoriation, inflammation, redness, and edema of the cervix, vaginal walls, or vulva may or may not be present with more than one infection; and pruritus is not an uncommon finding. Eyeballing also leads to missing coexisting infections and treating only part of the problem. Definitive diagnosis of vulvovaginal/cervical infections is made by microscopic findings on a wet mount or from diagnostic testing for specific diseases. The various methods of diagnosing sexually transmitted diseases are detailed in the discussion of each.

There are two vulvovaginal/cervical infections whose primary transmission may be other than sexual: candidiasis and bacterial vaginosis. The rest of the infections are primarily or exclusively sexually transmitted. Each state mandates the reporting of certain sexually transmitted diseases, usually at least syphilis and gonorrhea. Midwives need to know their state reporting regulations and be in compliance with them.

TABLE 15-2	Essential Primary Health Care STD-Related Services
Risk assessment history and evaluation (see Table 15-1)	
Counseling regarding high-risk behaviors or occupation	
Provision of Hepatitis B vaccine as indicated	
Obtaining a Papanicolaou smear	
Screening for STDs: wet mount, diagnostic testing of vaginal/cervical samples, blood test	
Treatment of STDs	
Partner notification and treatment as indicated	
Follow-up on effectiveness of treatment and counseling	

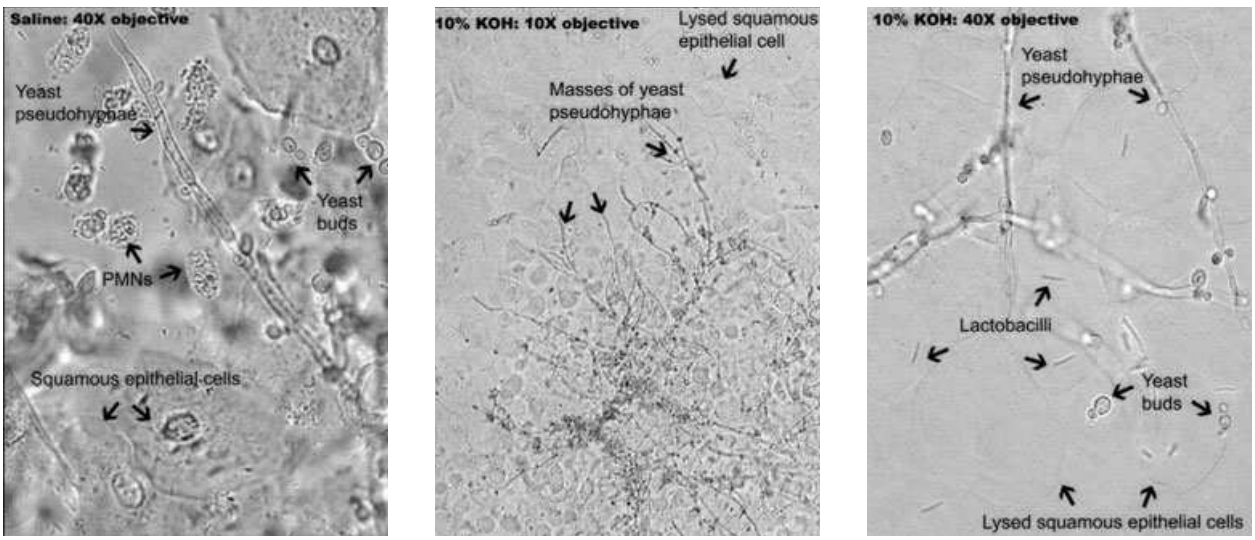
The midwife needs to be particularly sensitive to the impact of the news on a woman who learns she has a sexually transmitted disease. The woman needs to be given time to express anger, grief, and guilt (often felt by a woman who is pregnant and whose STD may affect her baby); the midwife needs time to provide explanations, facts, and support; and the two of you need time to develop a plan that includes telling the sexual partner, fulfilling reporting requirements, treatment, follow-up, and a discussion of sexual practices and future sexual relationships.

Vulvovaginal Candidiasis (Monilial Vulvovaginitis; Yeast Infection)

Commonly caused by *Candida albicans*, from which it takes its name, candidiasis is the vaginal infection with which most women are familiar. Predisposing factors include pregnancy, broad-spectrum antibiotic therapy, diabetes mellitus, diets high in refined sugars, obesity, HIV, and use of corticosteroids, immunosuppressant agents, and exogenous hormones, including contraceptive hormones. Candidiasis is thought to be hormonally dependent, based on the observation that *Candida* is rarely isolated from premenarchal girls or postmenopausal women [10]. Pregnancy almost doubles the incidence of *Candida*, with increased symptomatology in the third trimester. *Candida* vaginitis can occur concomitantly with STDs and should also be treated in this event.

The stereotypic clinical picture of monilia is of a white, thick, cottage cheese-like discharge, with white or white-yellow adherent plaques or patches on the cervix or vaginal walls. The discharge of monilia may also be thin and watery, or there may be none at all. Women complain of intense itching; the reddened, edematous, and excoriated vulva and vagina often seen during an examination may be the result of scratching or attempts to "wipe out" the discharge. There is generally no odor. The vaginal pH is normal (″4.5).

Diagnosis is made from microscopic evaluation of a wet mount (wet smear slide; wet prep) of discharge and plaques obtained during the speculum examination. (See Chapter 59 on making a wet smear slide.) Although the characteristic pseudohyphae and budding spores of *Candida* (see Figure 15-1) can be seen on a regular saline wet mount, they



(a) (b) (c)

FIGURE 15-1 *Candida* pseudohyphae and budding spores under microscopic examination. (1) saline, 40×, (b) KOH, 10×, (c) KOH, 40×, PMNs = polymorphonuclear cells.

Source: Used with permission from Washington State Department of Health STD/TB Program, Seattle STD/HIV Prevention Training Center, and Cindy Fennell, MS, MT, ASCP.

can be seen more easily if you add a drop or two of 10% KOH to your mix. The effect of the KOH is to destroy or blanch all the other cells on the slide except for the fungus. Up to 20 percent of wet mounts give false-negative results. Nickerson's medium for culture has a sensitivity of 95 percent, but most clinicians rely on a combination of wet mount and symptomatology to make a diagnosis and initiate treatment.

Any number of anti-fungal agents are available over the counter for treatment of *Candida*. Antifungal agents (see Table 15-3) include nystatin (Mycostatin); any agents that have an imidazole preparation, such as miconazole (Monistat), clotrimazole (Gyne-Lotrimin; Mycelex), butoconazole (Femstat), and ketoconazole (Nizoral); and agents containing a triazole agent, such as terconazole (Terazol). With the exception of fluconazole (Diflucon) and ketoconazole (Nizoral), all come in suppository or cream form; a few also come as vaginal tablets. The usual dosage is one suppository or one applicatorful of cream intravaginally hs for 7 days, although there are some 1-day and 3-day regimens. The cream may also be applied topically on the vulva for relief of symptoms. If a nondiabetic woman is experiencing recurrent *Candida* not related to antibiotic therapy, her sexual partner should also be treated.

Fluconazole and ketoconazole have the advantage of being oral tablets and absorbable, which eliminates the inconvenience of vaginal therapy and provides treatment to the digestive tract. However, ketoconazole is a very potent drug with hepatic side effects and potential for liver damage. Fluconazole has several gastrointestinal side effects and the woman generally does not experience symptom relief for 2 to 3 days. Nystatin also comes in oral form but is not absorbable, works only on the digestive tract, and is not as effective for *Candida* vaginitis as the azole drugs. None of the oral formulations should be used when a woman is pregnant or breastfeeding.

Fewer than 5 percent of women have recurrent (four or more) episodes of symptomatic infection a year. Vaginal cultures should be obtained on these women to identify unusual species of *Candida* that do not form pseudohyphae or hyphae and are not easily recognized from microscopic evaluation of a wet mount. Treatment is a longer duration of topical therapy (14 days) or a repeated oral dose (3 days later) before initiating a maintenance antifungal regime (see CDC Treatment Guidelines) [8].

In addition to being given information on the etiology and course of the infection and on how to insert the suppositories or cream, the woman should be given the following instructions:

1. Insert the medication when you are ready for bed and lying down and will stay lying down for several hours (after your last trip to the bathroom, kitchen, etc.).

TABLE 15-3 Primary Treatment Guidelines for Genital Tract Infections

Recommended Regimen*	Treatment During Pregnancy	Evaluation/ Treatment of Sex Partner	Note**
Candidsasis (Monilia; Yeast) Topically applied azole drugs: see Note butoconazole (Femstat; Gynazole-1) clotrimazole (Gyne-Lotrimin; Mycelex) miconazole (Monistat) tioconazole (Monistat1; Vagistat-1) terconazole (Terazol) as intravaginal cream or ointment, vaginal tablets, or vaginal suppositories × 1, 3, or 7 days depending on dosage fluconazole (Diflucon) 150 mg po in a single dose	Yes, see Note	No	Over the counter formulations are available. Butoconazole cream, clotrimazole cream, miconazole cream and vaginal suppositories, tioconazole ointment, and terconazole vaginal suppositories are oil based and may weaken latex condoms, cervical caps, or diaphragms. Pregnancy: Only 7-day topical azole therapies are recommended. Do not use oral medications.
Bacterial Vaginosis (BV) metronidazole (Flagyl) 500 mg po BID × 7 days or, metronidazole gel 0.75%, one full applicator (5 g) intravaginally QD × 5 days or, clindamycin (Cleocin) cream 2%, one full applicator (5 g) intravaginally hs × 7 days or, alternatively (less efficacious), metronidazole 2 g po in a single dose or, clindamycin 300 mg po BID × 7 days *Pregnancy Regimen* metronidazole 250 mg po TID × 7 days or, clindamycin 300 mg po BID × 7 days	Yes, see *Pregnancy Regimen* and Note	No	Instruct woman to avoid alcohol during and for 24 hours after treatment with metronidazole. Clindamycin cream is oil based and may weaken latex condoms, cervical caps, or diaphragms. *The use of clindamycin vaginal cream during pregnancy is not recommended*; some experts prefer the use of systemic therapy for low-risk pregnant women to treat possible subclinical upper genital tract infections; no long-term maintenance regimen with any therapeutic agent is recommended. TOC unnecessary if asymptomatic after treatment or reinfection is not suspected *except* for pregnant women high risk for preterm delivery who should be reevaluated one month after completion of treatment.
Trichomoniasis metronidazole (Flagyl) 2 g po in a single dose or alternatively, 500 mg BID × 7 days	Yes, see Note	Yes	Instruct woman to avoid alcohol during and for 24 hours after treatment. TOC unnecessary if asymptomatic after treatment or reinfection is not suspected. Pregnant women can be treated with the single dose regimen; *metronidazole is secreted in breast milk; use single-dose therapy and discontinue breastfeeding for 12–24 hours* to allow excretion of dose.†
Chlamydia azithromycin (Zithromax) 1 g po in a single dose or, doxycycline 100 mg po BID × 7 days *Pregnancy Regimen* erythromycin base 500 mg po QID × 7 days or, if erythromycin cannot be tolerated, amoxicillin 500 mg po TID × 7 days	Yes, see *Pregnancy Regimen* and Note	Yes	Treat presumptively for chlamydia if woman has gonorrhea because of high incidence of coexisting infection. Instruct woman to abstain from sexual intercourse for 7 days and until all sex partners are cured. TOC unnecessary if asymptomatic after treatment or reinfection is not suspected, unless there was an earlier recent infection or the woman is pregnant. *Doxycycline is contraindicated in pregnancy; erythromycin estolate is contraindicated during pregnancy*. The pregnancy regimen is not as efficacious; retest 3 weeks after completion of regimen.

TABLE 15-3 Primary Treatment Guidelines for Genital Tract Infections (continued)

Recommended Regimen*	Treatment During Pregnancy	Evaluation/ Treatment of Sex Partner	Note**
Gonorrhea (uncomplicated) cefixime (Suprax) 400 mg po in a single dose or, ceftriaxone (Rocephin) 125 mg IM in a single dose or, ciprofloxacin (Cipro) 500 mg po in a single dose or, ofloxacin (Floxin) 400 mg po in a single dose or, levofloxacin (Levaquin) 250 mg po in a single dose PLUS (for treatment of chlamydia if not ruled out) azithromycin 1 g po in a single dose or, doxycycline 100 mg po BID × 7 days *Pregnancy Regimen* Treat with cephalosporin (cefixime, ceftriaxone) or, if unable to tolerate a cephalosporin, spectinomycin 2 g IM in a single dose	Yes, see *Pregnancy Regimen* and Note	Yes	Dual therapy treating both gonorrhea and chlamydia is recommended. May use 1% lidocaine solution as a dilutant to reduce pain of injection. TOC unnecessary if asymptomatic after treatment or reinfection is not suspected. *Quinolones (ciprofloxacin, ofloxacin, and levofloxacin) are contraindicated for pregnant women.*
Pelvic Inflammatory Disease (PID) *Regimen A* ofloxacin 400 mg po BID × 14 days or, levofloxacin 500 mg po BID × 14 days with or without metronidazole 500 mg po BID × 14 days *Regimen B* ceftriaxone 250 mg IM or, cefoxitin (Mefoxin) 2 g IM *plus* probenecid 1 g po in a single dose concurrently or, other parenteral third-generation cephalosporin (e.g., ceftizoxime [Cefizox] or cefotaxime [Claforan]) *plus* (for both options in Regimen B) doxycycline 100 mg po BID × 14 days with or without	Yes, see Note	Yes	Treat empirically in presence of cervical motion tenderness or uterine adnexal tenderness and no other cause of pain. *Pregnancy:* hospitalize for parenteral antibiotics; contraindicated for ofloxacin, levofloxacin, and doxycycline. Treatment of sexual partner(s) during 60 days preceding woman's symptoms imperative to prevent reinfection.
Genital Herpes Simplex Virus (HSV) *First Clinical Episode:* acyclovir (Zovirax) 400 mg po TID × 7–10 days or, acyclovir 200 mg po 5 times a day × 7–10 days or, famciclovir (Famvir) 250 mg po TID × 7–10 days or, valacyclovir (Valtrex) 1 g po BID × 7–10 days	Yes, see Note	Yes, for evaluation and counseling; treatment if symptomatic	There is no cure for HSV. Instruct patient to henceforth use condoms for every sexual exposure. Antiviral therapy is not recommended for women without clinical manifestations of infection. Topical acyclovir therapy is substantially less effective and its use is discouraged. Suppressive therapy does not totally eliminate viral shedding or the potential for transmission although it does reduce the frequency of recurrences; discontinue acyclovir after 1 year of continuous suppres-

TABLE 15-3 Primary Treatment Guidelines for Genital Tract Infections (continued)

Recommended Regimen*	Treatment During Pregnancy	Evaluation/ Treatment of Sex Partner	Note**
Genital Herpes Simplex Virus (HSV) (cont.) *Episodic Recurrent Infection:* acyclovir 400 mg po TID × 5 days or, acyclovir 200 mg po 5 times a day × 5 days or, acyclovir 800 mg po BID × 5 days or, famciclovir 125 mg po BID × 5 days or, valacyclovir 500 mg po BID × 3–5 days or, valacyclovir 1 g po QD × 5 days *Daily Suppressive Therapy:* acyclovir 400 mg po BID or, famciclovir 250 mg po BID or, valacyclovir 500 mg po QD (less effective with very frequent recurrences) or, valacyclovir 1 g po QD			sive therapy to allow assessment of patient's rate of recurrent episodes. See CDC Guidelines for discussion of treatment of patients with genital herpes who are also HIV-infected. *Pregnancy:* Treat primary and nonprimary first episodes and recurrent episodes with acyclovir; may continue with suppressive therapy for duration of pregnancy; for women with history of genital herpes, may use suppressive therapy starting at 36 weeks to reduce potential of recurrence at term; systemic acyclovir crosses the placenta, is concentrated in amniotic fluid and breast milk, and reaches therapeutic levels in the fetus.
Human Papillomavirus (HPV) Genital Warts (condylomata acuminata) cryotherapy with liquid nitrogen (*external genital, vaginal, urethral meatus, anal warts*) or cryoprobe (*external genital warts only*) or, podofilox (Condylox) 0.5% solution or gel BID × 3 days then no treatment for 4 days. Repeat 7-day cycle as necessary for total of 4 cycles (*self-treatment for external genital warts only*) or, imiquimod (Aldara) 5% cream three times a week up to 16 weeks. Wash area with mild soap and water 6–10 hours after application (*self-treatment for external genital warts only*) or, podophyllin 10–25% in compound tincture of benzoin. Air dry. Wash off in 1–4 hours. Repeat weekly if necessary (*external genital, urethral meatus warts*) or, trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80–90%. Apply sparingly. Dry. Repeat weekly if necessary (*external genital, vaginal, anal warts*)	Yes, see Note	No	*Podofilox, imiquimod, and podophyllin should not be used during pregnancy*. When using TCA, BCA, or podophyllin, protect the adjacent tissue with petroleum. When using podophyllin, be sure it is dry before contact with clothing. When using TCA or BCA be sure it is dry before woman sits or stands; powder with talc or sodium bicarbonate (baking soda) after treatment to remove unreacted acid and counteract any sensation of burning. Treat any vaginal or cervical infection. Emphasize careful cleaning and dryness of warts and surrounding area to woman. Presence of genital warts is not an indication for cervical colposcopy.

TABLE 15-3 Primary Treatment Guidelines for Genital Tract Infections (continued)

Recommended Regimen*	Treatment During Pregnancy	Evaluation/ Treatment of Sex Partner	Note**
Syphilis (primary, seconday, early latent) benzathine penicillin G, 2.4 million units IM in a single dose or, if allergic to penicillin and *not pregnant*, doxycycline 100 mg po BID × 14 days or, tetracycline 500 mg po QID × 14 days	Yes, see Note	Yes	Test all patients with syphilis for HIV infection. Reexamine clinically and with titers at 6 and 12 months (also at 24 months for latent syphilis), expect a fourfold decrease. Pregnant women who have primary, secondary, or early latent syphilis may have a second dose of benzathine penicillin G, 2.4 million units IM 1 week after the initial dose, *doxycycline and tetracycline are contraindicated in pregnancy*; pregnant women who are allergic to penicillin should be treated with penicillin after desensitization.
Syphilis (late latent, latent of unknown duration, or tertiary) benzathine penicillin G, 7.2 million units, administered in three doses of 2.4 million units IM each, at 1 week intervals or, if allergic to penicillin and *not pregnant*, doxycycline 100 mg po BID × 28 days or,	Yes, see Note	Yes	

* From CDC STD Treatment Guidelines, 2002 [8].

** Also see text.

TOC, test-of-cure; po, orally; QD, once daily; BID, twice daily; TID, three times daily; QID, four times daily; hs, at bedtime; IM, intramuscularly.

2. Use a small towel under your buttocks to catch drainage.
3. Use a panty liner during the day.
4. Use all medication as prescribed, even if symptoms subside.
5. Wear only cotton underwear for symptomatic relief.
6. Avoid tight-fitting clothing; loose clothing will increase air circulation for symptomatic relief.
7. Do not douche with feminine hygiene products.
8. Do not use tampons during treatment.
9. Use condoms or abstain from sexual intercourse during treatment.
10. Make an appointment for your next visit.

Many women know from experience when they have a monilial infection. Some women prefer to use plain yogurt douches or an intravaginal applicatorful of yogurt twice a day for 1 week. Other self-help remedies have been used, with unknown effectiveness.

Bacterial Vaginosis

Bacterial vaginosis (BV) has been known in preceding years as *Gardnerella vaginalis* vaginitis, *Haemophilus vaginalis* vaginitis, *Corynebacterium vaginale* vaginitis, and nonspecific vaginitis. The name changes reflect the various anaerobic organisms that have been found through the years and held responsible for this vaginal infection. Bacterial vaginosis is the result of a major change in vaginal flora from a predominance of *Lactobacillus* to a predominant mixture of anaerobic bacteria, including those mentioned above and *Mobiluncus*, with a lack of lactobacilli. These organisms also cause an increase in vaginal pH to between 5.0 and 6.0. Vaginitis, by definition, is an inflammation of the vagina. Since this vaginal infection does not

cause an inflammation, the term *vaginosis* is used instead.

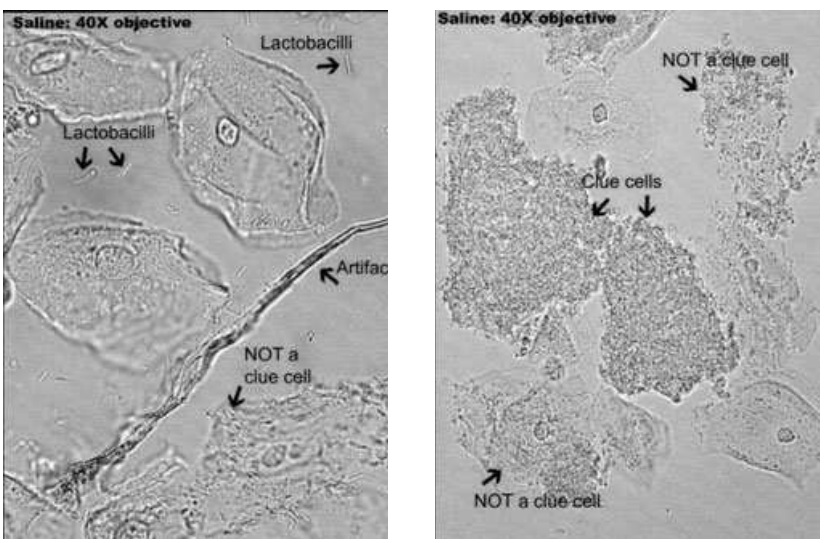
Bacterial vaginosis has been implicated with pelvic inflammatory disease, endometritis, and vaginal cuff cellulitis after invasive procedures including IUD insertion, endometrial biopsy, and therapeutic abortion. Women who have bacterial vaginosis during pregnancy are in special need of treatment as BV has been implicated in premature rupture of membranes, preterm labor, preterm birth, postpartum endometritis, and wound infection after cesarean section [8].

The clinical picture of bacterial vaginosis includes the increased pH; scanty, thin, homogeneous, milky, gray or white, malodorous discharge; and a positive "whiff" test. The pH can be tested with Nitrazine paper and a sample of discharge from the speculum. Discharge on your gloved fingers should not be tested, especially if you have used a lubricant, which may raise the pH. The discharge may be copious, and upon occasion there is vaginal irritation, pruritus, and burning and pain of the vulva, although these are usually absent. The woman may have noticed a "fishy" odor. The "whiff" test is done by adding a drop of 10% KOH to a specimen of the discharge, which releases amines and a potent "fishy" odor.

Microscopic examination reveals clue cells, a lack of lactobacilli, and very few white blood cells. The normal epithelial cell is translucent and has a clearly demarcated border. A clue cell is a desquamated epithelial cell with adherent bacteria. The bacteria appear as little black dots, which obscure the border of the cell, making it indistinct or jagged. This gives the cell a granular or speckled appearance (see Figure 15-2). However, up to 40 percent of women with bacterial vaginosis will not have clue cells [10, p. 775]. Culture is not a recommended diagnostic tool because it is not specific and Pap smears are not diagnostic because they have low sensitivity for bacterial vaginosis [8].

Diagnosis, thus, must be based on a combination of the symptoms and microscopic evidence and the ruling out of other vaginal infections. (For example, *Trichomonas* can also increase the pH and produce a fishy odor, although not as pronounced. A *Trichomonas* infection, however, is highly pruritic with vulvovaginal irritation, and trichomonads are present in the discharge.) Diagnosis and treatment of any sexual partners is not indicated for bacterial vaginosis.

The most effective treatment of bacterial vaginosis is with metronidazole (Flagyl) (see Table 15-3). Dosage is either 2 g po for one dose, or 500 mg po BID for 7 days (which offers the highest cure rate and is the recommended regimen of the Centers for Disease Control and Prevention [8]), or 250 mg po TID for 7 days. Metronidazole also comes in a



(a) (b)

FIGURE 15-2 Microscopic diagnosis of bacterial vaginosis (BV). (a) no BV; note normal epithelial cells and presence of lactobacilli, (b) BV; note clue cells and lack of lactobacilli.

Source: Used with permission from Washington State Department of Health STD/TB Program, Seattle STD/HIV Prevention Training Center, and Cindy Fennell, MS, MT, ASCP.

gel form, 0.75%; the typical dosage is one applicatorful intravaginally BID for 5 days. Multiple studies and meta-analyses indicate no significantly increased teratogenic risk with first trimester exposure to metronidazole [8, 11].

Clindamycin (Cleocin) 300 mg po BID for 7 days or clindamycin cream, 2% (Cleocin Vaginal Cream) (one applicatorful intravaginally hs for 7 days) can be given during the first trimester. Clindamycin cream is the preferred treatment, based on a general desire not to use systemic medications during the first trimester and to avoid possible gastrointestinal side effects. Pregnant women also can be treated with ampicillin (500 mg po QID for 7 days) or amoxicillin (500 mg po TID for 7 days); however, this treatment is only 50 to 60 percent effective and may cause *Candida* overgrowth. Clindamycin may also cause a *Candida* infection. Sulfa vaginal creams are palliative only and should not be given to women of Mediterranean or African origin or descent without first screening for G6PD. Because of the association of bacterial vaginosis with premature rupture of membranes, preterm labor/preterm delivery, and with postpartum endometritis, it is essential that it be effectively treated.

In addition to being told the etiology and course of the infection and being taught how to take the medication prescribed, the woman should receive the following instructions:

1. If taking metronidazole or using metronidazole gel, avoid alcohol intake during treatment and for 24 hours after completion of treatment.
2. If using clindamycin cream, do not use latex or rubber products such as condoms, diaphragms, or cervical caps during treatment and for 72 hours after completion of treatment. The oil base in clindamycin cream may weaken these products.
3. If using an intravaginal gel or cream,
   a. Insert the medication when you are ready for bed and lying down and will stay lying down for several hours (after your last trip to the bathroom, kitchen, etc.).
   b. Use a small towel under your buttocks to catch drainage.
   c. Use a panty liner during the day.
   d. Do not use tampons during treatment.
4. Use all medication as prescribed, even if symptoms subside.
5. Wear only cotton underwear for symptomatic relief.
6. Avoid tight-fitting clothing; loose clothing will increase air circulation for symptomatic relief.
7. Do not douche.
8. Do not use intravaginal yogurt or other commercial products of lactobacilli; they are ineffective and may contain contaminants potentially harmful to the vaginal microecosystem [12].
9. Make an appointment for your next visit.

Trichomonal Vaginitis (Trichomoniasis)

The causative organism for trichomonal vaginitis is *Trichomonas vaginalis*, a one-cell flagellated anaerobic protozoan. *Trichomonas* is primarily sexually transmitted. *Trichomonas* may coexist with other sexually transmitted infections, such as chlamydial and monilial infections. Up to 50 percent of women with gonorrhea also have trichomonal vaginitis [13].

Trichomonas presents clinically as a malodorous, copious, frothy or nonfrothy, thin or thick, white/yellow-green/gray discharge with pruritus. The odor may be "fishy," and a "whiff" test may be positive. The vagina may be inflamed, ecchymotic, erythematous, or excoriated. There may be a distinctive pattern of petechiae on the vaginal walls or cervix, a condition known as "strawberry patches" or "strawberry cervix." The woman may report dysuria, dyspareunia, or postcoital bleeding. Or the woman may be asymptomatic but harboring the parasite, which may be found in the bladder, urethra, Skene's glands, and Bartholin's glands, as well as the vagina and endocervix. Severe cases of *Trichomonas* can cause the woman great pelvic and lower abdominal pain with tender inguinal lymph nodes.

Definitive diagnosis is made by finding the motile trichomonads upon microscopic examination of the discharge. The trichomonad is pyriform or ovoid, with four anterior flagella and an undulating membrane. They are visible on a wet mount made with a mixture of discharge and normal saline (see Figure 15-3). The slide should be examined immediately while the trichomonads are alive, motile, and easy to identify. You should also check the woman's Pap smear report to see if *Trichomonas* was identified.

Treatment is with metronidazole (Flagyl) (see Table 15-3). The regimen recommended by the Centers for Disease Control and Prevention is 2 g po in a single dose; the alternative regimen is 500 mg BID for 7 days. Multiple studies and meta-analyses indicate no significantly increased teratogenic risk with first trimester exposure to metronidazole [8, 11]. Clotrimazole (Gyne-Lotrimin) vaginal cream (1 applicatorful intravaginally hs for 7 days) or metronidazole gel (1

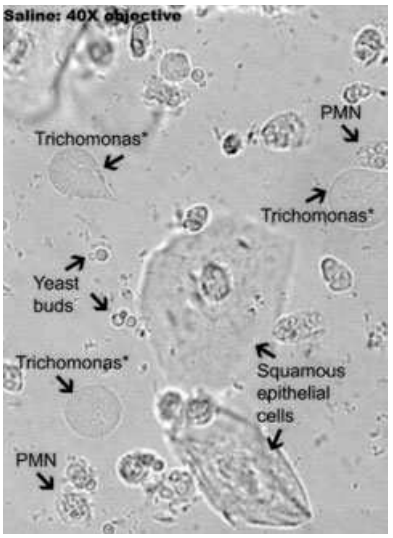


FIGURE 15-3 Trichomonads seen microscopically. Must be motile for identification.

Source: Used with permission from Washington State Department of Health STD/TB Program, Seattle STD/HIV Prevention Training Center, and Cindy Fennell, MS, MT, ASCP.

applicatorful intravaginally every day for 5 days) can be used for symptomatic relief but is not curative.

The woman's sexual partner should be simultaneously treated with metronidazole. Follow-up is not necessary if asymptomatic after treatment. The woman should be evaluated for coexisting gonorrhea, chlamydia, and syphilis.

The woman should be informed of the etiology and course of the infection and given the following instructions:

1. Avoid alcohol intake during treatment and for 24 hr after completion of treatment.
2. If breastfeeding, stop during treatment and for at least 24 hr after.
3. If taking the multiple-dose regimen, take all medication, even if symptoms subside.
4. Wear only cotton underwear for symptomatic relief.
5. Avoid tight-fitting clothing; loose clothing will increase air circulation for symptomatic relief.
6. Do not douche.
7. Do not have sexual relations until you and your partner have completed treatment and are without symptoms.
8. Make an appointment for your next visit.

Chlamydial Infections

Chlamydia trachomatis is the most prevalent sexually transmitted disease in the United States. There are several serotypes of human *Chlamydia trachomatis*, which cause trachoma, lymphogranuloma venereum (rare in the United States), and a number of urogenital infections that may be transmitted to the baby during delivery and result in ophthalmia neonatorum and chlamydial neonatal pneumonia. This discussion will be limited to the urogenital infections, which may, if the woman is pregnant, be transmitted to the baby at the time of delivery. A number of urogenital infections can occur, including endocervicitis, salpingitis, pelvic inflammatory disease, urethritis, cystitis, and postpartum infection. *Chlamydia trachomatis* is also implicated in infertility, ectopic pregnancy, premature rupture of the fetal membranes, and preterm labor/preterm delivery. *Chlamydia trachomatis* is often found coexisting with *Trichomonas* and *N. gonorrhoeae*.

Fifty percent of women infected with *Chlamydia trachomatis* are asymptomatic. This means that you will not be able to provide the woman with information she may want to know about when she became infected. Because of the widespread incidence and potential devastating effects of this infection, a cervical culture for chlamydia should be part of the annual physical examination of sexually active women and of the initial prenatal examination. There is an increased incidence of *Chlamydia trachomatis* in women using oral contraceptive pills, probably because the pills cause cervical ectopia, which makes the woman more vulnerable to a chlamydial infection.

Women with symptomatology will present with mucopurulent discharge from the cervix and an edematous, congested cervix with ectropy of the columnar epithelial cells (which line the endocervix). Unless there is a coexisting vaginal infection, there will not be vaginal symptomatology, because *Chlamydia trachomatis* does not infect squamous epithelial cells (which line the vaginal walls). A wet mount of the mucopurulent discharge will reveal a high number of white blood cells but only confirms there is an infection. Diagnosis is made by cervical culture, or by a variety of nonculture tests of cervical specimens including DNA probes or amplification, enzyme immunoassays (EIA), and polymerase chain reaction (PCR), or by either cervical or urine nucleic acid amplification tests. The nonculture cervical specimen tests have the advantages of being less expensive than cultures with more timely results, wider availability, and easier handling and processing [14]. The nucleic

acid amplification tests are more expensive than the DNA probe or EIA. DNA and RNA amplification tests have greater than 90 percent sensitivity and specificity. Culture has nearly 100 percent specificity and 80 percent sensitivity while the DNA probe and EIA are also high in specificity but only 60 to 65 percent in sensitivity [14]. Serologic tests are not recommended [10, p. 777].

Treatment is with antibiotics. The regimen recommended by the Centers for Disease Control and Prevention is either doxycycline 100 mg po BID for 7 days or azithromycin (Zithromax) 1 g po in a single dose (see Table 15-3). Doxycycline is contraindicated during pregnancy. Preliminary data suggest that azithromycin is both safe and effective during pregnancy [8], but the CDC does not yet recommend it for use in its pregnancy regimen. Instead, the recommended regimen for pregnant women is erythromycin base (500 mg po QID for 7 days), erythromycin ethylsuccinate (800 mg po QID for 7 days), or erythromycin ethylsuccinate (400 mg po QID for 14 days). Erythromycin estolate is contraindicated during pregnancy. If erythromycin cannot be tolerated, then use amoxicillin (500 mg po TID for 7 days). The Centers for Disease Control and Prevention recommend the presumptive treatment of chlamydia in patients who are being treated for gonorrhea because of the high incidence of coexisting infection [8, p. 36].

The most recent sexual partner should be seen, evaluated, and treated. If there is more than one sexual partner, then all partners the woman has had sexual contact with during the 60 days prior to the onset of symptoms or diagnosis should be evaluated, tested, and treated. The woman and all partners should abstain from sex until all sexual partners have completed treatment. Pregnant women should be retested 3 weeks after completing therapy as erythromycin is less efficacious. Also, gastrointestinal side effects might interfere with compliance in taking all the prescribed medication.

The woman should be informed of the etiology and course of the infection and the potential effects of the disease on her pregnancy and on the newborn if she is infected and is not treated while pregnant. She should be given the following instructions:

1. Complete all medication, even if you have no symptoms or your symptoms subside.
2. Do not have sexual relations until you and your partner have completed treatment and are without symptoms.
3. Make an appointment for your next visit.

Gonorrhea

Gonorrhea is a sexually transmitted disease caused by gram-negative intracellular diplococcal bacteria called *Neisseria gonorrhoeae*. A high incidence of women with gonorrhea also have coexisting chlamydia and, to a lesser extent, *Trichomonas*. Women with *N. gonorrhoeae* also should be screened for syphilis, as both have a high prevalence in the same risk populations. Infection may involve the urethra, Skene's glands, Bartholin's glands, vulva, vagina, cervix, endometrium, fallopian tubes, ovaries, peritoneum, rectum, conjunctiva of the eyes, oral mucosa, and joints (yielding gonococcal arthritis). In the female, the infection is most commonly found in the lower genital tract. It can cause pelvic inflammatory disease (PID) with resulting tubal scarring that can cause ectopic pregnancy or leave the woman infertile.

During pregnancy the adherence of the membranes to the decidua provides a barrier to ascending infection. However, if not treated or if treated inadequately, the infection will ascend rapidly after delivery, with resulting gonorrheal endometritis, salpingitis, oophoritis, and pelvic peritonitis. *N. gonorrhoeae* has also been implicated in premature rupture of the membranes and preterm labor/preterm birth. Failure to detect and treat gonorrhea in pregnant women also may result in neonatal gonorrheal ophthalmia, which may in turn cause blindness. For this reason, prophylactic treatment of the newborn's eyes shortly after birth with silver nitrate, erythromycin ophthalmic ointment, or tetracycline ophthalmic ointment is essential (and mandated in most states by law) to prevent gonococcal ophthalmia neonatorum.

Because of the asymptomatic start of a gonococcal infection, the prevalence of the disease, and the potentially devastating outcomes of this infection, a culture for *N. gonorrhoeae* should be included as a routine part of the annual physical examination of sexually active women and of the initial prenatal examination.

The common site of initial infection in women is in the lower genital tract. The woman is most often asymptomatic until the infection has ascended to the upper genital tract and she experiences the signs and symptoms of complications, such as pelvic inflammatory disease. She may have none, any, or all of the following:

1. lower abdominal pain
2. urethritis with tenderness, urinary frequency, and dysuria

3. expression of purulent discharge from Skene's or Bartholin's glands or the urethra
4. tenderness in the area of Skene's or Bartholin's glands (skenitis or bartholinitis)
5. acute PID (pelvic inflammatory disease) in the nonpregnant woman
6. a history of vaginal discharge, metrorrhagia, and menorrhagia
7. yellowish, purulent, or mucopurulent vaginal discharge

Diagnosis is either by culture or by DNA probe. Culture plates use Thayer-Martin medium, which must be at room temperature at the time of streaking the plate with a sample of the discharge and then immediately incubated. Refrigeration will kill the gonococci. Candle jars are used in some settings. Other settings use a transport medium, which is then recultured in the lab; but reculturing must occur within 3 hr of obtaining the specimen to avoid false negatives. While culture is the most sensitive and specific test for detecting gonorrhea, DNA probe also has a very high sensitivity and specificity. EIA are significantly lower in both sensitivity and specificity and serology is not sufficiently sensitive or specific for use [14].

Treatment for uncomplicated gonococcal infections is with the cephalosporin ceftriaxone (Rocephin) 125 mg IM in a single dose. Oral doses of cefixime (Suprax), ciprofloxacin (Cipro), ofloxacin (Floxin), or levofloxacin (Levaquin) may also be used. Cefixime does not provide equivalent sustained, high bactericidal levels in the blood. Quinolones (ciprofloxacin, ofloxacin, and levofloxacin) are contraindicated for pregnant women and for persons less than 18 years of age who weigh less than 45 kg (99 lbs). Ceftriaxone is expensive, and the injection is painful. Use of 1% lidocaine solution as a diluent may reduce the pain of the injection. If a pregnant woman cannot tolerate a cephalosporin, she should be treated with spectinomycin (2 g IM in a single dose). (See Table 15-3.)

Quinolones are not effective in the presence of quinolone-resistant gonorrhea. Quinolone-resistant gonorrhea is common in parts of Asia and the Pacific and has an increased prevalence in Hawaii and California. Therefore, quinolones (ciprofloxacin, ofloxacin, levofloxacin) are not recommended for treatment in Hawaii and California [8]. When a woman is positive for gonorrhea, a recent travel history should be obtained and correlated with her history of sexual intercourse to ensure an appropriate treatment is selected. Women who do not respond to treatment should have a culture and antimicrobial susceptibility done and her case reported to the local health department for purposes of surveillance of antimicrobial resistance [8].

All women with gonorrhea also should be treated for presumptive or diagnosed *Chlamydia trachomatis* infection, and a serology should be drawn to screen for syphilis.

The woman's most recent sexual partner should be seen, evaluated, and treated. If there is more than one sexual partner, then all partners the woman has had sexual contact with during the 60 days prior to the onset of symptoms or diagnosis should be evaluated, tested, and treated. The woman and all partners should abstain from sex until all sexual partners have completed treatment and no longer have symptoms. Follow-up for test of cure is not needed [8, p. 38]. Persistent infection is usually due to new infection or untreated chlamydia, but in their absence, and treated with a quinolone, quinolone-resistant gonorrhea must be suspected.

The woman should be informed of the etiology and course of the infection and the potential effects of the disease on her pregnancy, her postpartum recovery, and the newborn if she is infected and is not treated while pregnant. The midwife should review and discuss the woman's sexual practices, including number of partners and use of condoms. The need for her to contact and refer her sexual partner(s) for evaluation and treatment should be discussed. The woman should be instructed to abstain from sexual relations until she and her partner(s) have completed treatment and are without symptoms. Finally, she should make an appointment for her next visit.

Syphilis

Syphilis is a sexually transmitted disease caused by the spirochete *Treponema pallidum*. The disease progresses through four stages: primary, secondary, latent (early and late), and tertiary. Central nervous system disease (neurosyphilis) can occur during any stage of syphilis. The disease is transmitted through the placenta to the fetus of a woman in any stage of syphilis. Forty percent of women with untreated syphilis experience fetal or neonatal loss due to spontaneous abortion, stillbirth, or perinatal death. Another 40 percent of women give birth to babies with congenital syphilis. Congenital syphilis is a destructive disease with effects ranging from crippling lesions in the internal organs and long bones to death. The placenta of a syphilitic fetus is abnormally large and heavy with a pale yellowish-gray color. Coexisting infection with HIV is common,

and women with syphilis should be tested for HIV. The midwife should inform the consulting physician of any clinical or laboratory findings indicative of syphilis for further evaluation, treatment, and collaborative management of this disease.

Primary syphilis is characterized by a chancre, a primary ulcerous lesion, at the site of infection. It is usually single, filled with spirochete-laden purulent discharge, and highly infectious. The chancre begins as a painless papule that then erodes and becomes well demarcated with induration of the base and circumference. It appears approximately 10 to 90 days after infection and in women is more common in the genital area, on the clitoris, labia, fourchette, vulva, or cervix. Since the chancre is usually painless and heals spontaneously in two to eight weeks, it may be missed. There may be associated adenopathy. Antibody response is not measurable for three to six weeks after infection, so it is possible for a woman to have a chancre and test negative for syphilis. The antibody response, however, will be present by the time the chancre has healed.

The manifestations of secondary syphilis appear anywhere from four weeks to six months after infection (the average time is six to twelve weeks). It is possible for the rash of secondary syphilis to appear while the lesion of primary syphilis is still present. Manifestations of secondary syphilis include the characteristic papular rash of the palms of the hands and soles of the feet; patchy alopecia of head hair, eyebrows, and eyelashes; condylomata lata on the vulva or perineum; lesions of the mucous membranes, especially around the mouth; and symptoms of a systemic illness: low-grade fever, sore throat, hoarseness, malaise, headache, anorexia, and generalized adenopathy. Condylomata lata are highly contagious, flat, moist, wartlike lesions that should not be confused with the condylomata acuminata of HPV (human papillomavirus). The manifestations of secondary syphilis heal themselves within two to ten weeks, even if they are untreated. If untreated, the skin rash may recur, with less potency with each recurrence, during the next two years. High levels of antibodies are present during secondary syphilis.

Latent syphilis has no clinical manifestations. Early latent syphilis is the period of one year from the time of having acquired syphilis. Late latent syphilis is after one year of acquiring syphilis, during which the woman is seroactive but there is no evidence of the disease (i.e., no recurrence of secondary syphilis); late latent syphilis continues in the untreated woman until tertiary syphilis develops.

Tertiary syphilis can appear anywhere from one or two years after infection to 30 years or more later. It is associated with high morbidity and mortality and takes two forms: gumma and cardiovascular syphilis. Gumma are soft tissue granuloma tumors, which occur most frequently in the liver but may also occur in the brain, heart, bone, and skin. When a granuloma bursts, an ulcer forms that is painless but slow to heal and destructive of the organ and bone. Cardiovascular syphilis may result in aortic valve disease, aortic aneurysm, and coronary artery disease.

Neurosyphilis can occur in any stage of syphilis. Clinical symptoms of central nervous system disease (e.g., cranial nerve palsies, personality changes, ophthalmic or auditory symptoms, loss of reflexes) warrant examination of the cerebrospinal fluid. The disease may also present as acute syphilitic meningitis, syphilis of the spinal cord, vascular neurosyphilis, or syphilitic eye disease.

Diagnosis of syphilis depends on the stage the disease is in. The definitive methods for diagnosing primary syphilis are darkfield examination, in which the *Treponema pallidum* spirochetes are observed, and direct fluorescent antibody tests of exudate or tissue from the chancre. Screening tests follow a two-step process. First are the nontreponemal serologic tests, which demonstrate the presence of reagin (antibodies to nontreponemal phospholipid antigens) in serum. The most common are the VDRL (Venereal Disease Research Laboratory) and the RPR (rapid plasma reagin) tests. If the VDRL or RPR is positive (reactive), treponemal testing should be done; usually the FTA-ABS (fluorescent treponemal antibody absorbed) test, which uses treponemal antigens and is more specific, is preferred. If the FTA-ABS is also positive (reactive), the woman should be treated. If the VDRL or RPR is reactive and the FTA-ABS is nonreactive, the woman's history should be scrutinized for exposure to syphilis and signs of the disease. The many other conditions that would make the VDRL or RPR a false positive (such as acute bacterial or viral infections including infectious mononucleosis, leprosy, or malaria; rheumatoid arthritis; intravenous drug use; and collagen vascular disease, to name a few) should be investigated, and the tests should be repeated in a month. Because the nontreponemal tests can be serially quantified, they are also used to help identify the stage of syphilis or degree of disease activity; to ascertain new or previously treated disease (in addition to a careful history and documentation of treatment); and to determine adequacy of treat-

ment. Current infection is characterized by a fourfold increase in titer or a high titer; previously treated infection is characterized by a low titer that does not increase. Adequate treatment would show a fourfold decrease in titers. The same test (VDRL or RPR) should be used in serial testing. Although equally valid, RPR titers are often slightly higher than VDRL titers and the quantitative results from these two tests cannot be compared directly [8].

The treponemal tests cannot be used to measure the stage of syphilis, degree of disease activity, or adequacy of treatment, because once a woman tests positive, she is most likely to test positive for life. Pregnant women should be tested at their first prenatal visit and again at 28 weeks, as it is possible to have had primary syphilis at the time of the first testing and to have tested negative (see above). They also could have acquired syphilis since their first prenatal visit and not have noticed symptomatology. If a woman is diagnosed and treated for gonorrhea, chlamydia, or condylomata acuminata, she should be tested again for syphilis because of the frequency of coexisting infections. (Some clinicians would also include trichomoniasis and new cases of herpes simplex virus in this list for retesting for syphilis.) The woman should be tested again at the time of labor and delivery; this test also screens for syphilis in the baby and is preferable to testing cord blood, which can yield false negatives. Some states mandate that women be tested at the time of delivery.

Treatment of syphilis has the double goal of prevention of transmission and prevention of progression of the disease. In pregnant women, treatment includes prevention of transmission to the fetus, so that the baby will not be born with congenital syphilis. Because congenital syphilis is such a terrible disease, the possibility of a Jarisch-Herxheimer reaction to the treatment (with the possible effect of preterm labor, fetal distress, or, in rare instances, stillbirth) is not considered a reason to forgo or to delay treatment. Jarisch-Herxheimer reaction occurs within a few hours of treatment. It is an acute febrile reaction with headache and myalgia that lasts 12 to 24 hours. Congenital syphilis is a worse outcome, and the only way to prevent it is by treatment as soon as possible.

The preferred drug for treatment of all stages of syphilis is parenteral penicillin G. The preparation used, dosage, and length of treatment depend on the stage and clinical manifestations of the disease. Parenteral penicillin G is the only drug considered effective for syphilis during pregnancy. Tetracycline and doxycycline (used in nonpregnant women who are allergic to penicillin) are contraindicated during pregnancy, and erythromycin will not cure an infected fetus. The advice of the Centers for Disease Control and Prevention regarding pregnant women who are allergic to penicillin is to desensitize them and then treat them with the penicillin [8, p. 19]. The desensitization process and subsequent treatment with penicillin take several hours and should take place only under controlled circumstances in the hospital with emergency equipment ready.

The following treatment schedules are those recommended by the Centers for Disease Control and Prevention and are the same for both pregnant and nonpregnant women. See also Table 15-3. The treatment schedules are in accord with the stage of syphilis [8, pp. 20–23]:

Primary, Secondary, and Early Latent Syphilis

Benzathine penicillin G, 2.4 million units IM in a single dose

For pregnant women, a second dose of benzathine penicillin G, 2.4 million units IM 1 week after the initial dose (according to some experts)

For nonpregnant women who are allergic to penicillin, doxycycline 100 mg po BID for 14 days or tetracycline 500 mg po QID for 14 days

Late Latent Syphilis, Latent Syphilis of Unknown Duration, and Tertiary Syphilis

Benzathine penicillin G, 7.2 million units, administered in three doses of 2.4 million units IM each, at 1-week intervals

For nonpregnant women who are allergic to penicillin, doxycycline 100 mg po BID for 28 days or tetracycline 500 mg po QID for 28 days

Women with neurosyphilis require even larger doses of penicillin involving either intravenous or IM injections daily for 10 to 14 days.

Both clinical and serologic testing follow-up is imperative. For nonpregnant women treated for primary or secondary syphilis, this means clinical and serologic evaluation at 6 and 12 months postreatment with the expectation of a fourfold decrease in quantitative nontreponemal serologic test titers within six months after therapy. For nonpregnant women treated for early latent, late latent, or latent syphilis of unknown duration, follow-up testing is at 6, 12, and 24 months with the expectation of a fourfold decrease in quantitative nontreponemal serologic test titers within 12 to 24 months after therapy. For a pregnant woman with syphilis,

serologic titers may be checked monthly if she is at high risk for reinfection, but should be checked at least in the third trimester and at the time of labor and birth. Most likely, a woman will give birth before her serologic response to treatment can be definitively assessed [8]. The pediatric health care provider should be notified of the mother's diagnosis, treatment, and titers.

It is also imperative to follow up with the woman's sexual partner(s). Determination of the partners' risk for syphilis is based on when the contact was in relation to the woman's stage of disease and the duration of her symptoms (i.e., three months plus duration of symptoms for primary syphilis, six months plus duration of symptoms for secondary syphilis, and one year for early latent syphilis). Partners exposed within the preceding 90 days could be infected and be seronegative, so they should be treated presumptively even if they are seronegative at the time of evaluation. Partners exposed more than 90 days before diagnosis should also be treated presumptively if test results are not immediately available or opportunity for follow-up or compliance is uncertain.

The woman should be informed of the etiology and course of the infection, the effects of the disease on her baby if she is infected and is not treated while pregnant, and the need for notification of her sexual partner(s). She should be instructed not to have sexual relations until she and her partner(s) have been treated and titers indicate adequacy of treatment. She should be taught the signs and symptoms of primary, secondary, and tertiary syphilis and the signs and symptoms of Jarisch-Herxheimer reaction, which is common when women with early syphilis are treated. In pregnant women, it may also induce preterm labor or cause fetal distress. If the woman is pregnant when treated, she should be taught the signs and symptoms of preterm labor, how to do fetal movement counts, and when to call the midwife. Finally, the woman should be given the schedule of follow-up visits for clinical and serologic evaluation.

Genital Herpes Simplex Virus (HSV)

Herpes simplex virus has two serotypes: HSV-1 and HSV-2. HSV-1 is usually associated with oral herpes; HSV-2 is usually associated with genital herpes. However, it is not uncommon to find HSV-1 as the causative organism in genital herpes infection, most likely as a consequence of oral-genital sexual practices. HSV-1 causes up to 30 percent of first-episode cases of genital herpes. The difference is that recurrences are much less frequent for genital HSV-1 infection than for genital HSV-2 infection [8, p. 13]. This affects prognosis and counseling. After invasion of the body, HSV resides in a latent state in nervous system ganglia. HSV lesions are common in women with HIV infection [8, p. 16].

HSV is transmitted to the baby in approximately 50 percent of vaginal deliveries by mothers with an active infection. Transmission of the infection during delivery may result in neonatal death (in approximately 60 percent of those infected) or severe central nervous system or ocular damage. The baby may also contract HSV through an ascending infection if the membranes rupture or through close contact with an infected mother or care provider after birth.

It is not possible to distinguish clinically between the lesions of HSV-1 and HSV-2. The classifications of primary first episode and nonprimary first episode refer to whether there has been a previous asymptomatic infection. A primary first episode is much more severe; recurrences are much less severe.

Symptomatic primary first episodes last about three weeks. After an incubation period of 3 to 6 days, a large number of thin-walled vesicles occur singly or in clusters over the genital area, ulcerate, crust over, and undergo reepithelialization. They may become secondarily infected. Specific ulcers, diffuse inflammation, and friability may be noted over the cervix and vaginal walls. There may be a vaginal or urethral discharge. The vulvar lesions are extremely painful, and there may be pruritus and severe edema. Systemic symptoms of fever, malaise, headache, and myalgias start early after the onset of the lesions and last about a week. There is usually very tender inguinal lymphadenopathy. This clinical picture is evident in about one-third of women with newly acquired genital HSV-2 infection. The other two-thirds of primary first episodes are either asymptomatic or mild.

Recurrent episodes are about half as long as primary episodes, with fewer vesicles, no systemic symptoms, and no inguinal lymphadenopathy but do result in viral shedding. Recurring episodes usually are caused by reactivation of latent virus rather than a new infection. The latent virus that causes the eruption of a recurrent episode may come from a single ganglion, which would account for the common unilateral distribution of the lesions. The pain and itching are generally less severe. Recurrence is more likely with a more severe primary first episode and with HSV-2. There is no pat-

tern of recurrence either in general or for an individual woman. What triggers a recurrence is not known but may be associated with emotional stress; trauma; anesthesia; hormonal changes of menstruation, pregnancy, or oral contraceptive use; heat; moisture; fever; or climate changes. About half of infected women have prodromal signs of an impending recurrence consisting of itching, a tingling sensation, neuralgia, vulvar pain or burning, or increased vaginal discharge (heavy, clear, sticky, nonodorous) if the cervix or vaginal wall is involved, a few hours to a few days before eruption. Some women have the prodrome without eruption of lesions.

Because the clinical picture varies so much, a clinical diagnosis of genital herpes should be confirmed by laboratory testing. It is also important not to misdiagnose benign conditions of the genitals such as pimples, infected hair follicles, or nabothian cysts. Lesions are opened and cultured with a specific commercially prepared medium. The sensitivity of this virologic cell culture test declines rapidly as lesions begin to heal and false-negative results are common. Cervical Pap smears are even less sensitive and neither they nor the culture should be relied upon for diagnosis [8]. A negative culture or a negative smear does not rule out the disease. Type-specific serologic tests, although not 100 percent sensitive or specific, are more useful in either confirming a clinical diagnosis of genital herpes or diagnosing a woman who is asymptomatic. The most accurate tests are those that are based on the HSV-specific glycoproteins G1 and G2 for diagnosis of HSV-1 and HSV-2, respectively. The type-specific gG-based assays should be specifically requested for serologic testing [8].

There is no cure for HSV and antiviral therapy is not recommended for women without clinical manifestations of infection. Systemic acyclovir (Zovirax) (200 mg po five times a day for 7 to 10 days or until clinical resolution is attained) will reduce symptoms of a first clinical episode but has no effect on recurring infections or on the frequency and severity of recurrences once the drug is discontinued. Topical acyclovir is substantially less effective than the systemic treatment. Oral and intravenous acyclovir cross the placenta, is concentrated in amniotic fluid and breast milk, and reach therapeutic levels in the fetus [15]. (See Table 15-3 for medication regimens for first clinical episodes, recurrent episodes, and suppressive therapy.)

After the first clinical episode is over, a discussion should be held with the woman about future antiviral therapy for recurrent episodes. There are two options: episodic therapy or suppressive therapy. Episodic therapy reduces the severity of the pain and shortens the duration of the lesions. In order to be effective, episodic therapy must be initiated during the preceding prodrome or with the first day of lesions. For this reason, the midwife should provide the woman with a prescription and instructions to start treatment immediately when symptoms begin. Suppressive therapy reduces the frequency of recurrent genital herpes by 70 to 80 percent and improves the quality of life as long as the woman is on the drug. Women should discontinue suppressive therapy after a year to ascertain their natural frequency of recurrence as this decreases over time. Viral shedding is reduced but not eliminated with suppressive therapy.

There may be viral shedding and transmission of HSV even when the woman is asymptomatic. Since 70 percent of neonatal infection occurs without a maternal history of HSV infection and HSV has occurred in approximately 10 percent of babies delivered by cesarean section in which the membranes were intact, weekly testing of women with known HSV infection is not justified. The following management is suggested for various situations during pregnancy, labor, and birth [8, 15, 16]:

woman acquires genital herpes during first half of pregnancy: higher risk of transmission of herpes to her baby; avoid invasive transcervical procedures until lesions have healed; treat with acyclovir; some experts suggest continuing with suppressive therapy for duration of pregnancy; examine closely for recurrence of lesions or experiencing prodrome at time of labor and birth; may deliver vaginally if no lesions or prodrome.

woman acquires genital herpes in late pregnancy: baby is at high risk for herpes; avoid transcervical invasive procedures; may be treated with acyclovir; birth is by cesarean section.

woman has history of genital herpes: some experts advocate suppressive therapy with acyclovir starting at 36 weeks' gestation to reduce the frequency of recurrence at term; if no lesions or prodrome at time of labor and birth, she may give birth vaginally—cesarean section is not warranted.

woman at term has active genital herpes lesions or symptoms of prodrome: birth is by cesarean section.

woman at term has active genital herpes and membranes rupture: immediate cesarean section.

woman with preterm rupture of membranes and active genital herpes: some experts advocate ex-

pectant management and treatment with acyclovir to gain the benefits of time and glucocorticoids; avoid invasive transcervical procedures; mode of birth depends on the presence of active lesions or prodrome at the time of birth.

woman has recurrent active herpes lesions in only nongenital areas of her body (e.g., buttock, thigh, foot): may deliver vaginally; cover lesions with an occlusive dressing prior to birth.

postpartum woman with active herpes: may breastfeed if no lesions on her breasts, otherwise contraindicated; attention to handwashing before handling her baby is vital.

The diagnosis of this chronic, painful sexually transmitted disease is shattering to women. Time should be taken by the midwife to help a woman through her initial reaction and beginning efforts to cope. In addition, the woman should be instructed not to douche, not to have sexual relations until reepithelialization has occurred, and to always use condoms during intercourse. She should also be given information on the following topics:

1. etiology and course of infection
2. recurrences and possible prodrome
3. effects of the disease (if the woman is pregnant) on the baby of a recurrence at the time of delivery; necessity for cesarean section in that case
4. importance of informing obstetric health care providers that she has HSV infection
5. importance of telling her sexual partner(s) and future sexual partner(s) that she has HSV infection
6. need for careful handwashing to prevent spread of virus to mouth or eyes, particularly when caring for a baby
7. comfort measures:
   a. Keep the lesions dry; use a hair dryer on the cool setting.
   b. Wear soft cotton underwear.
   c. Wear loose-fitting clothing.
   d. Use pain medication such as aspirin (except during pregnancy) to reduce inflammation and relieve pain.
   e. If she is having trouble walking, use topical analgesic ointment or spray.
8. need for annual Pap smears
9. referral to a support group, if desired
10. importance of making an appointment for her next visit

Sexual partners should be informed. Symptomatic partners should be evaluated and receive the same treatment (see Table 15-3). Asymptomatic sex partners should be offered type-specific serologic testing and instructed on how to recognize symptoms of herpes.

Condylomata Acuminata (Genital Warts; Venereal Warts)

Condylomata acuminata are caused by human papillomavirus (HPV). HPV infection is classified as clinical, subclinical, or latent. Condylomata acuminata represent the clinical manifestation of HPV, are most often caused by HPV types 6 and 11, and are the most common sexually transmitted viral disease. The incidence of condylomata acuminata is at least three times that of genital herpes simplex virus; one or more of the over 60 genotypes of HPV infect about one-third of the sexually active population [17]. Approximately 10 percent of these genotypes manifest themselves as condylomata or dysplasia.

HPV infection is associated, in concert with facilitating co-factors, with the development of cervical dysplasia that leads to premalignant and malignant epithelial lesions in the lower genital tract. Papillomaviruses are epitheliotropic viruses that infect the surface epithelia and mucous membranes. This infection produces warts and epithelial proliferations. Over 90 genotypes of HPVs have been identified, 21 of which occur predominantly or exclusively in the anogenital area. HPV types may be grouped according to their association with cancer, with HPV 6, 11, 42, 43, and 44 considered low-risk types; HPV 33, 35, 39, 40, 45, 51–56, and 58 considered medium- or intermediate-risk types; and HPV 16, 18, and 31 considered high-risk. Intermediate-risk and high-risk viruses are considered to have the potential to produce tumors, especially malignant tumors. HPV types 16 and 18 are most frequently associated with anogenital cancers. These viruses are found in approximately 60 to 95 percent of anogenital cancer tissue samples [18].

Less than 1 percent of women with HPV infection, however, develop cervical cancer. This means that HPV alone does not result in neoplastic cell changes. For cellular changes to occur with HPV infection, there must be additional co-factors such as smoking, history of sexually transmitted diseases, and more than three sexual partners over a lifetime.

Condylomata acuminata are seen in the vulvar, perineal, and perianal areas but may also be found attached to the vaginal walls, on the cervix, and in the urethra, anus, and mouth. The characteristic warts of condylomata acuminata may start as single

growths but usually come together in clumps that have a cauliflower appearance, with the head of the clump larger than the portion that attaches to the genitalia. Vaginal condylomata acuminata are also usually multiple, raised, and white and may bleed after sexual intercourse. Cervical condylomata acuminata may be single and flat and more difficult to distinguish from condylomata lata. There usually is an associated discharge, and the condition is exaggerated by untreated vaginitis/cervicitis. Women with condylomata acuminata should also be screened for syphilis, gonorrhea, chlamydia, trichomonas, and bacterial vaginosis.

Diagnosis is by gross observation and careful history and laboratory tests to rule out syphilitic condylomata lata. Condylomata acuminata frequently increase in size and number during pregnancy, perhaps stimulated by the leukorrhea of pregnancy, and regress after the woman gives birth. If birth occurs while condylomata are still present, care must be taken to avoid tearing or cutting into any of them because they may bleed excessively. The skill of the midwife in helping a woman give birth over an intact perineum decreases this risk. If an episiotomy absolutely must be cut, it is far better to cut an episiotomy in an unusual direction than to cut through condylomata acuminata. Extensive growth in the vagina and over the cervix may necessitate delivery by cesarean section because of dystocia. The pediatric health care provider should be notified when a baby is born vaginally to a woman with condylomata acuminata because these babies have an increased risk of developing laryngeal papillomatosis (vocal cord polyps). Cesarean section does not eliminate this risk. The presence of condylomata acuminata is not an indication for colposcopy as genital warts are not associated with the development of cervical cancer [8].

Treatment at all times is directed toward making the woman more comfortable and takes the form of attempts to eradicate the condyloma. Treatment during pregnancy is additionally directed toward reducing the possibility of the bulk of the condylomata acuminata complicating delivery. Treatments abound, but there is no guaranteed cure for condylomata acuminata or for HPV. Even surgical removal is followed by a high incidence of regrowth. As there is the possibility of spontaneous resolution of the warts and treatment is not without side effects, a woman may choose not to be treated.

The standard provider-administered topical treatment for external genital condylomata acuminata is a 10 to 25% solution of podophyllin in tincture of benzoin applied carefully to each wart without touching and chemically burning the surrounding tissue. You can protect the surrounding tissue by first covering it with petroleum, but be careful to not get the petroleum on the warts, which would render the treatment ineffective. If the condylomata acuminata are extensive, the treatment should be divided into weekly intervals so as not to trigger local and systemic side effects. The woman should wash the podophyllin off one to four hours after application. If she tolerates the initial treatment well with minimal inflammation and pain, then the solution can be left on for four to six hours with the next treatment. Podophyllin cannot be used for anal, vaginal, cervical, or oral condylomata acuminata, and is contraindicated in pregnancy. Possible systemic absorption is a concern.

The other standard topical treatment is trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80 to 90%, which can be used not only for external genital warts but also for vaginal and anal warts by both nonpregnant and pregnant women. Again, the surrounding skin should be protected to avoid burns. Apply sparingly and allow to dry before the woman sits or stands. The external layer of the warts turns white. Sodium bicarbonate can be used to counteract any burning the woman may feel from the treatment on the warts.

If topical treatment does not work, referral to your consulting physician for further evaluation and treatment such as cryotherapy, laser, or surgical removal may be indicated. As there is no evidence that reinfection plays a role in recurrence, there is no need to examine the sexual partner(s).

Any existing vaginal or cervical infection should be treated, and the moist environment created from the discharge should be reduced. Large clumps of external condylomata acuminata create hygienic and psychosocial-sexual difficulties. Vaginal discharge and feces may be entrapped in the clumps and cause a foul odor. Careful cleaning, a sitz bath after each bowel movement and when needed, and frequent change of cotton underwear will help promote cleanliness and dryness and help control the problem of odor. The aesthetics of having large, uncomfortable condylomata negatively affect the woman's self-image and sexual life.

The woman should be given information on the etiology and course of the infection, on the need to

discuss the infection with any sexual partner, and (if she is pregnant) on the possible effects of the infection on her giving birth and the baby. In addition, she should be given the following instructions:

1. Use condoms during sexual intercourse.
2. Do not engage in sexual intercourse during treatment.
3. Schedule annual Pap smears.
4. Comfort measures:
   a. Have any vaginal/cervical infections treated.
   b. Be sure to wash hands carefully.
   c. Be sure to clean carefully after bowel movements; use a sitz bath.
   d. Use a hair dryer on the cool setting to keep the area dry.
   e. Change cotton underwear frequently.
5. Make an appointment for her next visit.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) comprises any combination of endometritis, salpingitis, oophoritis, tubo-ovarian abscess, and pelvic peritonitis. The usual organisms involved in PID are *Neisseria gonorrhoeae* or *Chlamydia trachomatis* and perhaps the organisms involved in bacterial vaginosis. What starts out as a lower genital tract infection (vaginitis/cervicitis/urethritis/skenitis/bartholonitis) ascends, for a variety of reasons, past an altered cervical mucous barrier to become an upper genital tract infection. The cervical mucous barrier may be altered by menstruation or the influence of hormones. The ascension may be facilitated by douching, dilatation and curettage, and sperm. The ascension is first to the endometrium and then to the fallopian tubes, aided by sperm or by menstrual blood reflux. The inflammatory process in the tubes eventually leads to inflammation of the peritoneum [19].

Risk factors include exposure to *N. gonorrhoeae*, *Chlamydia trachomatis*, and bacterial vaginosis; multiple sexual partners; and douching practices. Diaphragms and cervical caps used with vaginal spermicides, and condoms decrease the risk of PID. The possible sequelae of PID include infertility due to tubal adhesions, ectopic pregnancy, chronic lower abdominal pain due to pelvic adhesions, and increased susceptibility to recurrence.

A woman may have very subtle symptoms of PID, so you must have a constant high suspicion level in order to diagnose it early in the infectious process. The earlier the diagnosis and treatment, the less severe the sequelae. An infected woman may experience lower abdominal pain, generally bilateral, which may or may not be severe. She most likely will have a vaginal/cervical mucopurulent discharge indicative of the infecting organism. If the urethra is involved, she will have the symptoms of urethritis: dysuria, frequency, and urgency. Metrorrhagia is a common symptom of endometritis. Fever above 101°F and nausea/vomiting are signs of clinical severity of the disease and reflect peritonitis. Upon pelvic examination you will find cervical motion tenderness, bilateral adnexal tenderness, and adnexal enlargement if the disease is well established in the fallopian tubes. Leukocytes will outnumber the epithelial cells in a wet mount. The woman will have an elevated erythrocyte sedimentation rate.

Midwives should treat empirically when a woman presents with cervical motion tenderness (CMT) or uterine/adnexal tenderness, there is no other cause for her pain (e.g., ectopic pregnancy; acute appendicitis), and she is sexually active. Prevention of long-term sequelae is linked with early treatment based on a presumptive diagnosis [8]. If the woman has an IUD, it should be removed either at the time of initiating antimicrobial treatment or shortly thereafter. Laboratory tests that document *N. gonorrhoeae* or *Chlamydia trachomatis*, leukocytosis, and an elevated sed rate increase the specificity of the diagnosis.

Hospitalization is indicated in the event of an uncertain diagnosis, suspected pelvic abscess, severity of symptoms including fever and nausea/vomiting, HIV, failed outpatient therapy, or pregnancy (in which case it is necessary to rule out ectopic pregnancy and outpatient therapy drugs are contraindicated). Treatment within the hospital is with intravenous broad-spectrum antimicrobial agents.

If the woman does not fall into the categories indicating need for hospitalization and it is the midwife's best judgment that the woman will comply with the regimen (including a clinical reevaluation within 72 hours), the midwife initiates outpatient treatment. Discussion with your consulting physician is appropriate if further evaluation by laparoscope or hospitalization or intravenous therapy are necessary. Following are the 2002 guidelines for outpatient treatment from the Centers for Disease Control and Prevention [8]. Treatment of PID has to cover both of the likely pathogens, *N. gonorrhoeae* and *Chlamydia trachomatis*, plus the other

possibilities, such as anaerobic bacteria. Negative endocervical screening does not preclude infection in the upper genital tract [10].

Regimen A

ofloxacin 400 mg po BID × 14 days, **or**
levofloxacin 500 mg po BID × 14 days, **with or without**
metronidazole 500 mg po BID × 14 days

Regimen B

cefoxitin 2 g IM plus probenecid 1 g po in a single dose concurrently, **or**
ceftriaxone 250 mg IM, **or**
Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime), **plus** (**for both options in Regimen B**)
doxycycline 100 mg po BID × 14 days, **with or without**
metronidazole 500 mg po BID × 14 days

If there is no clinical response within 72 hours, the woman should be hospitalized.

Instructions to the woman should emphasize the need to take all medications on schedule and to call you if her symptoms get worse. Other instructions are the same as those given for bacterial vaginosis, chlamydia, and gonorrhea. The woman may need time to express any concerns/anger she may have about potential infertility. The incidence of infertility increases with repeated episodes of PID, so in-depth counseling regarding prevention and her sexual practices is indicated. Her male sexual partner(s) during the sixty days preceding her onset of symptoms should be evaluated. Because the partner may be asymptomatic, the partner should be treated empirically for both *N. gonorrhoeae* and *Chlamydia trachomatis* as he most likely will have a urethral infection with one or the other of these organisms.

Anaphylactic Shock

Anaphylactic shock is a severe allergic reaction that may end in death. It is included here because this disastrous event may occur in individuals who are unknowingly allergic to penicillin. Allergic reactions may also occur in response to cephalosporins such as ceftriaxone (Rocephin) or cefixime (Suprax). A careful history of any previous evidence of sensitivity to penicillin or to cephalosporins should be obtained prior to both prescribing and administering these drugs.

The signs and symptoms of anaphylactic shock include the following:

1. diffuse urticaria
2. rhinitis
3. laryngeal edema
4. dyspnea
5. wheezing
6. marked pallor
7. hypoxia
8. cyanosis
9. tachycardia
10. convulsions
11. hypotension
12. pupil dilatation
13. vascular collapse
14. cardiac arrest

Anaphylactic shock is a very frightening experience, as the woman finds her airway closing. She may have a panic reaction. Knowing these signs and symptoms gives you and the woman the best chance to stop the progress of the reaction before it gets to convulsions, vascular collapse, cardiac arrest, and death. The reaction is exacerbated by a panic reaction. The woman needs to stay calm and concentrate on breathing as slowly and deeply as she can. Emergency treatment includes epinephrine, corticosteroids, and oxygen. Intubation may be required. Antihistamines are useful for lesser reactions or very early evidence from erythema or urticaria of a more severe reaction, which may lead to anaphylactic shock. If the woman is not in a hospital, parenteral penicillin and cephalosporins should only be given in a setting that has the necessary emergency drugs and equipment for life support pending transport to the hospital.

Family Planning and Contraception

History and Concepts of Family Planning

From earliest times, people have attempted by various means to prevent conception. They have tried magic, potions, and the insertion into the vagina or uterus of a variety of items such as stones, shells, coins, bottle caps, buttons, and jewelry. Bottled carbonated beverages have been used as high-pressure douches, and various materials, such as transparent kitchen wrap (e.g., Saran Wrap), have been wrapped around the penis in attempts to contain sperm as a condom does. These homemade "contraceptives" not only are useless but also are dangerous. Their use can cause mutilation or lead to sterility due to infection. These are not simply examples from antiquity. Many people still use such dangerous, nonmedical, and futile methods. Nearly half (48 percent) of all pregnancies in the United States are unintended [1]. Efforts must be made to replace folklore and ignorance with education and access to safe and effective contraceptive methods.

Great strides were made in the twentieth century in the area of family planning and its related fields. The topics, once taboo in public, are now widely discussed and debated. In 1910 a nurse, Margaret Sanger, began her historical and heroic fight for the right of families to limit their size, the right of women to health and freedom from their biological makeup, and the right of children to the love they receive when they are wanted and planned for.

Before the federal government became involved in family planning, the family planning movement in the United States was spearheaded by Planned Parenthood–World Population. This organization was founded in 1916 by Margaret Sanger as the Planned Parenthood Federation of America. It is a member and major financial supporter of the International Planned Parenthood Federation, which was also established by Sanger. Planned Parenthood–World Population was organized into regional offices and hundreds of family planning centers throughout the United States, operated by local affiliates. The historical concern and involvement of prominent citizens and organizations such as the Ford Foundation, the Rockefeller Foundation, and the Pathfinder Fund during that time greatly facilitated the national and international development and expansion of family planning programs.

National concern was first demonstrated by the Congress and the federal government through the provision of support for both domestic and international family planning programs in 1965. The Department of Health, Education and Welfare at that time created the position of Deputy Assistant Secretary for Population and Family Planning, established the National Center for Family Planning Services, and initiated programs through the Office of Economic Opportunities and various antipoverty programs. The United States Agency for International Development (USAID) has spearheaded the federal international program and is the largest single source of international population assistance.

The terms *birth control*, *contraception*, and *family planning* are often used interchangeably, although they are not identical in meaning. The term *birth control* has been attributed to Margaret Sanger. It refers to regulation of the number of children that are conceived or born. *Contraception* refers to the temporary prevention of pregnancy,

which is accomplished through the use of specific contraceptive, or birth control, methods. *Family planning* has the broadest connotation. It encompasses the additional considerations of the physical, social, psychological, economic, and religious factors that govern a family's attitudes about and influence decisions pertaining to the size of the family, the spacing of children, and the selection and use of a birth control method. The subject of family planning also encompasses the global ramifications of world population and issues of overpopulation, decreasing living space, and limited food; the theological acceptability of various methods of birth control; the physical and physiological hazards to an individual woman caused by continuous, repeated childbearing; maternal mortality; the role of women in a society; disease prevention and health promotion; and the rejection and abuse of unwanted children.

The ability to be effective in helping women or couples with family planning may be enhanced or hindered by the feelings and attitudes of the midwife regarding each of the following as it relates to family planning:

1. sex and sexuality
2. religion
3. race/ethnicity
4. economic status
5. marital status

Midwives, like all those who provide health care to women in a family planning clinic or any other setting, need to scrutinize their own feelings and attitudes in these five areas.

Any accusations that family planning promotes genocide can be averted by focusing on what should be basic rights for every woman:

1. the right to have a baby when she wants one
2. the right to be a healthy mother bearing a healthy baby

Selection of a Contraceptive Method

Before a specific contraceptive method is chosen, an individual or couple must first decide whether to practice family planning. A number of factors may influence this decision, including the following:

1. *Sociocultural factors:* current trends in family size; the effect on an individual of the size of the family in which the individual grows up; the importance the society places on having children; the importance the society places on having a male child to perpetuate the family name; whether the society posits a direct correlation between the number of children a man fathers and his virility; the social value of being a "woman" only if she has "given" a child to her partner.
2. *Occupational and economic factors:* the possibility of lengthy separation during military duty; the need to channel economic resources into school or the beginning of a vocation or business; economic ability to provide prospective children with food, clothing, shelter, medical and dental care, and future education; unemployment; homelessness.
3. *Religious factors:* endorsement of the principle of family limitation and the basic concept of family planning by all major religions.
4. *Legal factors:* elimination of all legal barriers to practicing family planning since the Connecticut state law that prohibited the use of any device for the purpose of preventing conception was declared unconstitutional by the Supreme Court in 1965.
5. *Physical factors:* conditions requiring that a woman not become pregnant for health reasons; age and the ticking of the "biological clock"; unhealthy lifestyles (e.g., alcoholism, drug abuse, cigarette smoking, bulimia, anorexia, gross obesity); use of teratogenic medications.
6. *Relationship factors:* stability of the relationship; the crisis period and innumerable adjustments caused by having a child.
7. *Psychological factors:* the need to have a child to love and be loved by; pregnancy considered proof of being loved (these two factors are common reasons for adolescent pregnancies); the erroneous belief that a child will hold together a disintegrating relationship; fear of childbearing or childrearing; threat to present lifestyle posed by parenthood.
8. *Current health status and genetic history:* the presence of or potential for conditions or diseases that can be passed to the baby (e.g., HIV, AIDS, Tay-Sachs, Huntington's chorea, sickle cell anemia).

If the decision of the individual or couple is to practice family planning, still other factors might influence their choice of a contraceptive method. Selection of a method is a matter of choice by the individual or the couple as long as there are no medical contraindications to the method chosen. This is sometimes called the "cafeteria" approach to family planning. Table 16-1 shows the percent-

TABLE 16-1 Percentage and Number of Women at Risk and Percentage at Risk Currently Using Various Methods, from the 1995 National Survey of Family Growth

	Percent Using among Women at Risk[1]						
Age	*15–44*	*15–19*	*20–24*	*25–29*	*30–34*	*35–39*	*40–44*

Implant	1.3	2.2	3.4	1.9	0.6	0.3	0.1
Spermicides	1.3	0.8	1.1	1.6	1.4	1.0	1.8
Intrauterine device	0.7	0.0	0.3	0.7	0.8	0.9	1.2
Other[2]	0.1	0.0	0.1	0.0	0.3	0.1	0.5
Female condom	0.0	0.0	0.1	0.0	0.0	0.0	0.0
	Number of Women in Cohort, Percent and Number at Risk[1]						
Number (millions) of women	60.2	9.0	9.0	9.7	11.1	11.2	10.2
Percent at risk	69.4	36.9	69.4	74.0	77.1	77.2	76.6
Number (millions) at risk	41.8	3.3	6.3	7.2	8.5	8.7	7.8

[1] At risk = those who EITHER are current contraceptive users OR are nonusers who have had sex in the past 3 months and are not trying to become pregnant, are not pregnant, or were not interviewed within 2 months after the completion of a pregnancy and are not sterile. Percentages may not add to 100 due to rounding.

[2] Other methods = cervical cap, sponge, and other unspecified methods.

Source: Reprinted by permission from Hatcher, R. A., et al., *Contraceptive Technology*, 17th rev. ed. New York: Ardent Media, 1998, p. 213.

age of women who are at risk for getting pregnant using each birth control method.

A couple or an individual has a need and a right to know the potential dangers and side effects of the different methods in order to make a decision. This information should be included in the general information presented about each contraceptive method. Many private offices and clinics require that women sign consent forms indicating that they understand the risks involved and acknowledging receipt of the specified method. This procedure is always followed for an IUD.

Barring medical contraindications, the factors that may influence the individual's or couple's selection of a contraceptive method include the following:

1. desire for permanent or temporary birth control
2. effectiveness of a given method; contraceptive method effectiveness varies widely (see Table 16-2). A little over half of women with unintended pregnancies (53%) become pregnant during a month they were using a contraceptive method [2]
3. Influence of the media (emphasis on positive or negative aspects or side effects of a method)
4. Possible side effects and questions of safety related to any method
5. Possible health benefits related to any method
6. Ability of a method to prevent disease (HIV; sexually transmitted diseases; cancer)
7. Length of anticipated use of a contraceptive method
8. Cost
9. Frequency of sexual intercourse
10. Number of sexual partners
11. Social factors (current social trends in the use of various methods)
12. Religious factors (whether a specific method is sanctioned by the religious body to which the couple or individual belongs)
13. Psychological factors (feelings about any aspect of a specific method, e.g., procedure involved,

TABLE 16-2 Percentage of Women Experiencing an Unintended Pregnancy Within the First Year of Typical Use and the First Year of Perfect Use and the Percentage Continuing Use at the End of the First Year: United States

	% of Women Experiencing an Unintended Pregnancy within the First Year of Use		% of Women Continuing Use at One Year[1]

Female sterilization	0.5	0.5	100
Male sterilization	0.15	0.10	100

Emergency Contraceptive Pills: Treatment with COCs initiated within 72 hours after unprotected intercourse reduces the risk of pregnancy at least 60–75%. Pregnancy rates lower if initiated in first 12 hours.[10] Progestin-only EC reduces pregnancy risk by 85%.

Lactational Amenorrhea Method: LAM is a highly effective, temporary method of contraception.[11]

1 Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year

2 Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason

3 Among typical couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason

4 The percentages becoming pregnant in columns 2 and 3 are based on data from populations where contraception is not used and from women who cease using contraception in order to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85) to represent the percentages who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether

5 Foams, creams, gels, vaginal suppositories, and vaginal film

6 Cervical mucus (ovulation) method supplemented by calendar in the pre-ovulatory and basal body temperature in the post-ovulatory phases

7 With spermicidal cream or jelly

8 Without spermicides

9 The median one-year continuation rate for 10 studies in the 1990s was 42%

10 The treatment schedule is one dose within 72 hours after unprotected intercourse, and a second dose 12 hours after the first dose

11 However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breastfeedings is reduced, bottle feeds are introduced, or the baby reaches 6 months of age

Tiger, GA: Bridging the Gap Foundation, 2001, p. 36; and from Hatcher, R. A., et al. *Contraceptive Technology*, 17th rev. ed. New York: Ardent Media, 1998, pp. 216–217.

whether it is associated with the sexual act, unfavorable past experience with a method)

14. Ease of using a particular method (ability of the individual to master the techniques involved in using a specific method, e.g., cervical cap, diaphragm; or what the individual has to undergo to have the method, e.g., IUD, sterilization procedure; or whether the individual is a reliable pill taker)

Effectiveness of a Contraceptive Method

Determining the effectiveness of a contraceptive method is a complex process based on the proportionate reduction in the monthly probability of conception. Since it is not possible to ascertain the proportion of women who would have become pregnant had they not used the contraceptive method under investigation, it is not possible to measure effectiveness directly [3, p. 215]. Instead, failure rates, or probability-of-failure rates, are calculated. Two major factors affect the likelihood that a contraceptive method will fail to protect the user [4]:

1. inherent efficacy of the method itself when used consistently and correctly. This factor is expressed as a "perfect use" statistic.
2. the human factor (user characteristics), including motivation, ability to master any technique required to use a method, inconsistent use, and inconsistent correct use. This factor is expressed as a "typical use" statistic.

The difference between perfect use and typical use yields another piece of information, which is how "forgiving" a method will be of typical or imperfect use. The narrower the margin of difference, the more forgiving a method is; the wider the margin of difference, the less forgiving the method is and the more apt a woman is to become pregnant while using the method.

The efficacy of particular contraceptive methods is addressed in the next several chapters. If a contraceptive method fails as a result of human error, the failure may be due either to improper use of the technique or to weak motivation. Some users may not have sufficient knowledge of pertinent reproductive anatomy and physiology, may not understand the method and how it works, or may not be able to master the skills needed to use the method. For one or all of these reasons, therefore, they do not use the method correctly. Motivation, however, is the dominant factor in human error. How strongly a couple or individual wishes to prevent a pregnancy directly affects the degree of regularity with which a contraceptive is used. Any method will fail if it is not used consistently. A major cause of contraceptive failure due to human error is irregular use of a method. However, in some cases the factors that might lead to human error, such as the individual's or couple's lack of acceptance of the procedure involved, may be counterbalanced by their motivation.

Two basic methods of calculating the effectiveness or failure rate of contraceptive methods have been used: the *Pearl Index* and the *Life-Table Index*. The Pearl Index is a formula, developed by Raymond Pearl in the early 1930s, that calculates the clinical (use) effectiveness of a contraceptive method according to the pregnancy rate per 100 years of exposure (or woman years). The pregnancy rate (pregnancies per woman years) is equal to

$$\text{number of pregnancies} \times 1200 \text{ months}$$

The *number of pregnancies* in the numerator refers to the total of three statistics that are generally available or that can be calculated: the numbers of live births, stillbirths, and abortions among those using a given method. The *1200 months* in the numerator refers to the number of months in 100 years (100 × 12 months). The *months of exposure* in the denominator refers to exposure to the possibility of pregnancy and is determined by deducting those months during which conception was impossible (e.g., months when a couple were physically separated or a woman was already pregnant) from the total months the man and woman were together. For example, suppose that 200 couples used a contraceptive method over an average period of two years and that 60 of the women became pregnant despite its use:

$$\text{Pregnancy rate} = \frac{60 \times 1200}{4800} = \frac{72{,}000}{4800} = 15$$

The effectiveness this contraceptive method is calculated to have is a pregnancy rate of 15 per 100 woman years.

For all sexually active couples not using a contraceptive method, the average pregnancy rate is 90 per 100 woman years. The effectiveness of a contraceptive method is considered to be high if the pregnancy rate is below 10 per 100 woman years (years of exposure); moderate if the pregnancy rate is between 10 and 20; and low if the pregnancy rate is more than 20.

The Pearl Index method of calculating the effectiveness of a contraceptive method has been criticized because it treats all data equally for whatever period of time is studied. The problem with this averaging of data is that the risk of pregnancy with any contraceptive method is highest during the first year of use and declines thereafter.

Today, most researchers use life-table rates to calculate the effectiveness of a contraceptive method, rather than the Pearl Index. Life-table rates treat each month of contraceptive use separately, thus controlling for the decreasing risk of pregnancy over time, and then compute these individual months cumulatively up to whatever point is desired (e.g., 12 months). Life-table rates express effectiveness of a contraceptive method as the number of pregnancies per 100 women in the first 12 months of use, in contrast to the Pearl Index, which expresses effectiveness of a contraceptive method as the number of pregnancies per 100 woman years.

Effectiveness rates estimated by one method cannot be mathematically translated into rates for the other method. The actual rates calculated by the two methods are not that much different for long-term studies but may be more importantly different regarding the first year of use.

In reading the family planning literature, it is important to know which statistical method was used to calculate failure rates or the effectiveness of a given method. Table 16-2 shows life-table calculations of failure and continuing use rates. The sixteenth and seventeenth editions of Hatcher's *Contraceptive Technology* include a series of tables that summarize studies of contraceptive failure by contraceptive method and shows the life-table or Pearl Index rates calculated by the researchers [3, pp. 803–844; 4, pp. 655–687].

Folklore Methods

Individuals or couples should be advised not to use "folklore" methods of contraception. These are either so-called contraceptive methods of long-standing reputation that, because of a basic fallacy in concept and low efficacy, might as well be labeled as folklore or products that, because of misleading advertising or misunderstanding or ignorance on the part of consumers, are thought to be contraceptive in action but are not. Folklore methods include the use of douches, the practice of coitus interruptus, and the use of vaginal cleansing agents.

Douches

One of the most common erroneous ideas is that douching following sexual intercourse is a contraceptive method. The notion is that a woman can flush the semen out of her vagina before the sperm can enter her uterus if she douches immediately following ejaculation. However, the majority of sperm are contained in the first few drops of ejaculate; furthermore, within 90 seconds of the deposit of semen at the cervical os, sperm have entered the cervical canal. The fact that it is almost impossible for a woman to douche within this period of time renders the entire supposition invalid.

Various reports in the past using the Pearl Index stated a pregnancy rate in excess of 30 per 100 years of exposure for couples using douches as a contraceptive method. This rate makes douching better than no contraceptive method at all—however, such low efficacy scarcely recommends the douche as a reliable method of contraception.

Coitus Interruptus

Coitus interruptus, commonly known as "being safe," "being careful," or "withdrawal," is based on the fact that the male can feel when he is about to ejaculate. This method depends on the male's withdrawing his penis from the vagina at exactly this moment and ejaculating outside of the woman's vagina. This action relies on split-second timing and ideal self-control by the male. If the male is late in withdrawing, even by a fraction of a second, the first few drops of semen, which contain the majority of sperm, are deposited in the vagina. The method also may fail if the male ejaculates on the external female genitalia.

Many couples have used coitus interruptus at least occasionally, and it is recommended in the absence of an authentic contraceptive method. Some couples have been satisfied with coitus interruptus as a contraceptive method and have used it successfully. However, coitus interruptus has been blamed for many family planning failures and has received much criticism. The male may not always be psychologically able to withdraw at the climax of sexual intercourse, and men frequently object that coitus interruptus limits full sexual gratification.

Vaginal Cleansing Agents

Vaginal cleansing agents are sometimes advertised as being "for feminine protection." This phrase often is misunderstood to mean protection from

pregnancy, when what is meant is protection from "smelling less than pretty." Not only are such agents unnecessary for female hygiene (and may indeed temporarily mask or worsen vaginitis), they also do not contain any spermicidal ingredients; nor do they even change the pH of the vagina to render it more hostile to sperm.

Sterilization

Sterilization is the surgical interruption or closure of pathways for sperm or ova, which prevents fertilization. The two methods of sterilization are vasectomy and tubal ligation. Although hysterectomy certainly is a permanent form of sterilization, it is a major surgical procedure with associated morbidity, and it is generally not done even in conjunction with cesarean section solely for the purpose of sterilization. Sterilization is considered a permanent birth control method. The midwife refers the woman or man to a physician for the surgical procedure desired.

Female sterilization can be accomplished either by literally blocking the fallopian tubes with a plug or by means of an inflammatory reaction induced by the chemicals in specific drugs or by cutting and interrupting the fallopian tubes so that the ovum and the sperm cannot meet. The blocking methods are as yet beset with a number of insertion or placement problems and side effects ranging from foreign-body reactions (to the silicone plug) to toxic psychosis (induced by the antimalarial drug quinacrine).

There are several methods of female sterilization done by laparoscopy. These include cauterization, silactic bands, and clips. Cauterization has a risk of subsequent fistula development and ectopic pregnancy with a 2.5 percent failure rate [5, 6]. Although the clips provide the greatest possibility for reversibility, the spring clip (Hulka-Clemens clip) also has the highest failure rate [6].

Ligating and then cutting and interrupting the fallopian tubes is by far the most effective means of female sterilization. If the tube is excised, the ends either retract or are deliberately buried in the uterine myometrium (proximal portion) and the broad ligament (distal portion). The procedure can be performed at any time, usually under general anesthesia. There is a large positive association between tubal sterilization and reduced risk of ovarian cancer [7]. Efforts at reversing this permanent sterilization procedure have high failure rates. In vitro fertilization would be the only other possible means for childbearing.

Male sterilization involves the same principles as tubal ligation. In a vasectomy the vas deferens is ligated and then closed by excision, cautery, or mechanical devices. The outpatient procedure is done under local anesthesia.

Vasectomy is safer than tubal sterilization, with less morbidity and mortality. It is simpler because the vas deferens is more easily accessible; it is more effective and less expensive. Men who have a vasectomy need to use a back-up method of contraception until the sperm count reaches zero. Reversibility is possible with microsurgery and will result in pregnancy over half of the time and in a return of sperm in ejaculate in over 90 percent of men [5, pp. 134, 136].

When counseling a woman or a couple about their alternatives for family planning, a midwife should include the permanent methods of birth control along with the temporary methods of contraception. Sterilization is the most popular method of birth control both in the United States and worldwide. However, neither male nor female sterilization is protective against HIV or sexually transmitted diseases. Table 16-1 shows that in the United States over one-quarter of women and just over 10 percent of men between the ages of 15 and 44 use sterilization. For women and men between the ages of 40 and 44, the numbers almost double, with nearly 47 percent of women and 19 percent of men sterilized.

Counseling for sterilization requires a knowledge of local resources and medical practices and should include answers to the following questions:

1. What sterilization methods are available? Where? Performed by whom? Precisely which procedures are used? How long does the procedure take?
2. How much will each method cost? What financial aid is available?
3. What will the surgery really mean in terms of what body structures get touched, changed, or possibly disfigured? How long will the woman/man be unable to work? How long will the woman/man be too uncomfortable for sex? Is the procedure reversible? What are the possible complications?

In addition, counseling should focus on eliciting and talking about the common fears and misconceptions related to sterilization. The most prevalent of these is the fear of "being changed"—experiencing a decrease in sexual desire, functioning, or en-

joyment—which is not true except as affected by the psyche.

The midwife should be thoroughly knowledgeable about the federal, local, and institutional requirements regarding sterilization procedures. These regulations are designed to ensure that no one is sterilized who is mentally incompetent or is not fully informed, and and to ensure adequate time to think about the procedure. Spousal consent is not legally required. The woman who wants a tubal ligation at the time of childbirth or in the immediate postpartum period must sign the informed consent papers early enough during the prenatal period for all the requirements to be met.

Future Methods of Contraception

It is well known and undisputed that the ideal contraceptive method has not yet been developed. The search continues for a method that is 100 percent effective and safe, free from side effects, easy to use, unrelated to the sexual act, and acceptable to all religions. New contraceptive methods are being explored, and existing methods are being studied for improvement. Basic in the research are the causes of side effects, the possible relationship between a given method and disease (safety), and the mechanisms of action. It is important that a means of predicting ovulation time accurately at least four days in advance be developed.

Potential new contraceptive methods that are types of existing methods (e.g., barrier methods, hormonal methods) will be discussed in the relevant chapters. This section will review methods that represent potential new types of contraception.

Vaccines

The immunologic approach to fertility control is fraught with problems, but the major one is finding an antigen that will be unique to the reproductive tract and will not cause a reaction in tissue outside of the reproductive system. Several hormones have been considered, especially human chorionic gonadotropin (hCG), and also substances found on the surface of the ovum or the sperm. The problem with hCG is that its subunits are too similar to other hormones, and the antibodies produced by the body in response to hCG might damage the pituitary gland or the kidney. The development of an antisperm vaccine has been proposed. Nothing is even close to clinical trials.

Male Methods of Contraception

Research on male methods of contraception has always lagged behind research on female methods. A number of possibilities that either are hormones or have an effect on hormones have been discussed:

1. *Melatonin (from the pineal gland):* Suppresses the release of gonadotropin-releasing factor. *Problem:* Melatonin is only produced by the pineal gland in response to darkness.
2. *Gossypol (found in cottonseed oil):* Decreases the percentage of motile sperm, increases the percentage of abnormal sperm, causes a gradual decrease in the number of sperm until the male exhibits azoospermia; may also have an anti-viral/anti-HIV effect. *Problems:* Side effects, lack of reversibility.
3. Tripterigium wilfordii *(plant used in herbal medicine in China):* Experimentation with rats is being carried out to determine what effect the plant has; may also be anti-HIV.
4. *Testosterone injections:* Inhibit spermatogenesis. A limited World Health Organization clinical trial was effective. *Problems:* Requires weekly injection; potential side effects.
5. *Progestins/progestin-androgen combination/antiandrogens:* Inhibit spermatogenesis. *Problems:* Side effects, including decreased libido and potency; inconsistent achievement of azoospermia; loss of secondary sex characteristics.
6. *Inhibin (gonadal peptide hormone):* Suppresses follicle-stimulating hormone (FSH) and inhibits spermatogenesis. *Problem:* Not much is known about the role of FSH in male fertility.
7. *Luteinizing hormone releasing hormone (LHRH):* Has four possible contraceptive actions. *Problems:* Side effects, including decrease in libido and in secondary sex characteristics; decreased testosterone.
8. *Male vaccine:* Uses antigens in the reproductive tract to stimulate the production of antibodies affecting hormones produced in the testes, pituitary gland, or hypothalamus.

Natural Methods of Family Planning

CARMELA CAVERO, CNM, MS, FACNM

The term *natural family planning* (NFP) describes methods of planning or preventing pregnancy based on periodic abstinence. NFP describes methods whereby couples may achieve, prevent, or space pregnancies based on their understanding of their fertility and the timing of intercourse. The World Health Organization defines natural family planning as

> . . . methods for planning or avoiding pregnancies by observation of the natural signs and symptoms of the fertile and infertile phase of the menstrual cycle. It is implicit in the definition of natural family planning, when used to avoid conception, that drugs, devices and surgical procedures are not used, there is abstinence from sexual intercourse during the fertile phase of the menstrual cycle and the act of intercourse, when it occurs, is complete. This definition of natural family planning indicates that there are two separate components involved. The first of these is fertility awareness; the second is the application of this knowledge to help in planning one's family, what we term the methodologies. [1]

Currently the most effective methods of natural family planning are (1) the ovulation method (Billings method; Creighton model) and (2) the sympto-thermal method. Other methods of natural family planning include (1) the calendar method, (2) the basal body temperature method, and (3) the lactation amenorrhea method.

The terms *natural family planning*, *rhythm*, *safe period*, *fertility awareness*, and *periodic abstinence* are sometimes used synonymously. However, the different terms may evoke different philosophical and psychological responses.

As noted in the World Health Organization definition, the natural methods of family planning are nonmechanical and nonchemical. They are often vastly misunderstood. Misunderstanding, when combined with a lack of commitment to abstinence from coitus during the fertile days, may render them ineffective for preventing pregnancy. However, when a couple properly understand the method, make a commitment to each other to abstain during the fertile days, jointly participate in determining the fertile days and the safe days, and develop nongenital expressions of love, then the effectiveness of natural family planning is equal to or better than that of the barrier methods of contraception (see Table 16-2, page 464).

It is important to note that the natural methods of family planning are suited only for use by a monogamous couple in a stable relationship who are willing to assume joint responsibility for their fertility and are motivated to apply natural family planning in their relationship. When couples become familiar with the methodology, they can use it to truly plan their family and bring about pregnancy when they feel the time is right—simply by switching from abstinence to intercourse on the fertile days.

At a conference held at Georgetown University in 1997, participants listed strategies for mainstreaming and expanding NFP usage. They suggested that family planning providers could enhance quality of care by adding fertility awareness education and NFP to the choice of methods offered [2]. Among women with access to all methods of contraception, the number choosing natural family planning is small. However, an increasing number of couples are turning to the natural meth-

ods of family planning, motivated either by religious or philosophical beliefs or by concern about the potential risks, side effects, and unknown long-term effects of artificial contraception.

The effectiveness of natural family planning methods depends not only on the willingness of the couple to apply what they know faithfully but also on proper instruction by certified instructors. A thorough understanding of natural family planning and of all the nuances that can make the difference between success and failure is acquired only through intensive training. In an effort to standardize the approach to teaching natural family planning methods, the World Health Organization, the Diocesan Development Program for Natural Family Planning, and other NFP providers have written requirements and guidelines for NFP teachers. On completion of an education program, the prospective instructor must pass an examination in order to become certified.

This chapter is intended to provide the midwife with an overview and basic knowledge of the different methods of natural family planning. It cannot, however, provide the expertise that comes from the extensive training and experience in these methods found in the standardized courses that lead to certification as an instructor in natural family planning. For the midwife who has not obtained this additional specialized training there is a list of resources at the end of the chapter. These organizations will help a midwife locate the nearest certified natural family planning instructor. The midwife can then refer a woman to whom she is providing primary care to a certified NFP instructor for the individualized instruction, counseling, and follow-up necessary for success in natural family planning.

The Calendar Method (Rhythm Method)

Research in the 1930s led to the development of the earliest of the natural family planning methods, the "rhythm" method, also known as the calendar method. The method was based on the finding that ovulation occurs on a single day approximately 14 days prior to the onset of the menstrual period; based on this finding, a woman's fertile period can be identified.

This method has many limitations because of the wide variation in the length of menstrual cycles. Because a fairly regular menstrual cycle is essential to any reliable estimation of the time of ovulation, the following women cannot depend on the calendar method: women with menstrual cycles shorter than 25 days, women with irregular menstrual cycles, women with menstrual cycles that vary in length by 8 days or more, postpartum women, women who are lactating, and women in the perimenopause.

The calendar method can only predict the days in a menstrual cycle during which a woman is more likely to get pregnant. This prediction is based on the projected time of ovulation as determined by calendar calculations made from the history of the length of the last 8 to 12 cycles. A woman must keep a record of menstrual cycles to identify the longest and shortest cycles so that all possible fertile days may be projected. The calculations used today allow for a variation factor of ±2 days around the approximately 14 days prior to the onset of the next menstrual period, 2 to 3 days for sperm survival, and 1 day (24 hours) for ovum survival, for a minimum total of 9 fertile days.

The woman subtracts 20 days from the length of her shortest cycle to determine her first predicted fertile day and 10 days from the length of her longest cycle to determine her last predicted fertile day. The couple then abstain from sexual intercourse during the projected fertile days to prevent conception.

Although this method may be selected by some couples in the United States and is still used in many countries, it has been supplanted by modern natural family planning methods that have proved to be more effective and require fewer days of abstinence. The latter methods differ from the calendar (rhythm) method in that they are based on clinical indicators of hormonal changes and identify the times of fertility and infertility as they occur in each and every cycle. These biological signs can be observed and interpreted by women and their partners.

The Ovulation Method (Cervical Mucus Method; Billings Method; Creighton Model)

The ovulation method is based on the recognition of changes in the cervical mucus during the menstrual cycle, which define both the fertile phase of the cycle and the time of maximum fertility within the fertile phase. The woman is taught to recognize changes in the characteristics of the cervical mucus and in the pattern of sensation at the vulva (wetness; feeling of lubrication; dryness) throughout the cycle.

The ovulation method was developed in the 1950s by two Australian physicians, Drs. Evelyn and John Billings, and introduced into the United States in the early 1970s. Validation of the method was conducted by correlating women's observations of the changing mucus, detectable at the vulva, and the rise in estrogen levels in the follicular phase of the cycle. The identifiable pattern showed that women can predict ovulation quite accurately without recourse to basal body temperature.

Changes in the cervical mucus during the menstrual cycle, thus, are under the influence of estrogen. The infertile pattern is detected in both the preovulatory phase and the postovulatory phase of the cycle. When the ovaries are in a relatively quiescent state, there is a lower level of estrogen and progesterone. The result is the absence of a sensation or mucus at the vulva.

The woman observes the sensation at the vulva and the presence of mucus throughout the day as she goes about her daily activities. She records her observation at the end of the day. During the first cycle of charting, abstinence is necessary in order for the woman to become familiar with her sensation and mucus. Then she must learn to distinguish her cervical mucus from semen, normal sexual lubrication, and vaginal discharges. She should not douche as this would eliminate vaginal secretions.

The cervical mucus changes throughout the cycle are as follows (see Figure 17-1):

1. There are a number of days immediately after menstruation during which the woman has an

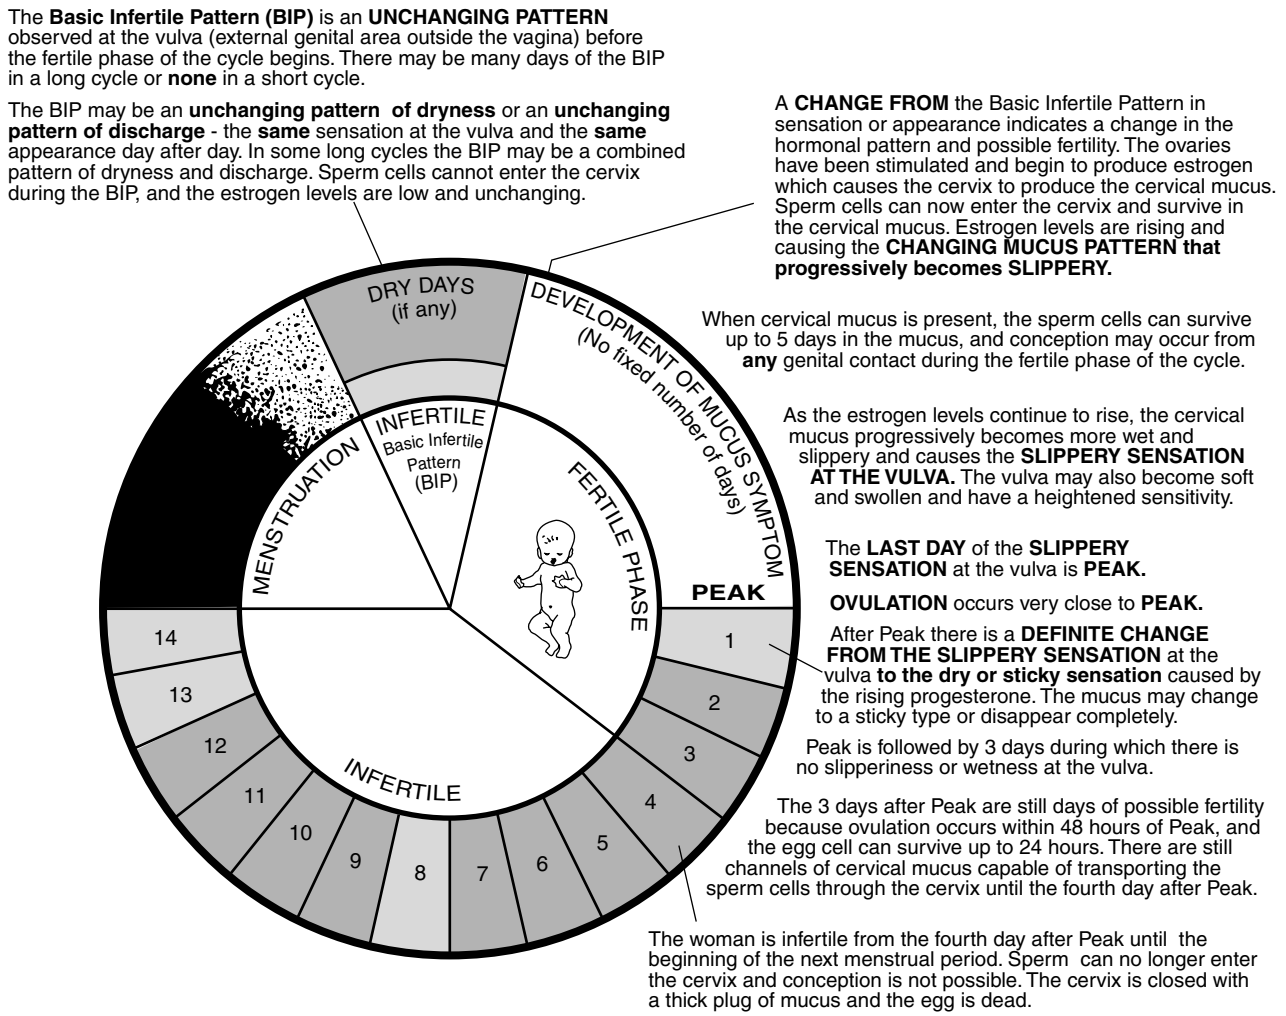

FIGURE 17-1 The Billings Ovulation Method of Natural Family Planning, 2000.

Source: Reproduced with permission of the Billings Family Life Centre. For further information visit www.woomb.org.

unchanging pattern of dryness at the vulva. Some women experience the appearance of discharge but characteristically this has the same appearance day after day. This is identified as the Basic Infertile Pattern (BIP). The number of days varies, being more in a long cycle and fewer in a short cycle. These are considered infertile days.

2. The preovulatory phase follows. The woman notices a change from the Basic Infertile Pattern in the sensation at the vulva or appearance of mucus. This change identifies the beginning of the fertile phase of the cycle. A changing sensation from wet to slippery is noted at the vulva. The mucus increases in volume and becomes clear and stretchy, with an egg-white consistency (spinnbarkeit). The last day of the slippery sensation at the vulva is called the Peak day. This is true even if mucus is not seen. This is the maximally fertile phase. The sensation changes to dry or sticky. The three days after the Peak day are still days of possible fertility because ovulation occurs within 48 hours of the Peak day and the ovum survives up to 24 hours.
3. The postovulatory infertile days begin on the fourth day after the Peak day and continue until menstruation. Menstruation will occur 11 to 16 days after the Peak day.

Couples who wish to avoid pregnancy must follow these rules:

1. The Early Day Rules
   a. Intercourse is to be avoided during the days of heavy menstrual bleeding. Mucus may be undetectable in the presence of the menstrual blood.
   b. Intercourse is permissible every other night as long as the observations indicate the Basic Infertile Pattern. The day after intercourse is considered a fertile day because the presence of seminal fluid may mask the mucus observation.
   c. When a change from the Basic Infertile Pattern is noted, the couple abstains that day and any other day of change as well as three more days when the BIP returns. "Wait and see 1, 2, and three."
   d. Usually the change from the BIP indicates the beginning of the fertile phase. These changes continue until the Peak day.
2. The Peak Day Rule: Intercourse is avoided until the fourth day after the Peak day has been identified. From this time until the end of the cycle, the couple may have intercourse every day and at any time.

A record of the observations is made on a chart with symbols or color-coded stamps: red is for bleeding, green is for dryness, white with a baby is for possible fertility, and yellow is for discharge. The couple then choose to have sexual intercourse during the fertile or infertile phases of the woman's menstrual cycle, depending on their family planning intention.

A modification of the Billings ovulation method is the Creighton Model of Natural Family Planning (CrM NFP). This model uses the same theory but has a standardized teaching plan and a code system for charting. The model is based on intensive education of the instructors and natural family planning clients and rooted in basic principles of fertility appreciation.

The Basal Body Temperature Method

The basal body temperature method detects when ovulation occurs. This is possible because progesterone, released by the corpus luteum, causes an increase in basal body temperature. Before a basal body temperature shift is considered ovulatory, the temperature must be at least 0.4°F above the previous six temperatures prior to the shift. Detection of this rise in temperature thus identifies the luteal, or postovulatory, phase of the menstrual cycle. The rise in basal body temperature occurring with ovulation may be abrupt (1 to 2 days), may occur as a slow rise extending over several days, may occur in a staircase pattern of sequential slight increases (0.2°F) every 2 to 3 days, or may occur in a zigzag pattern of sequential and progressively greater increases and decreases over a period of several days (e.g., an increase of 0.4°F, decrease of 0.2°F, increase of 0.4°F, etc.). In all temperature elevation patterns a sustained level of increase is evident. Occasionally a sharp dip in temperature precedes the rise in basal body temperature occurring with ovulation. The pattern of the rise in temperature may vary both from woman to woman and from cycle to cycle for the same woman.

The fertile days from ovulation through the postovulatory phase of the menstrual cycle are determined by considering that the fertile days continue either until there has been a sustained elevation or plateau of the temperature for 3 days

or until there have been 5 days of progressive increase (e.g., the zigzag, staircase, or slow rise pattern). The infertile days follow and continue through the luteal, or postovulatory, phase of the menstrual cycle until menstruation. The basal body temperature method, by itself, is only for determining when ovulation occurs and identifying the subsequent postovulatory fertile and infertile days. This method cannot predict the time of ovulation or determine the preovulatory fertile and infertile days.

Instructions for taking one's temperature are usually found on the back of the graph used for plotting the temperature and must be rigorously followed for the information to be of greatest usefulness. These instructions include how and when to take the temperature, what data to record, and how to record the data on the temperature record throughout the menstrual cycle. A basal body temperature, or ovulation, thermometer is most useful for detecting temperature change, increasing accuracy, and interpreting records. Such thermometers are calibrated in gradations of 0.1°F rather than the standard gradations of 0.2°F found on regular, or fever, thermometers. Basal body temperature thermometers may be purchased in most drug stores. The daily temperature reading should be recorded on graph paper, preferably paper designed for plotting tenths of a degree.

The woman should take her temperature every day—at the same time every day, if possible, and after 5 to 6 hours of uninterrupted sleep. Since any activity may raise the basal body temperature, the woman should take her temperature upon awakening and before doing anything else (e.g., talking, eating, drinking, kissing, smoking, getting out of or moving around in bed). The woman may select how she wishes to take her temperature—orally or, for greatest accuracy, rectally. Whichever way she chooses to take her temperature, she should always use the same site thereafter, since temperature readings vary from site to site.

Besides the phase of the menstrual cycle and the activities mentioned in the preceding paragraph, the following factors may affect the basal body temperature and possibly render the month's record invalid.

1. Illness
2. Emotional tension or upset; stress
3. Travel
4. Lack of sleep or irregular sleeping hours
5. Use of electric blankets
6. Sedatives
7. Gastrointestinal disturbances
8. Immunizations
9. Alcohol intake
10. The time of day
11. The climate

If a woman is aware of these factors and notes their existence on the temperature graph, she will be able to make a much more critical analysis and accurate interpretation of the record.

The Sympto-Thermal Method

The sympto-thermal method utilizes all the signs and symptoms that ovulation is impending or has occurred. Thus, it encompasses mucus observation and the basal body temperature method and adds other indicators of ovulation, as shown in Figure 17-2. Other signs and symptoms of impending ovulation or its occurrence experienced by some women are as follows:

1. Mittelschmerz. This midcycle pain encompasses a number of signs and symptoms, including
   a. pain located just off center in the lower abdomen and caused by the rupturing follicle
   b. spotting or breakthrough bleeding
   c. bearing-down or dragging pains
   d. general tenderness in the lower midabdomen and pelvic area
2. Increase in sexual interest (libido). This may also occur at other times during the cycle, however.
3. Mood changes. Feelings of depression or mercurial mood swings are more common during the postovulatory (luteal) phase of the cycle.
4. Cervical mucus ferning. Detection requires microscopic examination of dried cervical mucus. A fernlike pattern of the cervical mucus is observable during the days of the menstrual cycle when estrogen is predominant. Ferning is most pronounced at the time of ovulation. The fern pattern is readily distinguishable and is different from the beadlike pattern that replaces it during the postovulatory (progesterone) phase of the menstrual cycle. Under the influence of estrogen, cervical mucus also exhibits a prop-

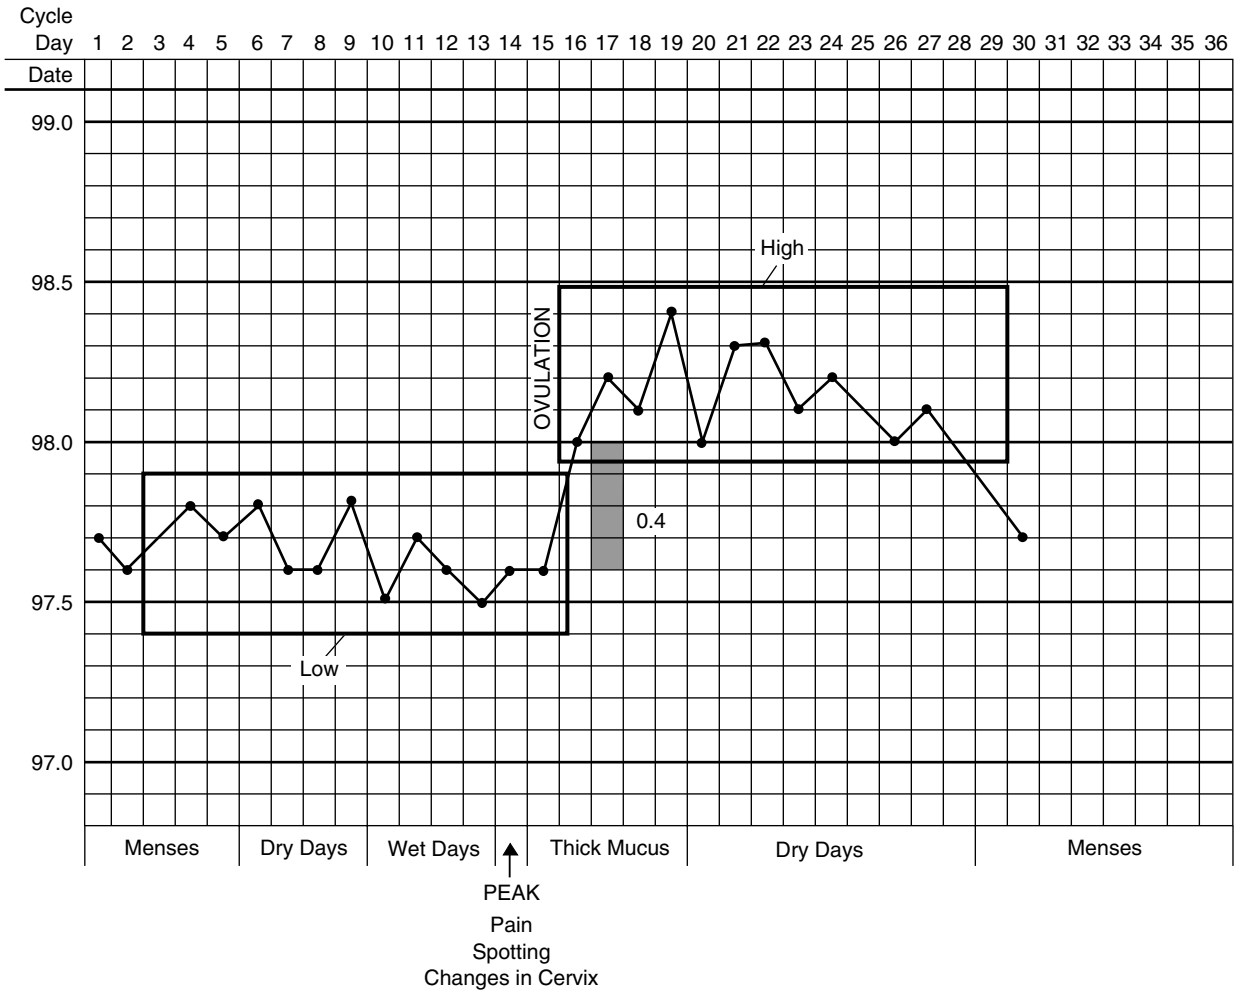

FIGURE 17-2 Sympto-thermal method.

Source: The Human Life and Natural Family Planning Foundation.

erty known as spinnbarkeit, which was mentioned previously as a distinctive characteristic of the "wet days."

5. Cervical changes. These changes include softening, slight dilatation of the cervical os, and a change in position to higher in the vaginal canal as ovulation approaches. After ovulation the cervix again becomes firm, closed, and lower in the vaginal canal. Detection of the cervical position is an optional sign.
6. Breast tenseness and tenderness. These symptoms occur during the postovulatory (luteal) phase of the cycle under the combined influence of estrogen and progesterone.

Other means of determining the time of ovulation are known (e.g., endometrial biopsy, hormonal assay of urine or blood, ultrasound examination of the ovaries), but practicalities prohibit their use for contraceptive purposes. There are also a number of commercial ovulation detection and hormone monitoring kits on the market. They vary widely in price, efficacy, and failure rates. Data are largely anecdotal.

The observations are entered on a specifically designed cycle chart (see Figure 17-3). As with the ovulation method, the effectiveness of the sympto-thermal method is dependent on good instruction by competent teachers, understanding of the method, and steadfast application of the rules.

Lactation Amenorrhea Method

The lactation amenorrhea method (LAM) was probably used in developing countries long before studies confirmed that pregnancies are rare during the first 6 months postpartum among women who practice full or nearly full breastfeeding. Ovulation is inhibited by the high levels of prolactin. A summary of 13 studies from eight countries gave rise to a conclusion, known as the Bellagio Consensus Statement, "that breastfeeding provides more than 98 percent protection from pregnancy during the first 6 months postpartum if the mother is fully or nearly fully breastfeeding and has not yet experienced vaginal bleeding after the 56th day postpartum" [2].

The guidelines for the use of LAM are as follows:

1. The baby must be less than 6 months old.
2. The woman has no vaginal bleeding after 56 days postpartum.
3. Breastfeeding must be the exclusive source of nourishment for the baby.

There is a 2 percent pregnancy rate among women who follow these guidelines for the first 6 months postpartum. It is recommended that the natural protection afforded by LAM be incorporated into the teaching of natural family planning. The woman should continue to be aware of and observe symptoms that alert her to the possibility of approaching fertility. Both the ovulation and the sympto-thermal methods include special instructions in regard to lactation and weaning.

Client/Couple Instruction

The instructional program for any of the methods of natural family planning consists of a series of classes as well as follow-up visits for chart review and clarification and reinforcement of the method. Ultimately, the goal is for the couple to develop sufficient confidence in their own observations and interpretations that they achieve autonomy in using their chosen method. Many women also feel a sense of great empowerment in learning to know their own bodies and to work successfully to fulfill their own fertility goals.

Technology and Natural Family Planning

Accelerated research in developing tests for predicting ovulation has produced some home monitoring products. If these products continue to be refined and meet the criteria of accuracy and ease of use, they will be valuable adjuncts to learning natural family planning for women who have problems identifying the signs and symptoms of ovulation or for women who would like a more objective manner of assessing fertility [3]. A number of small, handheld microscopes have been developed and marketed for the purpose of self-observation of fern-ing patterns in either saliva or cervical-vaginal mucus. Variable results were obtained and the conclusion of some published studies were that further research needs to be conducted to evaluate the use of these microscope fertility monitors [4–6].

CHAPTER

18

Nonhormonal Contraceptive Methods

Spermicidal Preparations

The active agent in most spermicidal preparations is nonoxynol-9, which inactivates sperm but has *not* been shown to be an effective vaginal microbicide [1]. Because spermicidal chemicals are toxic to normal vaginal epithelial cells, frequent or long-term use of a spermicidal preparation can damage the vaginal epithelium, and vaginal irritation and ulceration can result. In such an event a woman is more susceptible to the HIV virus [1, 2]. Allergies to nonoxynol-9 contraindicate the use of spermicidal preparations.

The greater part of a spermicidal preparation is an inert base, which acts as the vehicle. This nonreactive base also serves as a mechanical block to the cervical os. Most spermicidal preparations have an acid pH of 4.5 and thus create a hostile vaginal environment for the mildly alkaline semen. This is particularly important at the external cervical os because the cervical secretions become slightly alkaline at the time of ovulation and therefore receptive to the sperm.

Some spermicidal preparations are made, and are so designated in the accompanying literature, to be used with a condom alone and not in conjunction with a diaphragm. Others are made to be used only with the diaphragm or cervical cap and should not be used with condoms. Oil-based preparations increase the possibility of condom breakage and reduce the integrity of the condom. The midwife should emphasize to the woman the importance of reading the literature that accompanies each commercial spermicidal preparation.

All spermicidal preparations exhibit certain common features: ability to immobilize and kill sperm, widespread vaginal distribution with the initial thrust of the penis, and formation of a surface film on the inside of the vagina that withstands coital activity. The spermicidal preparation is inserted near the cervix, and coital movements distribute it throughout the vagina and over the cervix. However, the possibility of contraceptive failure due to inadequate distribution is inherent in the method.

In addition to these features, each preparation has its own specific characteristics. These are enumerated with each type of preparation: jellies and creams, aerosol foam, suppositories, sponges, and film. Two other types of spermicidal preparations, rarely used and difficult to find in the United States, are widely used in other countries and are presented here for general information: vaginal foam tablets and the sponge and foam.

Jellies and Creams

The jellies and creams are packaged in tubes. The kits in which they are sold also contain an applicator and instructions. Since these preparations can be diluted by vaginal secretions, an adequate amount of the preparation must be inserted in accord with the instructions. To facilitate depositing the spermicidal preparation near the cervix, the woman should lie on her back, insert the applicator in a downward and backward direction the full length of the vagina, and then withdraw it about half an inch before pushing the plunger. (See "Instructions for the Use of Spermicides," later in this chapter.)

Aerosol Foam

In aerosol form, the spermicidal agent is under pressure in a container with an inert gas. Foam, a vari-

ation of the cream spermicidal preparation, is released into an applicator when the applicator is pressed against the container. The procedure for inserting a spermicidal foam is the same as that for jellies and creams. (See "Instructions for the Use of Spermicides.")

Suppositories

Products advertised for feminine hygiene should not be mistaken for contraceptive suppositories. Contraceptive suppositories are cone-shaped and contain a spermicidal ingredient incorporated into a cocoa butter or glycerogelatin base. Their melting point is slightly below body temperature. This makes them a poor choice of method in areas where the weather is hot and refrigeration is lacking.

The average melting time of the suppository at body temperature is around 10 minutes; therefore the suppository should be inserted into the vagina at least 15 minutes before coitus, and some brands instruct users to wait 30 minutes. Some couples find this waiting period objectionable. Other couples object to the excessive messiness that can be associated with this method. The suppository is one of the least effective of the spermicidal preparations.

Vaginal Contraceptive Sponge

The vaginal contraceptive sponge, Today Sponge, was introduced to the market as an over-the-counter female contraceptive in 1983. Production was suspended in March 1994 and discontinued in January 1995. At issue were production costs and Food and Drug Administration (FDA) manufacturing requirements [3]. As of this writing, the Today Sponge is about to be reintroduced in Canada and the United States by a different manufacturing company. The Today Sponge is made of a soft polyurethane foam that contains 1000 mg of nonoxynol-9 that is continuously released into the vagina for a period of 24 hours. It also serves as a trap to absorb semen and as a physical barrier between sperm and the cervix. The sponge is wet with tap water and squeezed to activate the spermicide and produce a large amount of suds to facilitate insertion. It is left in place for 24 hours and no more than 30 hours to include a waiting period of 6 hours after the last act of intercourse. It has an attached loop that facilitates removal. The Today Sponge is contraindicated for use during menstruation or immediately after childbirth or abortion, or by a woman with a history of toxic shock syndrome.

Vaginal Contraceptive Film (VCF)

Vaginal contraceptive film is a water-soluble product that contains nonoxynol-9. Each piece of film is approximately 2 in. square and is inserted to cover the cervical os at least 5 to 15 minutes prior to sexual intercourse to give it time to dissolve. It remains effective for at least 1 hour after it has dissolved. Film can be used by itself or with a condom or placed inside a diaphragm or cervical cap.

Film can be bought across the counter and is easy for a woman to carry with her. It can be inserted with one finger, which should be dry. A new film should be inserted with each act of intercourse. Contraindications include sensitivity and allergy.

Vaginal Foam Tablets

The 1-gram vaginal foam tablet is round, flat, and white and contains a spermicide, a bacteriostatic agent, and ingredients that, when moistened, produce a carbon dioxide foam. The woman lies on her back and moistens the tablet with a little water or saliva. She waits to see or hear it fizz. If the tablet does not fizz when it is moistened, it should be discarded and another tablet used. When the tablet fizzes, the woman immediately inserts it into her vagina, pushing it in as far as she can with her finger. A 5-minute interval must be allowed between insertion and sexual intercourse for the initial foaming action to distribute foam throughout the vagina. The tablet further dissolves and there is additional foaming action at the time of ejaculation.

Women have complained about an irritative vaginal reaction, and both men and women have complained about a burning sensation during the foaming process. Women may object to this method if they have an aversion to inserting a finger into their vagina.

The vaginal foam tablet is considered one of the least effective of the spermicidal methods. However, it has been accepted by some women who are poorly motivated or minimally educated because of the simplicity of the technique involved. Because of their greater willingness to use it, they may use the vaginal foam tablet with increased regularity. Thus, for these women, it may be a more effective protection from conception than other contraceptive methods.

Sponge and Foam

In the sponge and foam method, a spermicidal powder or liquid is applied to a small water-moistened sponge. The sponge is squeezed gently so

that the powder or liquid forms a foam, and then the sponge is inserted into the vagina with as little loss of content as possible.

Reserve foaming power permits sexual intercourse any time within 6 hours after insertion. Within this period, coital movements produce more foam. If more than 6 hours elapse from the time of insertion to the time of sexual intercourse, the sponge must be removed and additional spermicidal powder or liquid applied; then the sponge is reinserted. The sponge should not be removed until at least 6 hours after sexual intercourse. If during this 6 hours the woman wishes to have intercourse again, another smaller sponge is inserted in addition to the first sponge.

The sponge and foam method is one of the least effective of the spermicidal contraceptive methods. Nevertheless, it is a simple method, and some women gain confidence that they are using an effective method when they see the sponge filled with foam.

Effectiveness, Complaints, and Management

It is imperative that users of spermicides other than the Today Sponge and the sponge and foam method observe the following principles if the preparations are to be an effective method of family planning.

1. Reapplication of the method if the woman gets up, walks around, or goes to the bathroom after insertion but before sexual intercourse.
2. Reapplication of the method if sexual intercourse does not occur within 60 minutes of the time of insertion.
3. Reapplication of the method before each act of sexual intercourse.
4. No douching until at least 6 hours after the last act of sexual intercourse. Douching prior to this time may dilute or remove the spermicidal preparation before the sperm have been completely inactivated, thereby rendering the method ineffective.

These principles may be rephrased and reiterated as instructions for the woman in using a spermicidal method. (See "Instructions for the Use of Spermicides.") They become the most important element of the care provided by the midwife when a woman chooses to use spermicidal preparations with or without condoms.

Table 16-2 (page 464) shows that there is considerable difference between the percent of failures of spermicides with perfect use and with typical use. The higher rate with typical use suggests that women using spermicidal preparations may be less well motivated than users of other methods to use a contraceptive method routinely. This may in turn reflect infrequent or inconsistent sexual contact. Spermicidal preparations are readily available in drug stores without prescription, and they are easy to use. Their cost varies according to type and brand, but it generally is not prohibitive. The Today Sponge, film, tablets, and sponge and foam are not good contraceptive choices for a woman who objects to inserting her finger in her vagina.

The messiness of spermicidal preparations has been the major complaint of couples using them. Postcoital leakage of some degree is common to all of the spermicidal preparations except film. One of the advantages of the aerosol foam is that it creates less postcoital leakage because a smaller amount (by weight) of foam is required than of jelly or cream. The least esthetic choice is the suppository since, when it is adequately dissolved, the spermicide drains freely over the perineum both during coitus and postcoitally. The woman's sexual pleasure may be lessened if she finds postcoital drainage annoying. The woman can control postcoital drainage by placing a clean towel or tissues between her legs against the perineum; this will absorb moisture and she will feel more comfortable.

Another objection has been from couples who enjoy oral-genital sexual activity as part of their lovemaking. Their complaint is that the spermicidal preparations do not taste good. This problem is increased as the amount of drainage increases.

Finally, some couples feel negative about having to watch the clock and time their actions in relation to the action of the spermicidal preparation.

Instructions for the Use of Spermicidal Foam, Cream, or Jelly

Instructions are central to counseling for contraceptive method effectiveness. The following instructions are for women who plan to use spermicidal foam, cream, or jelly.

1. Practice filling and inserting the applicator in the dark before actually using it for contraception.
2. If using foam, shake the can 15 times before filling the applicator.
3. Fill the applicator.
4. Lie down and insert the spermicide when and where you plan to have intercourse. If you get up, walk around, go to the bathroom, and so forth after insertion of the spermicidal preparation but before sexual intercourse, the method

is rendered invalid because a large portion of the spermicide will drain out as you change position. In this circumstance, if contraception is desired, another applicatorful of the spermicidal preparation must be inserted before sexual intercourse (again, while you are lying down). For the same reason you should not get up and go to the bathroom to insert a spermicidal preparation.

5. Insert the applicator into the vagina as far as it will go by pressing downward and inward.
6. Withdraw the applicator $^1/_2$ inch and then push the plunger. This will deposit the spermicidal preparation at the cervical os.
7. If coitus does not take place within 60 minutes of insertion of the spermicidal preparation, insert another applicatorful before sexual intercourse if contraception is desired.
8. Be sure to insert another applicatorful of spermicidal preparation prior to each act of repeated sexual intercourse if contraception throughout is desired.
9. Keep in mind that douching is not necessary or encouraged. However, if you douche, do *not* douche for at least 6 to 8 hours after the last sexual intercourse. The contraceptive protection of the spermicidal preparation may be lost if you douche earlier than this.
10. Use a small towel, tissues, or a panty liner between your legs to catch drainage and reduce messiness.
11. For greatest effectiveness in protecting against pregnancy, use the spermicidal preparation method of contraception in conjunction with a condom.

Condoms

The Male Condom

The male condom is a sheath of strong, thin, elastic rubber (latex), polyurethane (plastic), or collagenous material. It is unrolled down over the erect penis to catch the semen during ejaculation and prevent its being deposited in the vagina. Latex and polyurethane condoms also are effective in preventing transmission of HIV and reducing the risk of sexually transmitted diseases. However, male condoms do not cover all exposed areas, and according to the CDC "they are likely to be more effective in preventing infections transmitted by fluids from mucosal surfaces (e.g., gonorrhea, chlamydia, trichomoniasis, and HIV) than in preventing those transmitted by skin-to-skin contact (e.g., herpes simplex virus [HSV], human papillomavirus [HPV], syphilis, and chancroid) [2]. Natural membrane condoms, while preventing pregnancy, do not prevent HIV, hepatitis B, or herpes simplex virus infection.

Effectiveness, Complaints, and Management

Three techniques will enhance the efficacy of a condom:

1. The condom must be in place before the penis approaches the female genitalia because the HIV virus is found in the pre-ejaculatory fluid. Contrary to what was believed for decades, sperm are not found in the pre-ejaculatory fluid [4].
2. When a plain-ended condom is used, an overlap of $^1/_2$ inch should be allowed for collection of the semen, to decrease the possibility that the condom might break at the time of ejaculation (see Figure 18-1).
3. Because the penis becomes flaccid following ejaculation, it is important that the male withdraw from the vagina immediately following ejaculation while securely holding the edge of the condom so that there is no leakage of semen from the open end of the condom and so that the condom does not slip off into the vagina while the male is withdrawing.

These three techniques form the major portion of the vital instructions that both a woman and her partner should be given (see "Instructions for Use of the Condom").

If the condom is used consistently and correctly, the only reason for contraceptive failure is defects in the condom itself. Defects include weakness of material, which might allow the condom to break from the force of ejaculation, or minute holes,

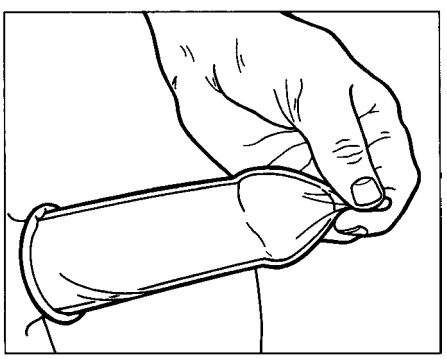

FIGURE 18-1 Leaving $^1/_2$ in. of empty space when using a plain-ended condom.

Source: Drawing reproduced by permission from *The Contraception Report*, Emron, Inc.

which render it ineffective. Condoms made in the United States are unlikely to have imperfections because they are manufactured under the supervision and quality control of the Food and Drug Administration. A condom can be tested by overdistending it with water or air and then checking for leakage, but testing it in this manner may weaken the condom and cause it to break when it is actually used. A condom is used once and thrown away. There is a combined average rate of approximately 4 percent for breakage and slippage [5]. The large discrepancy in the rates of failure for perfect use and typical use of the male condom (see Table 16-2, page 464) probably results from a combination of poor technique and inconsistent usage.

Condoms, variously known as "rubbers," "safes," "sheaths," or "prophylactics," are readily available. The cost varies with the brand, but generally condoms are not expensive. There are over 100 brands of condoms, of different sizes (length and width), shapes (tapered; straight), thickness, texture (smooth; ribbed), and color or translucency; with or without a reservoir tip or nipple tip; with or without scent; with or without a lubricant (a dry condom is usually preferred for oral sex); and with or without a spermicide (inside, outside, or both). A condom with a spermicide (either sold as a spermicidal condom or with a spermicide applied to its surface) is *not* considered a double method and is not recommended [2]. Spermicide applied to the outside of a condom (which may leach into the condom) is not nearly as effective at preventing pregnancy as a vaginal spermicide inserted separately at the cervical os. The combination of a condom and an intravaginal spermicidal preparation provides added protection, particularly if the condom breaks or there is leakage of sperm when the male withdraws.

Although it is widely used, many couples have negative feelings about the condom. Some couples feel it dulls sensation; others feel it creates a barrier between them at a time when they desire the feeling of oneness that can be attained during sexual intercourse. The objection that sexual foreplay is interrupted in order to put the condom on the penis can be eliminated if the woman puts the condom on the man as part of their foreplay.

Instructions for Use of the Condom

1. Put the condom on the penis *before* it approaches the woman's external genitalia or is inserted into the vagina.
2. Check condoms not made in the United States before use.
3. If the man is not circumcised, the foreskin should be pulled back before unrolling the condom.
4. Unroll the condom down over the erect penis all the way down to the hair at the base of the penis.
5. If the condom has a plain end rather than a nipple end, leave an overlap allowance of $^1/_2$ inch for collection of the semen. This overlap space should have no air in it. Form the empty space by holding the end of the condom in a collapsed state while starting to roll it down over the penis.
6. Be sure there is adequate lubrication on the exterior of the condom, as it is more apt to tear from friction if there is insufficient lubrication. If using a latex condom and you need lubrication, use either water or a water-based lubricant; oil-based lubricants may rot the rubber. Most household "lubricants" are oil-based and should not be used (e.g., baby oil, cooking oils, margarine/butter, mineral oil, petroleum jelly, suntan cream/oil); the one exception is egg white. Vaginal therapeutics such as Monistat also are not safe to use with latex condoms. With a polyurethane condom it does not matter what kind of lubricant you use.
7. Following ejaculation, the man must withdraw his penis before it becomes flaccid.
8. To prevent the condom from falling off or leaking fluid while withdrawing, the man should hold on to the rim of the condom near the base of his penis.
9. Remove the condom from the penis away from the woman without spilling any semen and throw it away.
10. For greatest effectiveness in protecting against pregnancy, use the condom in conjunction with a spermicidal preparation.

A spermicidal preparation and condom may also be used as a backup method "to cover" another primary method of contraception at times when the primary method may not be as effective, such as in the following circumstances:

1. During the first month of initiating oral contraceptive pills
2. When a woman fails to take an oral contraceptive pill during a pill cycle
3. When a woman uses medication known to decrease the effectiveness of the oral contraceptive pill
4. During the first month after insertion of an intrauterine contraceptive device

The Female Condom

The Reality Female Condom was approved for use in the United States by the Food and Drug Administration in 1993 but did not reach the general public until August of 1994. It is made of a thin sheath of polyurethane with a flexible and movable inner ring on the closed end that is inserted into the vagina and a larger fixed ring on the outer open end that remains outside the vagina and covers the introitus (see Figure 18-2). The female condom comes in only one size and does not have to be fitted by a health care professional. It is prelubricated and comes with extra lubricant. Additional lubricants or spermicidal preparations may be used with it. The female condom is designed for one-time use only and costs between $3 and $4.

Effectiveness, Complaints, and Management

The female condom not only protects the woman against pregnancy but also offers effective protection against HIV, gonorrhea, chlamydia, and trichomoniasis when used correctly. When compared to the male condom, it may also provide a greater reduced risk of skin-to-skin sexually transmitted diseases such as human papilloma virus (HPV/genital warts), herpes simplex virus (HSV), syphilis, and chancroid, because it covers a larger exposed area and is a barrier between the introitus and vulva and the base of the penis [6]. The large discrepancy between failure rates with perfect use and with typical use (see Table 16-2, page 464) no doubt reflects problems mastering the technique involved and inconsistent use. Even after a program of education involving a video, counseling, and model practice, 25 percent of 1144 study participants did not insert the female condom correctly on the initial try in a self-insertion practice session. Additional instruction enabled all but 3 percent to succeed with two or three attempts [7]. Even though fitting is not needed, time for instruction and practice should be provided for women who choose this contraceptive method. Success in insertion is necessary for the female condom to be effective and for a woman to continue to use it.

To insert, the ring inside the closed end is compressed, and the closed end of the sheath is inserted into the vagina as far as the woman can get it past the pubic bone, where the sheath covers the cervix and adheres to the entire vaginal canal. The open ring remains outside the vagina and partially covers the vulva and perineum (see Figure 18-3). The penis is inserted into the open end of the sheath. The female condom can be inserted up to 8 hours prior to sexual intercourse but must be in place before the penis comes near the woman's external genitalia if it is to provide protection from pregnancy and infection. After intercourse, but before standing up, the woman squeezes and twists the outer ring to keep the semen inside the condom, and then gently pulls out the condom and throws it away (see Figure 18-4).

Complaints about the female condom include that both partners can feel the inner ring during use,

that the outer ring presses into the woman, that the sheath sticks to and moves with the penis, and that the outer ring moves with penile thrusting during intercourse. Checking for correct placement and adding more lubricant takes care of most problems. Although the female condom costs more than the male condom, 36 states provide reimbursement by Medicaid or other similar programs [8]. The female condom is also available free or at a reduced price at many public or nonprofit clinics [8].

A positive aspect of the female condom is that it gives the woman a way to protect herself from HIV and sexually transmitted diseases without having to rely on her male partner. Some couples prefer the feel of the polyurethane compared to that of latex male condoms. Some men prefer the freedom of movement given by the looseness of the female condom compared to the male condom. Some women have reported that the edge of the outer ring provides clitoral stimulation.

Diaphragms

Description, Effectiveness, and User Response

The diaphragm provides a mechanical barrier between the sperm and ovum. It is dome-shaped, made of somewhat thicker latex rubber than the condom, and has a flexible metal spring encased in the rim. The spring permits compression of the diaphragm for insertion, yet allows the diaphragm to regain its shape and fit snugly against the vaginal tissues when in place. When the diaphragm is in proper position, with the dome side down and the rim snug against the anterior and lateral vaginal walls, it completely covers the cervix like a cup into which the cervix is suspended. The resulting barrier, combined with spermicidal jelly or cream spread around the rim and inside the dome of the diaphragm, denies sperm entry into the cervical os and access to an ovum, thereby preventing pregnancy. The diaphragm also provides some protection against cervical sexually transmitted diseases such as chlamydia and gonorrhea and resulting cervical dysplasia and pelvic inflammatory disease. The diaphragm does *not* protect women from HIV infection.

The dome of the diaphragm is approximately $1\,^1/_2$ in. deep at its apex. Each woman's vaginal size and contour is individual; thus the diameter of a diaphragm may vary from $5\,^1/_2$ to 10 cm (about $2\,^1/_4$ to 4 in.). Diaphragms are sized in increments of 5 mm

as measured across the diameter of the rim. They are available in sizes from 55 to 105 mm.

There are four types of diaphragms, which differ in the construction of the metal spring in the rim and in the width of the rim:

1. *Flat spring:* The spring in this diaphragm is a flat band made of lightweight stainless steel.
2. *Coil spring:* The spring in this diaphragm is a flexible circular coil of moderate strength.
3. *Arcing spring:* The spring in this diaphragm is a combination of a flat spring and a coil spring.
4. *Wide-seal rim:* Available in either coil or arcing spring, this diaphragm differs from the other types in that it has a flexible $1\,^1/_2$ cm wide flange attached to the inner edge of the rim.

The diaphragm is inserted into the vagina either by hand or with a mechanical inserter. (A mechanical inserter can be used only with a flat spring or a coil spring diaphragm.) To cover the cervix effectively, the diaphragm should be positioned as follows: posteriorly, the rim of the diaphragm fits behind the cervix into the posterior vaginal fornix; anteriorly, the rim of the diaphragm rests snugly against the soft tissues posterior to the symphysis pubis; and the diaphragm's entire circumference rests against the vaginal walls. It is important that the woman check to make sure the diaphragm is properly positioned after insertion. Proper positioning is not possible if the diaphragm no longer fits as a result of changes in the size, shape, or position of the pelvic structures. Therefore, a woman should be rechecked for both fit and possible change in size or type of diaphragm (1) a few weeks after her first sexual experiences; (2) after each pregnancy, regardless of the gestational age of the fetus and whether the pregnancy ends in abortion (spontaneous or therapeutic) or birth; (3) as part of her annual health care examination; and (4) if she has a weight gain or loss in excess of 10 lb (according to the manufacturer). One study has been done that suggests that refitting the diaphragm after weight gain or loss is unnecessary [9].

A spermicidal jelly or cream applied to the diaphragm greatly enhances its effectiveness because it provides double protection. The spermicidal preparation, which is made specifically for use with a diaphragm, is applied to the diaphragm before it is inserted by putting 1 to 2 teaspoonfuls in the dome and also spreading some around the rest of the inside of the diaphragm and around the rim. Approximately 6 hours are needed for the spermicidal preparation or vaginal secretions to immobilize and kill the sperm; therefore the diaphragm must remain in position for at least 6 hours following coitus. The diaphragm should be left in position if sexual intercourse is repeated within 6 to 8 hours, and an additional applicatorful of spermicidal jelly or cream should be inserted for each act of intercourse. Although douching is not recommended, women who wish to douche should wait at least 6 hours following the final act of intercourse to do so if they want to remain protected. Half of the douche should be used prior to removing the diaphragm; the remaining half should be used after removal.

The woman should check her diaphragm periodically for pinholes, wear, and brittleness of the rubber. It should be usable for at least two years if it is properly cared for by washing and thoroughly drying. Deodorant or perfumed soap should not be used on the diaphragm, nor should powders or talc. If a woman insists on using some form of powder, she may use cornstarch without harming the diaphragm. Oil-based lubricants will rot the rubber and should be avoided. Face creams and hand lotions are oil-based, so a woman should wash her hands thoroughly between using these and putting in her diaphragm. Most vaginal therapeutics for monilia and vaginal hormonal creams are oil-based and should not be used simultaneously with a diaphragm.

There are various potential reasons that a diaphragm might fail as a contraceptive method. Inherent in the method is the possibility of the diaphragm's becoming dislodged during sexual intercourse. Other major reasons for failure are improper positioning of the diaphragm upon insertion, negligence in using the spermicidal cream or jelly that accompanies the diaphragm, and inconsistent use.

Inconsistent use itself may result from any one or a combination of objections to the method. Some women have an aversion to touching themselves internally, as they must do to insert the diaphragm, check its position, and remove it. Other women object to what they consider the nuisance of inserting the diaphragm nightly or daily, as is recommended for consistent conception protection, or to the inconvenience of leaving it in for 6 to 8 hours after the last act of sexual intercourse. Although the diaphragm usually cannot be felt during sexual intercourse, some couples believe it creates a barrier between them. Some women state they lose all feeling of the anterior vaginal wall, which decreases their sexual pleasure. The taste of the spermicidal

jelly or cream is objectionable for those who enjoy oral sex during their lovemaking. On the other hand, an advantage of the diaphragm is that it catches menstrual flow, thus making coitus during menstruation less messy than it would be otherwise.

As shown in Table 16-2 (page 464), perfect use of the diaphragm with a spermicide has a 6 percent failure rate; the rate triples for typical use. This figure is for all women using this method. However, Trussell et al. distinguished between women who had intercourse fewer than three times weekly and those who had intercourse three times or more per week. They found that for those who had intercourse more frequently (who were usually younger), the risk of getting pregnant while using the diaphragm with spermicide was almost three times greater [10]. This finding has implications for counseling, which should take into account frequency of intercourse.

It was thought in the past that failure rates reflected the fact that some women found the techniques of the diaphragm method too difficult to learn, since a good understanding of female reproductive anatomy is beneficial. This idea has been thoroughly discredited with simple, clear instruction; supervision of practice in proper insertion, placement, and removal; and patience, time, and encouragement for this learning.

The cost of the diaphragm may be in addition to the cost of necessary examination for evaluation of pelvic structures and determination of the proper size and type of diaphragm. The cost varies according to the size of the diaphragm but is not high. The diaphragm usually comes in a kit that contains the diaphragm, an instruction pamphlet, a mechanical inserter (whose use is optional), and a tube of spermicidal jelly or cream. Periodic replenishing of the spermicidal preparation adds somewhat to the cost.

Contraindications and Side Effects

The diaphragm is contraindicated in the presence of any of the following:

1. Severe uterine prolapse (descensus) (second or third degree)
2. Severe cystocele (second or third degree)
3. Severe anteversion or retroversion of the uterus
4. Vesicovaginal or rectovaginal fistulas
5. Known allergy to the rubber of the diaphragm or to the accompanying spermicidal preparation

The first three conditions are contraindications because they render proper fit of the diaphragm difficult or impossible. Another contraceptive method is better if a good fit cannot be obtained with the diaphragm. The presence or absence of these contraindications is ascertained during the pelvic examination, as described in Chapter 61.

While a history of urinary tract infections is not a contraindication, it requires special attention as an association between diaphragm use and urinary tract infections has long been thought to exist. This association is most likely due to the pressure of the rim of the diaphragm against the urethra behind the symphysis pubis. Bacteria may be transferred to the urethra during vaginal intercourse. Pressure of the diaphragm rim on the urethra may hinder clearing these bacteria from the urinary tract. The woman should be taught to deliberately urinate after intercourse in an effort to reduce colonization of the bladder with vaginal bacteria.

Side effects include possible allergic reactions to either the rubber of the diaphragm, the spermicidal preparation, or both. In addition to concerns about urinary tract infections, women should be warned against wearing the diaphragm for prolonged periods of time or during menstruation to reduce any risk of toxic shock syndrome.

Management Plan for Use of the Diaphragm

Management of the care of the woman or couple selecting a diaphragm as the method of family planning consists of the following components:

1. Taking a general history, conducting physical and pelvic examinations, and obtaining laboratory tests and adjunctive studies (see Chapter 2)
2. Screening for any deviations from normal and for contraindications to the woman's use of the diaphragm (see Chapter 61)
3. Determining the type and size of the diaphragm for the individual woman
4. Teaching the woman how to insert, place, check, and remove her diaphragm
5. Scheduling her return visits
6. Instructing her in the use and care of the diaphragm

Fitting the Diaphragm The type of diaphragm to be used depends on vaginal size and contour, the position of the uterus, the amount of vaginal muscular support, and the depth of the arch behind the symphysis pubis. The different types of diaphragms are correlated with these anatomical characteristics as follows:

Flat spring: Used with normal vaginal size and contour, strong vaginal support, normal uterine

position, a shallow arch behind the symphysis pubis.

Coil spring: Used with either normal or unusual vaginal size and contour, strong vaginal support, normal uterine position, an average or deep arch behind the symphysis pubis.

Arcing spring: Used with unusual vaginal size and contour, poor vaginal support including first degree uterine prolapse or first degree cystocele, or mild displacements of the uterus (which could cause the rim of the flat spring or coil spring diaphragm to slide out of the posterior fornix into the anterior fornix, thereby leaving the cervix exposed). An arcing spring diaphragm is indicated for women who have had a vaginal delivery, as they will have at least some amount of a first degree cystocele.

The size of the diaphragm has to be determined individually for each woman, since the distance from the posterior fornix to the posterior aspect of the symphysis pubis varies from woman to woman. Generally, a nulligravida will be fitted with size 65, 70, or 75; a multipara with size 75, 80, or 85; and a grand multipara with size 85 or greater.

A woman can be fitted for her diaphragm either with fitting rings or with sets of the various sizes and types of diaphragms. The latter approach is far superior to using fitting rings because the rings are of no use in patient teaching and give no idea of the type of diaphragm appropriate for the woman.

In fitting a woman, start with a size in the middle of the probable range of sizes for her parity. With experience, you will be able to interpret mentally with a fair amount of accuracy what your fingers feel as a size during pelvic examination. Hatcher et al. give another way of estimating diaphragm size:

1. Insert your index and middle fingers into the vagina until your middle finger reaches the posterior wall of the vagina.
2. Use the tip of your thumb to mark the point at which your index finger touches the pubic bone.
3. Remove your fingers and place a diaphragm rim on the tip of your middle finger. The opposite rim of the potential right size diaphragm should lie just in front of your thumb tip. [11]

Remember that as a woman becomes accustomed to having a diaphragm in place and to the necessary digital manipulation, the resulting relaxation may require refitting her with a larger size diaphragm.

When fitting, lubricate the rim of the diaphragm with the same lubricant you use for performing a pelvic examination. Compress the sides of the diaphragm with the fingers and thumb of one hand, and introduce it into the vagina in the same way that you insert a speculum. Be sure to direct it downward and inward, thereby applying pressure against the posterior vaginal wall and avoiding the more sensitive anterior structures. Once the diaphragm is in the vagina, double-check its placement to be sure that the rim of the diaphragm is in the posterior fornix, the circumference is against the lateral vaginal walls, the rim is tucked up behind the symphysis pubis, and the cervix is covered, which can be felt through the rubber of the diaphragm.
