To check the fit of the diaphragm, insert the tip of your index finger so that the pad of your finger is facing you between the rim of the diaphragm and the symphysis pubis. Then rub your fingers along the rim, pressing against the lateral vaginal walls. End by running your fingers behind the cervix and feeling the rim in the posterior vaginal fornix. The diaphragm is too small if you observe any of the following:

1. There is more than enough space for the flat portion of your fingertip between the rim of the diaphragm and the symphysis pubis.
2. The diaphragm moves about freely in the vagina.
3. The diaphragm is not large enough to tuck up behind the symphysis pubis.
4. The diaphragm comes out when the woman coughs or bears down.

The diaphragm is too large if you observe any of the following:

1. The rim of the diaphragm fits tightly against the symphysis pubis, thereby not allowing the flat portion of your fingertip to fit between the rim of the diaphragm and the symphysis pubis.
2. The rim of the diaphragm buckles forward against the lateral vaginal walls.
3. The edge of the diaphragm bulges out the vaginal introitus.
4. Tucking the rim of the diaphragm up behind the symphysis pubis causes it to buckle forward against the lateral vaginal walls.
5. The woman feels discomfort when the diaphragm is in place.
6. The woman experiences any or all of the following after the diaphragm is in place for an hour or more:
   a. abdominal pain
   b. back pain
   c. difficulty in urinating

d. rectal pain
e. cramps in her thighs

The diaphragm is the right size and type if you observe the following:

1. The diaphragm fits snugly in the vagina without buckling forward against the lateral vaginal walls.
2. There is just enough room for the flat portion of your fingertip to fit between the rim of the diaphragm and the symphysis pubis.
3. The diaphragm covers the cervix.
4. The diaphragm tucks both into the posterior fornix and up behind the symphysis pubis.
5. The woman can feel the diaphragm but it does not cause discomfort when it is in place.
6. The diaphragm causes no discomfort after it has been in place for an hour or more.
7. The diaphragm remains tucked up behind the symphysis pubis when the woman bears down or coughs.

Teaching the Woman How to Insert, Place, Check, and Remove Her Diaphragm

Once the woman has been fitted for type and size of diaphragm, an essential component of management is to teach the woman how to insert her diaphragm, check it for placement, and remove it. Whether the woman is comfortable with her ability to perform these techniques may well determine whether she will actually use her diaphragm.

Pelvic models are invaluable in teaching a woman the landmarks (i.e., symphysis pubis, cervix, posterior fornix, lateral vaginal walls) she needs to know in order to place the diaphragm properly. In addition, the pelvic models will give her some idea of the depth and direction of the vagina and the proximity of the pelvic organs and reassure her that the vagina is a dead end and, therefore, a diaphragm cannot travel somewhere else inside her body or escape through the cervical opening (which obviously is too small). She should practice insertion and removal of the diaphragm with the model until she is ready to practice on herself. It is important, when she practices with the model, that the woman hold the diaphragm in such a way that the manipulative techniques will be the same as when she actually inserts her own diaphragm—she should not insert the diaphragm into the model from the direction of an outside examiner.

The next step is for the woman to wash her hands and then insert her middle finger into her vagina and explore until she has located and identified her symphysis pubis and cervix. To do this she needs to be supported in an upright sitting position while her feet remain on the same horizontal level as her hips (i.e., on the bed or examining table, or in stirrups). This portion of the teaching may also take place either before or after you have fitted the diaphragm. It helps if you have already done your pelvic examination so you can help her locate her cervix if necessary.

Finally the woman practices insertion, placement, and removal of the diaphragm on herself. Wash and dry the fitting diaphragm you used that fit her. Place it on something clean such as a paper towel. Have her hold it, dome side down, with one hand while with the other hand she squeezes from the tube and evenly spreads approximately 1 to 2 teaspoonfuls of spermicidal cream or jelly around the inside of the cup and around the rim of the diaphragm. Emphasize that the spermicidal cream or jelly is an inherent part of the diaphragm method and the diaphragm should not be used without it. This is because the vaginal vault expands with female orgasm and sperm may escape around the rim of the diaphragm. The woman would then be without protection unless the spermicidal jelly or cream were there to continue blocking the sperm from entering the cervix. Without the spermicidal cream or jelly, the effectiveness of the diaphragm method is reduced.

Have the woman assume the same position she was in when she explored her anatomical structures. Then have her compress the sides of the diaphragm between her thumb and fingers, with her hand on top of the diaphragm. With the hand not holding the diaphragm, she spreads her labia and introduces the end of the diaphragm in front of her thumb and index finger into her vagina in a downward and inward direction. In order to keep the rims of the diaphragm together during insertion and push it into the vagina at the same time, she should use the hand she used for separating the labia to push the diaphragm in by placing it behind the hand compressing the diaphragm and pushing until the rim of the diaphragm is under the symphysis pubis. She can then tuck the rim up behind her symphysis pubis with a finger of whichever hand she chooses. She then checks the placement of the diaphragm, feeling the rim behind the symphysis pubis and the cervix, which is now covered by the rubber of the diaphragm. You should check to make sure she has placed the diaphragm correctly. The woman removes the diaphragm by inserting a

finger into her vagina, bearing down, grasping the upper edge of the diaphragm posterior to the symphysis pubis, and pulling the diaphragm down and out. She should compress the sides of the diaphragm as it comes out in order to reduce the diameter. This makes the insertion and removal procedures more comfortable. Large doses of encouragement and praise throughout this process are helpful.

Have the woman practice until both you and she are sure of what she is doing and she is able to prepare, insert, check placement of, and remove the diaphragm correctly without any help from you. Then have her get up and insert the diaphragm in the alternative positions: (1) standing with one foot on a chair (at home she might place one foot on the edge of the bathtub or on the toilet lid) and (2) while in a squatting position. Check her placement each time. Then have her remove the diaphragm while she stays in the same position she was in when she inserted it. She may find one or both of these positions more convenient or easier than the in-bed position.

After the woman has practiced the techniques described above, you should instruct her on the use and care of the diaphragm (see "Instructions in the Use and Care of the Diaphragm").

The Return Visits After being fitted for her diaphragm and having learned the techniques of preparation, insertion, checking, and removal, the woman should leave the clinic or office with her diaphragm in place. Instruct her to leave it in place for several hours. If the diaphragm is too large, she will develop discomfort/pain in her abdomen, back, rectum, or thighs during this time. In this case she should take the diaphragm out, use condoms and a spermicidal cream or jelly for contraception, and make an appointment to be refitted as soon as possible.

The woman should make an appointment for her first revisit two weeks after being fitted. During these two weeks she is to practice using her diaphragm daily or nightly whether or not she has sexual intercourse. For contraception during this two-week practice time she should rely on the combination of a spermicidal preparation and condoms. Ask her to return for her revisit with her diaphragm in place.

At her two-week revisit, the following history related to the diaphragm should be elicited:

1. How many times she wore it
2. The longest period of time she left it in place
3. Whether she had any abdominal pain, back pain, rectal pain, cramps in her thighs, or difficulty in voiding after the diaphragm had been in place for several hours
4. Whether she had any difficulties with the preparation, insertion, checking, or removal techniques
5. What position she is using for insertion and removal
6. Whether she likes the method and why or why not
7. What her sexual partner thinks about the method

A pelvic examination is done to evaluate the following:

1. Whether the diaphragm is placed properly
2. Whether the fit, type, and size of the diaphragm are still correct
3. Presence or absence of any pelvic pain
4. Presence or absence of any vaginal irritation

If all is well, the midwife reviews the instructions with the woman and gives her an appointment for her annual examination (general screening history, physical and pelvic examinations, Pap smear, and other routine laboratory tests).

Instructions in the Use and Care of the Diaphragm

1. Insert the diaphragm prior to sexual foreplay so that you need not interrupt your lovemaking or feel pressure to hurry (possibly making insertion difficult) or to neglect using it.

   If coitus always happens at a certain time, then make the insertion of the diaphragm part of your daily routine prior to this time. For example, if coitus occurs only at night, then before going to bed, wash your face, brush your teeth, and insert your diaphragm—every night.

   If you teach your partner how to prepare, insert, and check the diaphragm, these steps can become part of sexual foreplay before the penis comes in contact with your genitals or is inserted into your vagina.
2. Empty your bladder and wash your hands with soap and water.
3. Shake excess cornstarch (if any) off your diaphragm.
4. Put 1 to 2 teaspoonfuls of spermicidal cream or jelly in the dome of the diaphragm; also, spread some spermicidal cream or jelly around the rim and the inside of the diaphragm.

   Spermicidal cream and jelly are equally effective. The jelly may be both more lubricating and more messy. Which is used will depend on

your need for lubrication and your preference. Always make sure you use *contraceptive* jelly or cream.

5. Compress the sides of the diaphragm, and insert it dome side down.
6. Tuck the rim of the diaphragm up behind the symphysis pubis, and check to be sure that the cervix is covered.
7. You can walk around, bathe, and urinate with your diaphragm in place because it will neither get lost in your body nor fall out. However, if you have a bowel movement, check the position of your diaphragm afterwards and reposition it if necessary. It may have slipped out of the posterior fornix, thus leaving the cervix exposed.
8. If more than 2 hours elapse between insertion of your diaphragm and sexual intercourse, insert an applicatorful of spermicidal jelly or cream in the vagina, without removing the diaphragm, before intercourse.
9. If coitus is repeated, add another applicatorful of spermicidal jelly or cream, without removing the diaphragm, before each act of sexual intercourse.
10. Leave the diaphragm in place for at least 6 to 8 hours after the last act of sexual intercourse. This is because it takes 6 to 8 hours for either the spermicidal preparation or the hostile vaginal environment, or both, to kill the sperm.
11. Douching is not necessary or encouraged. However, if you wish to douche, do so when you remove the diaphragm. Half of a body-temperature, tap water douche is taken prior to removing the diaphragm; use the other half of the douche after removing the diaphragm. The douche is divided into these two portions on the outside chance that any semen containing sperm remains in the vagina. Douching has a tendency to encourage sperm to move inward through the cervical os rather than outward from the vagina. Any such semen is thus washed out before the protective barrier is removed.
12. Remove the diaphragm by bearing down, catching hold of the rim of the diaphragm behind the symphysis pubis and pulling it down and then out, compressing the sides as it comes.
13. Care for your diaphragm according to the following instructions:
    a. Do the following after each use:
        (1) Wash with a mild, nonperfumed soap.
        (2) Rinse with clear water.
        (3) Dry thoroughly.
        (4) It is not necessary to powder the diaphragm; do not use perfumed powders or talcum powder, as they will rot the rubber. If you feel you must use a powder, use cornstarch, which will not harm the diaphragm.
        (5) Store in a dry container away from heat (heat will rot rubber); use either the case the diaphragm came in or a clean cardboard box.
    b. Periodically check the diaphragm for areas of rubber deterioration, weakening, or holes by holding it up to light and gently stretching the rubber.
    c. Replace the diaphragm every two years because the rubber will weaken and deteriorate.
    d. Never use petroleum jelly with a diaphragm, as it may rot the rubber.
14. Make an appointment to be refitted for a diaphragm in the event of any of the following:
    a. if you are just beginning to be sexually active (after approximately 20 to 30 acts of coitus)
    b. after having a baby
    c. after having an abortion
    d. after any pelvic surgery
    e. after a weight gain or loss of 20 lb or more
15. Make an appointment before your annual examination in the event of any of the following:
    a. You lose your diaphragm.
    b. Your diaphragm is damaged or deteriorating.
    c. Your diaphragm needs to be refitted.
    d. You or your sexual partner is no longer happy with this method of contraception.

Cervical Caps

The Prentif Cavity Rim cervical cap was approved for use in the United States by the Food and Drug Administration in 1988. The round cone-shaped latex rubber cervical cap with a thick rim fits over the cervix and, because of suction created between the dome of the cap and the cervix, settles snugly, but not tightly, into the cervicovaginal fornices. In principle, the cervical cap is not unlike the diaphragm in that it creates a barrier to the sperm by covering the cervix and also holds spermicide to protect against pregnancy. It reduces the risk of cervical sexually transmitted diseases but does *not* protect againt HIV.

In comparison to the diaphragm, the cervical cap is associated with a smaller incidence of urinary

tract infections, as the rim does not press against the urethra. However, the cervical cap cannot be worn during menstruation. A common complaint with the cervical cap is the increased vaginal discharge it creates and what is called "cap odor." This odor may depend on how long the cap is left in place, particularly after sexual intercourse, or may reflect the presence of bacterial vaginosis [12]. The failure rate for typical use of the cervical cap by nulliparous women is similar to the failure rate among women using the diaphragm; the rate jumps enormously for parous women [10]. As shown in Table 16-2 (page 464), it is important to note that even with perfect use, 26 percent of parous women will experience an accidental pregnancy within the first year of cervical cap use. There is as yet no rational explanation for this finding, but it has serious implications for counseling about contraceptive methods which should take into account a woman's parity.

Contraindications to use of the cervical cap include the following:

1. Current abnormal Pap smear
2. Known or suspected uterine or cervical malignancy
3. History of toxic shock syndrome
4. Current vaginal or cervical infection
5. Allergy to latex
6. Allergy to spermicides
7. Cervical irregularities that will interfere with cap suction or ability to be properly fitted (e.g., multiple Nabothian cysts, deep cervical lacerations, malformations such as those seen in DES daughters, exceptionally long or short cervix)
8. Inability of the woman to insert and remove the cap correctly

In addition, the cervical cap should not be used in the following situations:

1. During menstruation, with intermenstrual bleeding, or during the postpartum or postabortion period for the following reasons:
   a. the bloody discharge may interfere with suction
   b. concern with the theoretical possibility of toxic shock syndrome
   c. the need to be refitted after pregnancy
   d. to prevent injury by a too tight cervical cap during times when the cervix is engorged or stretched to a larger size
2. Following procedures that involve the cervix (e.g., cryotherapy, cauterization, laser surgery) until healing has taken place and a Pap smear is negative
3. After events and procedures that dilate the cervix (e.g., birth, spontaneous or therapeutic abortion, dilatation and curettage, endometrial biopsy, hysteroscopy) until the woman has been refitted

In fitting a cervical cap you first should observe the size, shape, and position of the cervix during the pelvic examination. This information enables you to rule out contraindicating cervical irregularities and determine the size of the cap. The cap, when properly positioned, should completely cover the cervix but not touch the cervical os (to allow room for spermicide) and be sealed 360° around the rim in the cervicovaginal fornices (see Figure 18-5).

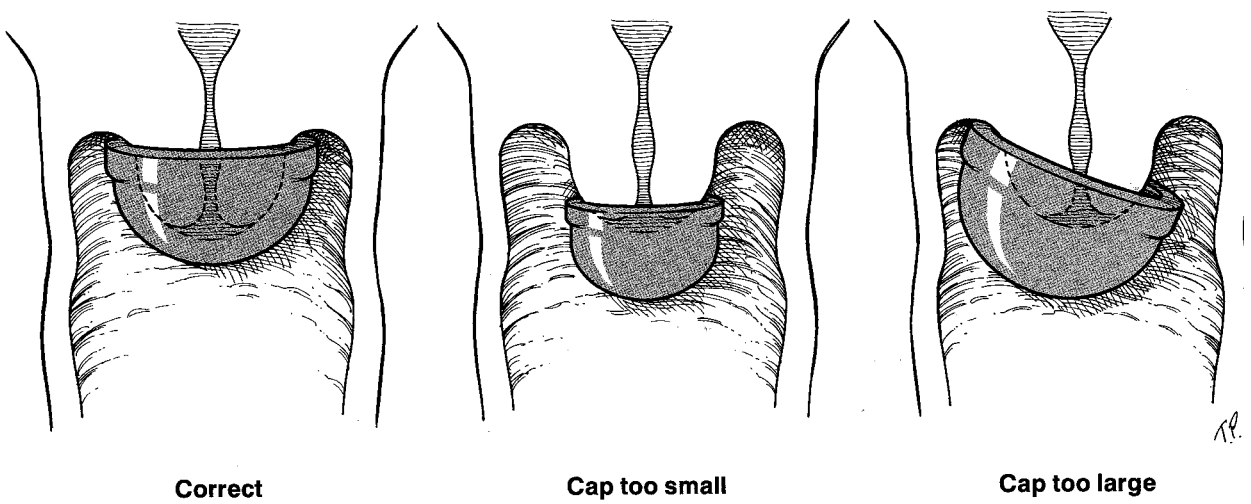

FIGURE 18-5 Proper and improper fit of the cervical cap: The cap should completely cover the cervix with the rim in the cervicovaginal fornices.

Source: Reproduced with permission from *Contemporary OB/GYN* (January 1993), p. 100.

Prentif Cavity Rim cervical caps are available in 22 mm, 25 mm, 28 mm, and 31 mm sizes; the numbers denote the diameter of the internal aspect of the rim. Estimates of the percentage of women who cannot be properly fitted with a cap range from 6 percent to 40 percent. As with the diaphragm, you should try two or more sizes to determine the most appropriate fit. The cap is compressed and inserted into the vagina. When the cap is released over the cervix, the suction that is created often draws the cap onto the cervix; if not, you may place the cap on the cervix. To remove the cervical cap you push/pull firmly against the rim to tip the cap and break the seal and then grasp the cap with your fingertips and bring it out. Ask the woman to bear down to help bring the cap within reach.

The fit of the cervical cap is checked by running your finger around the circumference of the rim. The cap should be sealed in the cervicovaginal fornices all the way around. If any of the cervix is exposed, the cap is not up into the fornices, or you are unable to rotate it, then the cap is too small (see Figure 18-5). Too small a cap will cause damage to the cervical tissue. The cervical cap is too large if you are able to dislodge it easily by pushing at it with a fingertip, if you find gaps between the cervix and the cap, or if it rotates too easily or falls off when you rotate it. A cap that is too large will not have an adequate seal and will not protect against either pregnancy or disease. (See Figure 18-5.)

To use the cervical cap, the woman fills the dome at least one-third full with a spermicide prior to insertion. Insertion should be at least half an hour before sexual intercourse, as the suction will have created a better seal by that time. The woman should check herself after insertion to make sure the cap is properly located on and over the cervix. She should also check herself between acts of sexual intercourse, as the cervical cap sometimes becomes dislodged as a result of penile thrusting.

Care of the cervical cap is the same as for a diaphragm. The cap differs from the diaphragm in the length of time it can be left in. The diaphragm should be removed 6 to 8 hours after the last act of intercourse and no longer than 24 hours after insertion. The cervical cap can be left in for as long as 48 hours, although there may be a foul odor after 24 hours. One concern with leaving the cap in so long is toxic shock syndrome, which has occurred in a few women who left diaphragms in place for 36 to 48 hours. To date no incidence of toxic shock syndrome with the cervical cap has been reported, but caution is indicated.

Follow-up care includes an appointment in two to four weeks to check the fit of the cervical cap and the woman's ability to use the cap and to assess her satisfaction with the method. In accord with a recommendation from the FDA, the woman should return in 3 months and 12 months for a Pap smear. If the Pap smear remains negative, the woman should make an appointment for her annual health assessment, which should include checking the fit of her cervical cap.

Instructions in the Use and Care of the Cervical Cap

1. Insert the cervical cap at least 30 minutes prior to intercourse to allow a good suction to form. You can insert it several hours ahead of time.
2. Empty your bladder and wash your hands with soap and water.
3. If you keep your cervical cap in cornstarch, shake the excess cornstarch off.
4. Fill the dome of the cap one-third full of contraceptive cream or jelly. Do *not* spread the cream or jelly on the rim of the cap, as that might prohibit the formation of a seal.
5. Compress the sides of the cervical cap, and insert it into your vagina.
6. Keep pushing the cap into the vagina until it touches your cervix; then release the cap and place it over your cervix.
7. Check the position of the cap. Make sure it covers your cervix and is sealed all around the rim.
8. You can walk around, bathe, urinate, and have a bowel movement with your cervical cap in place because it will neither get lost in your body nor fall out.
9. You do not need to add more spermicidal cream or jelly for repeated intercourse. If you decide that you want to add more spermicide, insert an applicatorful into your vagina. Do *not* remove your cap to add spermicidal cream or jelly.
10. Check the position of the cervical cap after each act of sexual intercourse if you are having repeated intercourse.
11. Leave the cap in for at least 6 to 8 hours after the last act of sexual intercourse in order to ensure that the sperm have died.
12. You can leave your cervical cap in for up to 48 hours, but you will probably want to remove it before 24 hours to avoid the development of a foul odor.
13. Douching is not necessary or encouraged. However, if you are going to douche, then do it

when you remove your cervical cap. Use half of a body-temperature tap water douche before removing the cervical cap; use the other half of the douche after removing your cervical cap. The douche is divided into these two portions on the outside chance that any semen containing sperm remains. Douching has a tendency to encourage sperm to move inward through the cervical os rather than outward from the vagina. Any such semen is thus washed out before the protective barrier is removed.

14. Check the position of the cervical cap before removing it. Contact your midwife if you find it out of position.
15. To remove the cervical cap, bear down to bring your cervix closer to the outside, locate the cap with your finger, push/pull on the rim to break the seal, take the cap off your cervix, and remove it from your vagina.
16. Follow these instructions for care of your cervical cap:
    a. After each use, do the following:
        (1) Wash with a mild, nonperfumed soap.
        (2) Rinse with clear water.
        (3) Thoroughly dry the cap (preferably air dry).
        (4) Dust with cornstarch, but never with talcum powder or any kind of perfumed powder, as this will rot the rubber.
        (5) Store the cap in a dry container away from heat and sunlight (heat rots rubber).
    b. If an odor develops, be sure to remove the cap daily for cleaning. Soak the cap in a vinegar solution (1 tsp apple cider vinegar to 1 qt water) to neutralize the odor without harming the cap. (This process will turn the cap brown.)
    c. Periodically check your cervical cap for areas of rubber deterioration, weakening, holes, or tears.
    d. Never use petroleum jelly (Vaseline) or any other oil-based products or lubricants.
17. Make an appointment to have your cervical cap checked or to be refitted in the event of any of the following:
    a. after having a baby
    b. after having an abortion (spontaneous or therapeutic)
    c. if you have any procedures done on your cervix
    d. if you have any intrauterine procedures done that involve going through your cervical canal
18. Make an appointment before your annual examination in the event of any of the following:
    a. You lose your cervical cap.
    b. Your cervical cap is damaged or deteriorating.
    c. You need to be refitted.
    d. You or your sexual partner is no longer happy with this method of contraception.

Other Vaginal Contraceptive Barrier Methods

Lea's Shield

Lea's Shield is a 55-mm diameter, one-size device made of silicone rubber that a woman does not have to have fitted. A study of the safety and efficacy of Lea's Shield found it to have high levels of safety and acceptability; when used with a spermicide, it compares well in efficacy with other barrier methods [13].

FemCap

The FemCap has widespread approval in Europe but is not yet approved by the FDA. A type of cervical cap, it is made of nonallergic silicone rubber. It fits over the cervix and has a wide brim (resembling a sailor's cap) that creates a groove between the dome and the brim. The brim seals the FemCap against the vaginal walls and directs the semen into the groove. A comparison study with the diaphragm showed significantly fewer urinary tract infections with the FemCap but considerably greater difficulty with removal even though it has a removal strap. Insertion and dislodging of the FemCap during coitus were also problematic, and the risk of pregnancy was greater [14].

CHAPTER

19

Intrauterine Contraceptive Devices

Description, Effectiveness, User Response, and Noncontraceptive Benefits

Although intrauterine contraceptive devices (IUCDs or IUDs) are used by less than 1 percent of women at risk for pregnancy in the United States (see Table 16-1), they are the most commonly used reversible contraceptive in the world [1, 2]. Such devices are made of a variety of materials in various shapes. Usually the basic material is polyethylene, an inert plastic. The material used must be (1) noninflammatory in the normal uterus, (2) flexible for insertion and removal, and (3) able to retain its "memory" so as to resume its shape when in position.

IUDs have a cervical appendage in the form of threads. The threads facilitate removal, enable a woman to check herself periodically to ascertain if the IUD is still in place, and permit an examiner to identify quickly the presence of the IUD.

IUDs are either medicated or nonmedicated. Medicated IUDs are those in which a chemical has been added to the basic material to enhance effectiveness by decreasing pregnancy rates, decreasing expulsion rates, and minimizing side effects. The two IUDs currently available in the United States are both medicated: the Copper T 380A (ParaGard) and the levonorgestrel-releasing intrauterine system (LNG-IUS/Mirena). Nonmedicated IUDs include the well-known Lippes Loop, which is still used in Indonesia [2] but has not been available in the United States since 1985, and a stainless steel ring used mostly in China. Historically IUDs have been named after the individual who developed them or for some feature of the IUD or the shape itself.

A number of IUDs are no longer on the market because they presented one problem or another. These include the so-called closed devices (e.g., Hall-Stone ring, Birnberg bow), removed from the market because of possible strangulation of a loop of intestine if they perforated the uterus; the Majzlin spring, removed from the market because of possible imbedding in the endometrium and myometrium; and the Dalkon shield, removed from the market because of association with spontaneous second trimester septic abortions.

The mechanism of action of the IUD is primarily by preventing fertilization. Copper ions from copper IUDs change the content of tubal and endometrial fluids, which impairs tubal transport and function of the sperm [3 ,4]. Hormonal IUDs impair tubal motility and thicken the cervical mucus, making it viscous, largely impenetrable to sperm, and impairing sperm mobility. IUDs also have a secondary mechanism of action of a local foreign body reaction that makes the endometrium unfavorable for implantation and is probably what makes the IUD efficacious for emergency contraception. With the IUD already in place, however, the primary mechanism of action is not abortifacient.

Research and statistics evaluating IUDs generally emphasize pregnancy, expulsion, removal, continuation, bleeding/pain, and infection rates. There is very little difference between perfect use and typical use rates for the IUD (see Table 16-2, page 464), and that difference probably can be attributed to unrecognized expulsion of an IUD. IUDs are second only to Norplant in the percent of women who continue use after one year, and they rival the hormonal methods in effectiveness.

The cost of IUDs varies depending on the device but generally is approximately $300. Added to this cost is the cost of examinations, laboratory

tests, and the insertion. The total cost of an IUD for a woman who is self-paying can run as high as $1000. However, it is a long-term method, which makes it cost effective when used over a period of five to ten years. The device comes in a sterile package, which includes not only the IUD but also a disposable inserter, insertion instructions, patient information, and informed consent brochures.

Many users have a favorable response to the IUD because this method of contraception is quite unassociated with the sexual act itself. An additional advantage is that the woman does not have to think about it daily or monthly or purchase supplies. Women who have an aversion to inserting a finger into their vagina may object to checking for the cervical appendage after each menstrual period. Some people object to the possible side effects associated with IUDs, and some women simply don't like the idea of having something inside of them.

Both copper and hormonal IUDs have noncontraceptive benefits. Copper-bearing and nonmedicated plastic IUDs convey probable protection against endometrial cancer [1]. Hormonal IUDs, specifically the LNG-IUS, reduce the number of days of menstrual bleeding, increase hemoglobin concentration, are an effective treatment for menorrhagia, and prevent or treat anemia [1]. Because of the action of the progestin levonorgestrel, many women develop amenorrhea or oligomenorrhea. No IUD provides protection against HIV or sexually transmitted diseases; this is why the IUD is recommended only for couples who are disease free and mutually monogamous. Otherwise, the use of condoms in addition to the IUD is necessary.

Contraindications and Side Effects

Contraindications [5–8]

The following are contraindications to the insertion of an intrauterine contraceptive device in a woman by a midwife:

1. Pregnancy
   - **a.** confirmed
   - **b.** suspected
   - **c.** possible (i.e., the woman has had coitus without a valid contraceptive method since the last normal menstrual period)
2. Pelvic inflammatory disease (PID)
   - **a.** history of chronic PID
   - **b.** presence of acute or subacute PID
   - **c.** history of PID within the past 3 months, including postpartum endometritis or an infected abortion
3. Cervical or uterine carcinoma (known or suspected)
   - **a.** unresolved, abnormal Pap smears (class III, CIN I, or greater)
   - **b.** unexplained or abnormal uterine bleeding
4. History or presence of valvular heart disease (contraindication because persons with this condition have increased susceptibility to subacute bacterial endocarditis). This does not include mitral valve prolapse.
5. Presence of myomata, congenital malformations, or developmental anomalies that distort the uterine cavity
6. Known or suspected allergy to copper or diagnosis of Wilson's disease (genetically inherited abnormal copper metabolism that allows fatal accumulation of copper in various organs)—contraindications only for IUDs with copper
7. Uterine sound measurements outside the limits stated in the most recent insertion instructions from the manufacturer (as of this writing, the uterus should sound to a depth of 6 to 9 cm for both ParaGard and Mirena).
8. High risk for sexually transmitted diseases (i.e., multiple sexual partners or partner with multiple sexual partners)
9. History of ectopic pregnancy or condition that would predispose to ectopic pregnancy—contraindication only for hormonal IUDs
10. Acute cervicitis or vaginitis (until diagnosed and successfully treated), especially with a recent or recurrent history of chlamydia or gonorrhea infection or bacterial vaginosis. Pelvic infection with an IUD, for reasons other than sexually transmitted diseases, is most likely due to the introduction of an organism into the uterine cavity during the insertion procedure.
11. Genital actinomycosis
12. Increased susceptibility to infection (e.g., chronic corticosteroid therapy, diabetes, blood dyscrasias, HIV/AIDS, leukemia, and IV drug abuse)
13. A previously inserted IUD that has not been removed
14. Acute liver disease, including active viral hepatitis, or liver tumor (benign or malignant)—contraindication only for hormonal IUDs
15. Known or suspected carcinoma of the breast—contraindication only for hormonal IUDs
16. Current deep vein thrombosis/pulmonary embolism—contraindication only for hormonal IUDs

17. Migraine headaches with focal neurologic symptoms—contraindication only for hormonal IUDs

The midwife should also carefully evaluate the presence and the implications of either of the following conditions and then decide whether to insert an IUD.

1. History of previous unsuccessful use or problems with an IUD
2. History of severe vasovagal response

Side Effects and Complications

The following side effects and complications are those most commonly identified with intrauterine contraceptive devices:

1. Vasovagal syncope with insertion
2. Immediate postinsertion spotting and cramping
3. Cramping, low back pain, or both for several days after insertion
4. Continuing severe pain from uterine cramping
5. Dysmenorrhea, especially for the first 1 to 3 months after insertion
6. Menstrual changes/disorders (menorrhagia, metrorrhagia, amenorrhea, oligomenorrhea)
7. Severe or prolonged bleeding
8. Anemia
9. Strings missing, too long, or too short
10. Embedment of IUD in the endometrium or myometrium
11. Expulsion of the IUD
12. Pregnancy, either with the IUD in place or subsequent to unnoticed expulsion of the IUD
13. Ectopic pregnancy
14. Spontaneous septic abortion
15. Cervical or uterine perforation
16. Pelvic inflammatory disease (PID)
17. Ovarian cysts—hormonal IUDs only
18. Danger from medical diathermy (short-wave and microwave) in the abdominal, sacral, or pelvic areas—copper IUDs only

There is no evidence that IUDs are carcinogenic.

Management Plan for the IUD

Management of the care of the woman with IUD contraception consists of the following components:

1. Informing the woman of the effectiveness rates, providing her with product information, discussing potential side effects and complications, and having her sign the informed consent form in the brochure provided by the manufacturer
2. Conducting a general history, physical and pelvic examinations, and laboratory tests including pregnancy test, Pap smear, chlamydia and gonorrhea cultures, and hemoglobin/hematocrit (see Chapter 2)
3. Screening for any deviations from normal and for any contraindications to insertion of an IUD
4. Selecting the IUD appropriate for the individual woman
5. Inserting the IUD
6. Teaching the woman how to check for her IUD
7. Giving the woman instructions regarding her IUD and follow-up care
8. Scheduling and managing return visits
9. Managing the possible side effects and problems related to an IUD
10. Removing the IUD when indicated

Insertion of an IUD is a two-visit process. The first visit encompasses the first four components of the management plan and is a pre-insertion visit. During the first visit, after the woman decides she wants an IUD, a history, physical, and pelvic examination are performed and laboratory tests done to rule out any contraindications. Together, you and the woman then determine which IUD would be best for her. Anticipatory guidance and counseling are done at this visit preparatory for both the insertion procedure and for possible side effects during the first 3 to 6 months. Questions are answered until the woman is satisfied and fully informed. She then is given an appointment to return for the insertion itself immediately after the lab results are back. This appointment can be at any time during the menstrual cycle so there is no reason for delay. She is also counseled regarding staying pregnancy- and infection-free until that time. Pending laboratory results, the second visit is for the insertion procedure.

Selection of the Appropriate IUD

The following comments about each IUD are designed to give the midwife information that will be helpful in selecting the IUD most appropriate for an individual woman.

Copper T 380A (ParaGard) The ParaGard is a T-shaped piece of polyethylene wrapped with copper wire on the stem and with copper sleeves on each of

the transverse arms. A monofilament polyethylene thread, tied so that there are two strands, serves as the transcervical appendage. Barium sulfate is added to the device to make it visible on x-ray. In 1994 the Food and Drug Administration extended to ten years the length of time the Copper T 380A could effectively remain in utero [9]; after ten years the IUD should be replaced.

To reiterate some key features of the Copper T 380A:

1. It can be used for long-term contraception.
2. It can also be used for emergency contraception.
3. It protects against endometrial cancer.
4. It is a good option for those women who cannot or do not want to use hormones.
5. All copper IUDs are contraindicated in women with allergies to copper or diagnosed with Wilson's disease.
6. Although there is less bleeding as a side effect with the copper IUDs than there was with the nonmedicated IUDs, bleeding can still pose a problem.
7. The return of fertility is rapid when it is removed.
8. It does *not* protect against sexually transmitted diseases or HIV infection.

Levonorgestrel Intrauterine System (LNG-IUS or Mirena)

The Levonorgestrel Intrauterine System is a modified T-shape (the horizontal bar is slightly curved and bent on the ends) made of polyethylene with a cylinder of polydimethylsiloxane around the stem. The polyethylene is compounded with barium sulfate to make it visible on x-ray. The cylinder contains a reservoir of 52 mg of levonorgestrel, a progestogen also used in oral contraceptive products, a small amount of which is released daily into the uterine cavity over a period of 5 years. To reiterate some key features of the LNG-IUS:

1. Basically it is a hormonal method with all the same contraindications, benefits, cautions, and side effects that go with other forms of progestin-only hormonal contraceptives.
2. It is one of the most effective contraceptive methods, including sterilization (see Table 16-2, page 464).
3. It increases hemoglobin concentration and can be used to treat menorrhagia and anemia.
4. It causes the menstrual bleeding pattern to be altered and irregular. During the first 3 to 6 months, the number of bleeding and spotting days are irregular and may increase. During the second 6 months, the number of bleeding and spotting days are still irregular but decrease. Amenorrhea develops in approximately 20 percent of women by the end of the first year.
5. The return of fertility is rapid when it is removed.
6. It does *not* protect against sexually transmitted diseases or HIV infection.

Timing of IUD Insertion

The midwife must be certain that the woman is not pregnant and that she is free of any vaginal or uterine infection at the time of insertion. Many clinicians prefer to insert an IUD during a woman's menstrual period. Carrying out the procedure during the woman's period eliminates the risk of inserting an IUD into a pregnant uterus. However, a woman may be more susceptible to developing an infection from an IUD insertion during her menses. Also, if there is too much of a wait or she does not like the idea of an examination and a pelvic procedure being done while she is menstruating, a woman may not return. In fact, IUD insertion can take place on any day of the menstrual cycle. However, the midwife must be convinced of the woman's sexual intercourse and contraceptive history since her last normal menstrual period before making a decision to insert an IUD at any time other than during her menses or a few days immediately following. Both removal and expulsion rates are lower when IUDs are not inserted during menses [8, p. 80].

Although some authors list immediate postpartum and postabortion IUD insertion as an option, the midwife should be cautious and, if possible, provide the woman with an interim contraceptive method and wait to insert the IUD until completion of involution or until the 4- to 6-week postpartum or 2-week postabortion visit. The insertion procedure immediately postpartum or postabortion is a bit tricky because of the softness of the uterus. Unless the midwife is very skilled in the procedure and very familiar with the intrauterine feel of the immediate postpartum uterus, there is a higher risk of perforation. Because of the process of involution there is also a higher rate of expulsion.

Medications for Insertion

Before the procedure, some clinicians like to offer the woman some medication, especially if she is tense and anxious or has a history of dysmenorrhea. Such medication might include a nonsteroidal anti-inflammatory drug (NSAID) or oral analgesic

1/2 to 1 hour prior to the procedure. Another option is to use a local anesthetic at the tenaculum insertion sites or a paracervical block. Generally speaking, this is not necessary and not done. Prophylactic antibiotics to prevent postinsertion infection no longer are thought to be beneficial [10–12] and are less important than proper screening of candidates for IUDs, maintaining asepsis, using strict sterile technique, and cleaning the cervix (see Step 7 below).

Procedure for Insertion of the IUD

The insertion of an IUD varies in specific details according to the device and the inserter made for it. You should study the manufacturer's instructions prior to inserting an IUD unfamiliar to you. There are, however, some steps in the technique of inserting an IUD that should be followed, regardless of which IUD is being inserted. These are as follows:

1. Obtain the woman's signed informed consent.
2. Ascertain that the Pap smear and chlamydia and gonorrhea diagnostic testing done at the initial (preinsertion) IUD visit (discussion; review of informed consent; screening history, examination, laboratory tests) are negative and that her hemoglobin/hematocrit and any other tests are within normal limits.
3. Ensure by history, examination, and/or pregnancy test that the woman is not pregnant.
4. Explain the procedure to the woman (pelvic examination, speculum, tenaculum, and IUD insertion).
5. Perform a bimanual examination. Do not trust anyone else's bimanual examination findings prior to inserting an IUD. Specific findings prior to an IUD insertion are to
   a. rule out pregnancy
   b. rule out acute pelvic inflammatory disease
   c. determine position, size, shape of uterus
6. Insert the speculum and adjust for greatest visualization and exposure.
7. Thoroughly clean the cervix with an antiseptic solution such as povidone-iodine (Betadine) or benzalkonium chloride (Zephiran) to decrease the risk of infection. Ask the woman if she is allergic to iodine before using an antiseptic solution that contains iodine.
8. Apply a tenaculum to the cervix.
   a. Apply a single-tooth tenaculum to the anterior cervix at 10 and 2 o'clock, approximately 1.5 to 2 cm (about 3/4 in.) from the level of the external os.
   b. Angle the tenaculum from above downward so the bite will not be so shallow that the tenaculum is in danger of tearing out of the cervix when pulled on or so deep that the cervical canal is obstructed.
   c. You may find it easier to manipulate the tenaculum if you use both hands, with one hand for control of each side of the tenaculum.
   d. Close the tenaculum *slowly*, one notch at a time. Forewarn the woman that she may feel a short, sharp pain at this time. If she does experience pain, wait until it passes before proceeding to the next step of sounding the uterus.
   e. The tenaculum can also be applied at 8 and 4 o'clock if the posterior cervix is more accessible than the anterior cervix.
   f. The tenaculum should never be applied at 3 or 9 o'clock, as the major blood vessels to the cervix are positioned at these locations and excessive bleeding might result.
9. Sound the uterus to confirm the position of the uterus, rule out uterine canal obstructions, and measure the depth of the uterine cavity.
   a. Forewarn the woman that she may feel a cramp when the uterine sound passes through the internal cervical os.
   b. Hold the sound between your thumb and your first two fingers as you would a pencil or a fork. This gives you more delicate, sensitive control of the uterine sound.
   c. Pull steadily and strongly on the tenaculum in order to straighten out the axis of the uterus.
   d. Using gentle pressure, insert the sterile uterine sound into the cervical canal until you feel the resistance of the internal os. At this time one of three things will happen:
      (1) The sound will slip easily through the internal os, and you will have felt slight to no resistance from the internal os.
      (2) The internal os will resist the tip of the sound, requiring the application of steady, mild pressure against the os to cause it to open and admit the sound into the uterine cavity. Take care not to apply too forceful a pressure so when the os opens the sound does not plunge into, and possibly through, the uterus.
      (3) The internal os will resist the mild pressure of the tip of the sound against it and will not open readily. (In fact it will open—but patience is required.) This situation usually occurs in women who

are quite nervous and focused on the procedure.

Position yourself comfortably. While continuing to apply steady, firm (but not forceful) pressure against the internal os, distract the woman by conversing with her on any subject unrelated to health care, IUDs, and so forth. This works best if the woman does the talking. Get her to tell you about her daily routine and ask questions about such things as her home, job, schooling, and children. As she talks, suddenly you will feel the internal os relax and open, and the sound will slip into the uterine cavity. This may take from several seconds to a few minutes to accomplish.

You will probably have to repeat this process when inserting the IUD in its inserter through the internal os later.

e. Let the sound find its own way in the uterine cavity once it has passed the internal os; do not try to push it in in accord with what you think the uterine position is. Use the sound to validate or reject your bimanual findings.

f. Once the uterine position has been confirmed or determined, gently push the sound until it meets resistance. You should be at the top of the fundus. Tap against it. This should evoke a cramp; ask the woman if she felt one. If not, you may not be at the top of the fundus. Pull hard on the tenaculum to straighten the uterine axis, and again guide the sound until it meets resistance. Tap again; you should be at the top of the fundus now.

g. Measure the depth of the uterine cavity:

(1) When the tip of the sound is touching the fundus, place a sterile cotton-tipped applicator next to the sound, with the applicator tip at the external cervical os.

(2) Remove the sound and the applicator from the uterus and vagina at the same time.

(3) Measure the depth of the uterine cavity by measuring the length of the sound from where the tip of the applicator touches the sound to the tip of the sound.

h. If the speculum exam, bimanual exam, and measurements are all within the realm of normal, proceed with the next step.

10. Load the IUD into its inserter. This is a sterile procedure. This step is done just prior to inserting the IUD, because plastic devices start to lose their "memory" (shape retention ability) as soon as they are loaded. The less time the IUD is in the inserter, the less memory loss there will be to resume its shape.

11. Insert the IUD into the uterine cavity.

a. Forewarn the woman that she may feel a cramp at this time.

b. First pull firmly and steadily on the tenaculum to again straighten the uterine axis. Maintain this traction until the IUD is inserted.

c. Insert the IUD in its inserter into the cervical canal and through the internal os, as described in 9(d) above.

d. Insert the IUD into the uterine cavity by removing it from its inserter in accord with proper procedure for the IUD being used. Be sure of the procedure being used for the device you are inserting; some are pushed into the uterine cavity, others are placed in the fundus and then the sheath of the inserter is withdrawn.

Insertion of the device from its inserter should be done *slowly* in order to reduce the possibility of vasovagal syncope.

Undue force should never be needed. If undue force seems to be required, *STOP* and reevaluate. Never forcibly push an IUD into a uterine cavity—you risk pushing it into the uterine wall instead.

12. Remove the inserter and the plunger in accord with proper procedure for the IUD being used.

13. If there are strings to be cut, cut them no shorter than approximately $1^1/_2$ to 2 in. (3.75 to 5 cm) from the external cervical os. This leaves enough string that, as the IUD resumes its shape and as the uterus resumes its usual position (both of which cause some of the string to be taken up into the uterus), there will still be enough to be seen and felt. If the strings are still too long at the woman's first revisit, they can be shortened at that time.

14. Remove the tenaculum. If there is bleeding from the application sites, apply pressure with a sponge stick or with a 4×4 gauze on a ring forceps until the bleeding stops. Some clinicians do not do this, believing that with removal of the speculum the vaginal walls will apply sufficient pressure to stop the bleeding.

15. Remove the speculum.

16. Wipe off the woman's perineum.

17. Allow the woman to rest and recover if she needs to.

18. Teach the woman how to check for her IUD (see next section).

19. Give her a perineal pad to wear, and have her get dressed.

20. Chart all findings. Include the type of IUD inserted, whether you had any difficulty with the insertion, the measured depth of the uterine cavity, the position of the uterus, and the length of the strings.
21. Answer any questions the woman may have, and give instructions regarding the IUD and follow-up care (see below).

Safety Features in IUD Insertion Procedure There are a number of safety features to the insertion of an IUD. When strictly adhered to, these safety features reduce considerably the risk of perforating the uterus or introducing intrauterine infection during insertion.

1. Careful selection of the woman: taking of history, physical, pelvic and laboratory tests to rule out any contraindications to the use of the IUD
2. Use of only sterile instruments (including the speculum) and strict adherence to sterile technique throughout the procedure
3. Thorough cleaning (scrubbing) of the cervix with antiseptic solution
4. Careful bimanual examination to determine uterine position
5. Proper application and use of the tenaculum on the cervix
6. Careful sounding of the uterus and measurement of its depth
7. Slow and gentle pace

Instructions Regarding the IUD and Follow-Up Care

Review the following with the woman:

1. The information on the card you give her:
   a. the name of the IUD she has
   b. the date it was inserted
   c. where to call for help, information, or removal of her IUD
2. How long she can keep the IUD:
   a. If she has a Copper T 380A, it must be replaced in 10 years to remain fully effective.
   b. If she has a LNG-IUS, it must be replaced every 5 years to remain fully effective.
3. How to check herself for the IUD strings. In addition to giving her the following instructions on periodically checking for her IUD, give her some trimmed strings to feel so she knows what to check for and have her feel for the strings of her IUD now.
   a. Wash your hands.
   b. Lie down in bed, sit on the toilet or the edge of a chair, or squat.
   c. Insert your middle finger into your vagina in a downward and inward direction, and locate your cervix.
   d. Feel for the strings of the IUD at the end of your cervix; do not pull on the strings.
   e. Check for your IUD at the end of each menstrual period and as often as you want between these monthly checks.
   f. Immediately call and make an appointment to be seen as soon as possible if either you cannot feel the strings or you feel the end or a portion of the device. In the meantime consider yourself unprotected and use a spermicidal preparation and condoms.
4. The date of her first revisit in 6 weeks
5. The effectiveness rate, side effects, and danger signs associated with her IUD and when to call you immediately with a problem or for an appointment. She should call if she experiences any of the following:
   a. suspicion of pregnancy
   b. foul smelling discharge
   c. known exposure to a sexually transmitted disease
   d. fever associated with severe cramps
   e. dyspareunia, pelvic pain, or tenderness
   f. unusual vaginal bleeding or spotting
   g. unable to feel strings, or feel them shorter or longer, or feel the end of the IUD

In addition, the following information and instructions should be given:

1. You may have some spotting or bleeding and cramping for a day or so after insertion of your IUD. Take over-the-counter analgesics every 3 to 4 hours for pain.
2. Avoid sexual intercourse for the first 24 hours after insertion of your IUD.
3. There is an adjustment period to your IUD of approximately 3 months.
   a. During this time your menstrual periods may be longer and heavier than they were before you had an IUD inserted.
   b. The length and amount of menstrual flow you have by the third month after insertion of your IUD will probably be what your normal menstrual period will be like with an IUD.
   c. You may have some cramping, especially with your menstrual periods. This is more likely if you have not had a baby. If you did not experience cramps when your IUD was inserted or immediately afterward, you most likely will not have cramps later. Cramps

may be alleviated with over-the-counter analgesics.

4. If your IUD comes out spontaneously, it is most likely to do so during a menstrual period. Therefore, in addition to checking for the strings of your IUD after each menstrual period, you should do the following:
   a. Look for your IUD on your sanitary pads or tampons before discarding them (it is alright to use a tampon after the first 48 hr after insertion of your IUD).
   b. Check yourself for your IUD after any time you have some abdominal cramping.
   c. If you find your IUD externally, if you are unable to feel the strings, or if you feel the device coming through your cervix, you should
      (1) make an appointment to be seen as quickly as possible
      (2) consider yourself unprotected from becoming pregnant
      (3) use another contraceptive method until your appointment
5. Use a spermicidal preparation and condoms for the first month after insertion of your IUD.
6. If you should get pregnant with your IUD still in, you should have the IUD removed in order to decrease the risk of serious infection. The chance of spontaneous abortion if the IUD is removed is half what it is if the IUD is left in. A therapeutic abortion is possible if you wish to terminate the pregnancy.
7. The IUD is inserted in accord with the angle of your uterus. Therefore, you should obtain medical help to have your IUD removed when desired. You may injure yourself if you or your sexual partner pulls on the IUD strings.
8. Remember to be seen annually, no matter what type of IUD you have, for a physical and pelvic examination, including a Pap smear.

Return Visits

After the woman has her IUD inserted, she should be instructed to use a spermicidal preparation and condoms for the first month. This more fully protects her from conception while the IUD is rendering the cervix, uterus, and Fallopian tubes inhospitable for fertilization and implantation and during the time when the IUD is more likely to be expelled spontaneously.

The woman should return for her first revisit in approximately 6 weeks. This visit is deliberately timed to be after her first postinsertion menstrual period. By this time the first month of higher incidence of spontaneous expulsion will be over; the IUD can be checked to determine that it remains correctly positioned. In addition, the woman should have had experience with checking for her IUD herself and some of the immediate side effects should have diminished. The revisit provides an opportunity to answer questions and to encourage and reassure the woman, which results in an increased user rate. The following data pertinent to the IUD are elicited at this revisit:

History

1. Menstrual period (compare with pre-IUD menses)
   a. date
   b. length
   c. amount of flow
   d. pain
2. Intermenstrual (compare with pre-IUD)
   a. spotting or bleeding: how long, how much
   b. cramping: how long, how severe
   c. back pain: where, how long, how severe
   d. vaginal discharge
      (1) how long
      (2) color
      (3) odor
      (4) itching
      (5) burning on urination (before or after starting flow)
3. String checks
   a. date of last string check
   b. strings felt by partner during sexual intercourse
4. Satisfaction with method (both woman's and partner's)
5. Any medicines being taken: which ones, why
6. Any visits to a doctor or emergency room since IUD inserted: why
7. Use of spermicidal preparation and condoms: when, any problems
8. Presumptive signs of pregnancy if indicated

Physical examination

1. Abdominal examination for lower abdominal tenderness
2. Check for CVA tenderness if indicated for differential diagnosis
3. Probable signs of pregnancy if indicated

Pelvic examination

1. Speculum examination
   - **a.** visualization of strings
   - **b.** length of strings; trim if indicated
   - **c.** vaginal discharge; note characteristics and do cultures and wet mount if indicated
2. Bimanual examination
   - **a.** pain with movement of cervix or uterus
   - **b.** uterine tenderness
   - **c.** uterine enlargement
   - **d.** adnexal tenderness
   - **e.** probable signs of pregnancy if indicated

Laboratory

1. Hemoglobin or hematocrit
2. Routine urinalysis if indicated for differential diagnosis
3. Cervical cultures and wet mount if indicated
4. Pregnancy test if indicated

If the results of the above examinations are satisfactory, the woman is given an appointment for her annual examination, which will include a general screening history, physical and pelvic examinations, Pap smear, chlamydia and gonorrhea cultures, other routine laboratory tests (see Chapter 2), and a repetition of the IUD revisit outlined above. Instructions on checking her IUD, and when to call with a problem or for an appointment prior to her annual appointment, are reviewed with the woman during this return visit as well.

Management of Side Effects and Problems

Vasovagal Syncope (Fainting) Although it is infrequent, syncope may occur during or immediately following insertion of the IUD. The cause is thought to be excessive pain, especially in a woman who is quite nervous, fearful, or emotional at the time of insertion. Gentle manipulation of the instruments and handling of the uterus combined with slow insertion of the IUD may forestall or reduce the incidence of syncope. Abrupt, hurried, rough actions may enhance its occurrence.

In the rare event of syncope, place the woman in as much of a Trendelenburg position as possible (remove the pillow from under her head and place it instead under her hips and raise her legs), be sure she has an open airway, and keep her warm. If necessary, administer an aromatic (smelling salts). If syncope is severe and constitutes an emergency, administer 0.4 to 0.5 mg of atropine intramuscularly. Atropine acts as a respiratory and circulatory stimulant.

Immediate Postinsertion Spotting and Subsequent Menstrual Patterns and Bleeding Forewarn the woman about immediate postinsertion spotting and give her a perineal pad to protect her clothes. Heavier than usual menses and intermenstrual spotting or bleeding are not uncommon during the initial months with either copper bearing or hormonal IUDs. Immediately following insertion, women usually experience varying amounts of spotting or bleeding. Spotting may continue for a few days, and some women have light intermenstrual bleeding during the first menstrual cycle. Women with the Copper T 380A usually have two or three longer and heavier menstrual periods and then their periods gradually return to what the woman had before insertion or remain slightly heavier than her pre-IUD periods; four- or five-day periods are not uncommon. Women with the LNG-IUS generally experience menstrual irregularities and an increased number of days with frequent spotting or light bleeding for the first 3 to 6 months. Some women will have heavier menstrual periods than their normal. Thereafter the number of spotting and bleeding days decreases, usually to one day of bleeding from 8 months on, but continues to be irregular. Approximately 20 percent of women will become amenorrheic [13].

All women, regardless of type of IUD, should be counseled before insertion on what to expect their menstrual periods to be like postinsertion. Women are much less likely to discontinue the method when they know what to expect. Women who become amenorrheic on the LNG-IUS need reassurance that they are not pregnant. After a negative pregnancy test, a woman can find continuing reassurance by feeling the IUD strings and having no signs and symptoms of a pregnancy (which you have taught her). Women with the Copper T 380A should have their hemoglobin/hematocrit closely monitored, especially if they were borderline anemic pre-insertion; iron should be prescribed for the first 2 to 3 months if they have heavy bleeding.

Women with severe or prolonged bleeding, menorrhagia and/or metrorrhagia after the initial uterine adjustment to the IUD should be evaluated for partial expulsion and cervical and uterine pathology. Partial expulsion of an IUD is ascertained as follows during speculum examination:

1. Note if the strings of the IUD are longer than expected.
2. Look for protrusion of the IUD from the external cervical os.
3. If you are unable to see the IUD at the external cervical os, do the following:

a. Apply a tenaculum to the cervix as described earlier in this chapter.
b. Explore the cervical canal with a uterine sound in an effort to locate the IUD in the canal or at the internal cervical os.

If the bleeding is not caused by the partial expulsion of the IUD, the midwife should proceed to evaluate the woman for cervical and uterine pathology (see Chapter 14).

If the IUD is partially expelled, remove it and replace it if the woman is not pregnant, does not have an infection, and wants another IUD. In these circumstances, if she is not contraindicated for progestogen hormones, she would be a good candidate for an LNG-IUS, which is used for treatment of menorrhagia and anemia as well as contraception. Because of all the manipulation involved in removing and replacing an IUD, a course of prophylactic antibiotics is indicated: doxycycline 100 mg po every 12 hours for 7 days. If the woman is allergic to tetracyclines, substitute erythromycin 500 mg po QID for 7 days.

A hemoglobin/hematocrit determination should be done and compared with previous findings to see if the blood loss has been such that the woman is becoming anemic and a prescription for iron is indicated. A woman may consider that heavy bleeding in the absence of pathology is sufficient reason to request that her IUD be removed and to select another contraceptive method.

Cramping, Low Back Pain, Dysmenorrhea Women usually experience varying amounts of cramping after IUD insertion. Cramps, which range from light and of brief duration in multiparas to severe and lasting several days in nulligravidas, occur when the uterus contracts in an effort to expel the IUD. The woman should be forewarned of this possibility and advised to take over-the-counter analgesics for the pain. If the insertion induced continuing painful cramping, prescribe ibuprofen (Motrin; Advil) 400 mg po every 4 hours as needed.

Dysmenorrhea for the first 1 to 3 months after insertion is not uncommon. It is worse in those already afflicted with dysmenorrhea. The usual comfort measures (e.g., lying down, warm soaks in the bathtub, heat to the lower abdomen or back) and analgesics are in order. Use of the LNG-IUS may lessen dysmenorrhea in about one-third of users [13].

If the woman continues to experience severe pain from uterine cramping, PID and perforation must be ruled out. Also consider ovarian cysts if the woman has an LNG-IUS and has severe lower abdominal pain. These tend to spontaneously resolve [13, 14]. A woman may consider severe, unremitting cramps without pathology sufficient reason to request that her IUD be removed and to select another contraceptive method.

Pregnancy A woman who becomes pregnant with her IUD in situ should be informed of the risks involved if the pregnancy continues with the IUD in place. These risks include intrauterine infection, sepsis, spontaneous abortion, spontaneous septic abortion, placenta previa, and premature labor. Women who become pregnant with their IUD in place should be evaluated for ectopic pregnancy as the incidence of such a pregnancy is higher in these women.

If the strings of the IUD are not visible at the cervical os or accessible in the cervical canal, an ultrasound should be done to ascertain whether the IUD is in the uterus, outside of the uterus, or missing entirely. If the IUD is missing, you must assume that there was an unnoticed expulsion and either provide prenatal care or referral for abortion in accord with the woman's decision regarding continuation of the pregnancy. If the IUD is there, the option of a therapeutic abortion should be discussed with the woman or couple. Her risk of a life-threatening spontaneous septic abortion in the second trimester is vastly increased if the IUD is left in place. If the decision is in favor of a therapeutic abortion, the midwife should help the woman make arrangements or refer her to someone who can do so.

If the strings of the IUD are visible, the IUD should be removed whether or not the woman or couple wish to terminate the pregnancy. The IUD should be removed because the incidence of spontaneous abortion is lower in women whose IUDs are removed than in those whose IUDs remain in during the pregnancy and because the risks enumerated above are minimized with removal of the IUD. Approximately 25 percent of women abort spontaneously following removal of the IUD. The incidence of spontaneous abortion is approximately 50 percent for women whose IUDs are left in situ. If a woman wishes to terminate her pregnancy, remove the IUD and then refer her for a therapeutic abortion. Removing the IUD immediately eliminates the possibility of a septic spontaneous abortion in the interim prior to the therapeutic abortion.

Pelvic Inflammatory Disease (PID) The current prevailing thought about IUDs and pelvic inflamma-

tory disease (PID) is that PID is most likely associated with the introduction of organisms at the time of insertion of the IUD and not with the IUD itself, as was previously thought and debated [15, 16]. It is important for the midwife to exactly follow rules of cleanliness in performing pelvic examinations; to adhere strictly to sterile technique in the intrauterine procedures involved in inserting, checking, and removing IUDs; to instruct the woman in hygienic measures related to the perineum and vagina; to screen for, identify, and treat sexually transmitted diseases (especially chlamydia and gonorrhea) before they develop into PID; and to screen for the signs and symptoms of PID. (See Chapter 15 for a discussion of the signs, symptoms, and treatment of PID.)

If a woman shows any signs and symptoms of PID, antibiotic therapy should be started immediately and the IUD removed. Some clinicians prefer to wait a couple of days before removing the IUD in order to achieve therapeutic blood levels of the antibiotics prior to removal. She should be given an alternative contraceptive method. The woman should be told the signs and symptoms of a worsening condition, the need to take her medication absolutely as prescribed, and when and how to call you. If the woman is considering the possibility of having another IUD inserted, you need to review carefully with her any history that would place her at risk for developing another infection. Even under the most benign circumstances another IUD should not be inserted for at least 3 months after successful therapy for PID. The woman should be encouraged to use a different primary contraceptive method.

Missing IUD Strings The woman herself is usually the first to notice that IUD strings are missing, when she is unable to feel them when checking herself. In such a situation there are four possible reasons why the strings cannot be felt or seen on speculum examination:

1. The strings were cut too short and retreated fully into the cervical canal as the device assumed its original shape, the uterus resumed its usual position after being pulled down by use of the tenaculum, and uterine contractions caused the strings to be sucked in.
2. The woman is pregnant.
3. The IUD has perforated through the uterus.
4. The IUD was spontaneously expelled without the woman's being aware that this happened.

When managing a woman whose IUD strings are not visible, you must *first* ascertain whether she is pregnant *before* doing any further search for the IUD. This determination is made on the basis of history, physical and pelvic examination for the signs and symptoms of pregnancy, and a pregnancy test (see Chapter 21). Additional history you need includes the following:

1. When the IUD was inserted
2. Type of IUD inserted
3. Any previous problems with IUD expulsion
4. Normal pattern of checking herself for IUD strings
5. When she last felt the IUD strings
6. Length of time between when she last felt the IUD strings and when she first was unable to feel them
7. Number of times she had coitus during this period of time and subsequently
8. Use of any other contraceptive method since she was unable to feel the IUD strings

If there is no evidence of pregnancy, you may proceed with your search for the IUD. Using sterile instruments and technique, position the speculum and apply a tenaculum to the cervix (see the procedure for IUD insertion earlier in this chapter). Explore the cervical canal for the strings of the IUD, using a narrow sponge forceps or long Kelly clamp. If you find the strings, remove the IUD, replace it (being careful to leave the strings long), and prescribe prophylactic antibiotics (e.g., doxycycline 100 mg po every 12 hr for 7 days).

If no strings can be found, insert a uterine sound into the uterus and feel for the IUD with the sound. If you find the IUD and cannot bring any strings into view to use for removal, remove the IUD using alligator forceps. Replace the IUD if the woman so desires, if there has been no other problem with the IUD, and if there is no reason to suspect a contraindication. (Again, be careful to leave the strings long on the replacement IUD.) Prescribe prophylactic antibiotics as described above.

If you are unable to feel the IUD with the uterine sound, obtain an ultrasound. If no IUD is present, determine whether the woman wants another IUD and insert one if she does. If the IUD can be seen but it is not clear whether it is in the uterus, contact your consulting physician for further methods of identifying the location of the IUD. If x-ray films are taken, some means must be used to identify whether the IUD, if visible, is within the uterus

or outside the uterus in the abdominal cavity. This is done in one of the following ways:

1. A marker IUD (an IUD of a different type or shape) is inserted into the uterine cavity for purposes of identifying whether the missing IUD is in utero, is in the abdominal cavity, or was expelled.
2. A uterine sound or catheter filled with radiopaque dye is inserted into the uterus.
3. A hysterogram is made (an x-ray film is taken immediately after injection of a radiopaque dye into the uterus via the cervical os); this procedure is contraindicated if there is intrauterine infection or PID.

The midwife will need to refer the woman to the consulting physician for removal of an IUD that is partially or wholly outside of the uterine cavity.

Procedure for Removal of the IUD

The usual reasons for removal of an IUD are a woman's desire to become pregnant; replacement of a medicated device; severe, unremitting cramps; and heavy, lengthy menses with or without intermenstrual bleeding. Other reasons include partial expulsion of the IUD, PID, and pregnancy with visible IUD strings.

After the procedure is explained to the woman and a bimanual examination is performed, a sterile speculum is inserted, the cervix is cleaned, and the tenaculum is applied to the cervix as described in steps 4 through 8 of the procedure for insertion of an IUD detailed earlier in this chapter. Then do the following:

1. Clamp a long-handled forceps or needle-holder on the strings.
2. Pull steadily and strongly on the tenaculum to straighten the uterine axis.
3. Exert a steady, pulling traction on the strings.

If no strings are visible, then use alligator forceps and proceed as follows:

1. Pull steadily and strongly on the tenaculum to straighten the uterine axis.
2. Insert the alligator forceps into the uterine cavity (as detailed in step 9, parts (a) through (e), in the description of the procedure for inserting a uterine sound earlier in this chapter).
3. Grasp the IUD with the alligator forceps.
4. Pull steadily and strongly on the tenaculum to straighten the uterine axis.
5. Pull evenly and steadily with the alligator forceps to remove the IUD from the uterine cavity.

If you meet with great resistance during the removal, *STOP!* Contact your consulting physician before you either break off the IUD strings or (if the strings were unavailable to start with) find yourself coping with a situation you can't handle (such as an imbedded IUD or an IUD partially perforating the uterus that was missed on ultrasound).

CHAPTER

20

Hormonal Contraception

Hormonal contraception takes a number of different forms:

1. Pills
   a. Combination
   b. Progestin-only
2. Emergency contraception
3. Injectables
4. Implants
5. Intravaginal ring
6. Transdermal contraceptive patch
7. Intrauterine device. The hormonal IUD, LNG-IUS (Mirena), is discussed in Chapter 19.

Hormonal contraception consists of a combination of an estrogen and a progestin or of a progestin only.

It has been known for some time that any of the sex hormones can suppress the production of the pituitary gonadotropins (specifically, for contraception, follicle-stimulating hormone [FSH] and luteinizing hormone [LH]). This suppression results when the sex hormone produces a negative feedback action on the hypothalamus, which inhibits secretion of the hypothalamic-releasing factor, which in turn suppresses FSH and LH. The administration of synthetic steroid preparations thus effectively inhibits the development of a graafian follicle and subsequent ovulation. Without ovulation, there is no ovum to be fertilized.

However, the antifertility effect of steroids is not wholly dependent on the inhibition of ovulation. High doses of estrogen postcoitally inhibit implantation of a fertilized egg because estrogen alters the usual progestational development of the endometrium. Thus oral hormones are also used to provide emergency postcoital contraception. Progestins also have the following contraceptive effects:

1. Creation of a hostile cervical mucus that is thick and largely impenetrable by sperm, thus decreasing sperm penetration, transport, and survival
2. Prohibition of the process of capacitation in the sperm resulting from changes in the cervical fluid, which would normally activate this process, thereby rendering the sperm unable to penetrate the ovum
3. Production of an atrophic endometrium that will not support implantation

Combination Pills

Description, Effectiveness, and User Response

The mechanism of action of the pill is a combination of the contraceptive action of estrogens and the contraceptive action of progestins. Three varieties of the combination pill are currently available:

1. *Monophasic:* The same amount and type of estrogen and progestin are taken each day for 20 or 21 days, followed by 7 days of no hormonal intake.
2. *Biphasic:* The estrogen dosage and type remain constant and the type of progestin remains the same but the level of progestin changes between the first and second week of the 21-day cycle of pills, which is followed by 7 days of no hormonal intake.
3. *Triphasic:* The estrogen type remains the same but the level may remain constant or may change in concert with the progestin; the progestin type remains the same but has three dif-

ferent levels during a 21-day cycle of pills, followed by 7 days of no hormonal intake.

In 2002 there were over 45 combination pills on the market in the United States. Many more were on the market worldwide.

The combination pill was the first type of hormonal contraception to be developed. Its name is derived from the fact that each pill contains a combination of an estrogen and a progestin. The main variations among the different formulations of the combination pill are the dosages, the relative proportions of the estrogenic and progestational components, and which estrogenic substance (ethinyl estradiol or mestranol) is used with which of the available progestins. The result is a variety of pills with somewhat different side effects, which allows for a certain amount of changing from pill to pill when necessary in order to best accommodate the individual woman's adjustment to the hormonal therapy.

The contraceptive steroids in the pill do not occur naturally but rather are drugs that produce a pharmacologic rather than a physiologic state. In reality, the menstruation of a woman on the pill is a pseudomenstruation, which is produced by the administration and then withdrawal of the hormonal pharmacologic drugs. A more precise term is *withdrawal bleeding*. The combined estrogen-progestin pill produces stromal edema, predeciduation, and some degree of glandular involution which, after a few cycles, yields a thin, hypoplastic-appearing endometrium. This accounts for the characteristic shorter duration and scantier flow often noticed by women taking the combination contraceptive pills.

There are two synthetic estrogens presently utilized in the combination contraceptive pills: ethinyl estradiol and mestranol. Each brand-name pill contains one or the other. Both are pharmacologic drugs different from naturally occurring estradiol, but they act in the same way. Mestranol is actually a derivative of ethinyl estradiol and is biologically inactive in the human body until converted metabolically into ethinyl estradiol by the liver. The conversion, however, is not 100 percent efficient, which means that ethinyl estradiol and mestranol are not bioequivalent microgram for microgram. Mestranol 50 mcg is bioequivalent to 35 mcg of ethinyl estradiol. Pills containing 50 mcg of mestranol, thus, are not high-dose pills as they are sometimes classified [1]. However, all the pills with less than 50 mcg of estrogen utilize ethinyl estradiol, whereas both ethinyl estradiol and mestranol are used in pills with 50 mcg of estrogen.

Seven progestins are presently utilized in the more common combination pills. Each brand name of pills contains one type of progestin. Each progestin varies in its estrogenic, progestational, and androgenic potency. Each brand-name pill thus varies in its estrogenic, androgenic, and progestational potency as determined by which estrogen is combined with which progestin. Table 20-1 lists the seven progestins and two estrogens and their comparative biological potency. Table 20-2 lists the progestin and estrogen utilized in the more common combination pills. This information is used to determine which pill to use to alleviate side effects.

Like the barrier methods and natural family planning, oral hormonal contraception has differ-

TABLE 20-1 Comparative Biological Potency of the Estrogens and Progestins in the More Common Oral Contraceptive Pills

Steroid	Estrogenic Activity	Androgenic Activity	Progestational Activity	Endometrial Activity
Estrogens				
Ethinyl estradiol	100.0	0.0	0.0	0.0

Source: Adapted from Dickey, R. P. *Managing Contraceptive Pill Patients*, 10th ed. Dallas, TX: Essential Medical Information Systems, 2000, table 4, pp. 88–91. Numbers in parentheses for multiphasic pills are the number of days in each phase. Used with permission.

ent effectiveness rates with perfect use and typical use. As shown in Table 16-2 (page 464), perfect use, especially of the combination pill, provides effectiveness comparable to that of sterilization, long-term hormonal contraception such as implants and injectibles, and two intrauterine contraceptive devices (the Copper T 380A and LNG-IUS; see Chapter 19). The pill's effectiveness with typical use, however, is worse than that of these same other methods. Typical use figures are affected by a woman's skipping pills for whatever reason: side effects, complications, anxiety about possible side effects or complications, illness, forgetfulness, lack of understanding the instructions, or a transient desire to become pregnant. The woman's compliance with pill-taking instructions is critical to efficacy of the method.

Although the pill is the most popular of all the methods of contraception in the United States, it has a high attrition, or discontinuation, rate. Nearly 30 percent of women who start the pill will not still be using it a year later. The most frequently cited reasons for discontinuing the pill are side effects and fear of potential side effects. Unfortunately, many women who discontinue taking oral hormonal contraception do so without initiating another contraceptive method even when they do not want to become pregnant.

The responses of women to the pill have been diverse. At one end of the spectrum are women who are afraid of using the pill because of the adverse publicity the pill has periodically received. At the other end of the spectrum are women who favor the pill for its ease of use, its disassociation with the act of sexual intercourse, and its high effectiveness rate.

Contraindications, Side Effects, and Complications

Contraindications The following are absolute contraindications to initiating combination oral hormonal contraception for a woman by a midwife:

1. Pregnancy (known or suspected)
2. Thrombophlebitis (presence or history of)
3. Thromboembolic disorders (presence or history of)
4. Cerebrovascular accident, cerebrovascular disease, or coronary artery disease (presence or history of)
5. Liver damage, impaired liver function, or acute hepatitis
6. Benign or malignant liver tumor (presence or history of)
7. Cholestatic jaundice of pregnancy or jaundice with prior contraceptive pill use
8. Type II hyperlipidemia (hypercholesterolemia)
9. Estrogen-dependent neoplasia (known or suspected)
10. Carcinoma of the breast (known or suspected)
11. Undiagnosed abnormal genital bleeding
12. Carcinoma of the endometrium (known or suspected)
13. Classic migraine headaches (with aura)/severe migraine with neurologic symptoms
14. Smoking by women over the age of 35
15. Diabetes mellitus
16. Leiden Factor V mutation or family history of multiple family members with multiple unexplained venous thromboembolism events at an early age

The following are relative contraindications to initiating combination oral hormonal contraception

for a woman by a midwife. The midwife should exert extreme caution in the presence of any of these conditions, discuss any particularly questionable situation with the consulting physician, make case-by-case decisions based on the total history, physical findings, and unique situation of that individual woman, or provide a different contraceptive method.

1. Hypertension; blood pressure greater than 140/90
2. Asthma
3. Cardiac disease (presence or history of)
4. Renal disease (presence or history of)
5. Gallbladder disease (presence or history of)
6. Ulcerative colitis
7. Sickle cell or sickle cell–hemoglobin C disease
8. Lupus erythematosus
9. Depression (presence or history of, especially if worse premenstrually or postpartum)
10. Elective surgery requiring lengthy immobilization
11. Varicose veins

The midwife should evaluate each woman who has any degree of mental retardation, substance abuse, or psychiatric disorder for reliability in pill taking and make a decision whether combination oral hormonal contraception is contraindicated on this basis. The midwife also should discuss with the woman her risk for HIV or sexually transmitted diseases and her need for a barrier method of contraception in addition to combination oral hormonal contraception. The pill gives no protection against the transmission of HIV or sexually transmitted diseases.

Side Effects and Risk of Complications The side effects of oral hormonal contraception are legion but have been much reduced since the advent of the lower dosages. Still, approximately 40 percent of women who use the pill have or perceive that they have side effects. These must be taken quite seriously and a woman given careful anticipatory guidance so that she does not simply discontinue taking the pill without being evaluated for the cause of the symptom or obtaining another method of contraception.

Experts have categorized the side effects (assuming nonmedical causes) by hormonal etiology; see Table 20-3. It is helpful to remember that each woman has her own individual hormonal makeup and balance. Therefore the same brand of pill may, for example, cause hormonal excess in one woman and hormonal deficiency in another woman. Both women may have side effects but the side effects may differ, since the underlying hormonal patterns are different.

There is a constant flow of information from reanalysis and meta-analysis of old data and from new findings from more recent studies that bring ongoing changes in thinking about potentially serious complications for women taking combination oral contraceptive pills. The following is a brief synopsis of conclusions, as of this writing, of these potential complications.

Cardiovascular system (myocardial infarction; cerebrovascular accidents; thrombophlebitis and venous thromboembolism [VTE], which includes deep vein thrombophlebitis and pulmonary embolism; and hypertension): Cardiovascular risk is based more on screening the women for risk factors than the hormonal makeup of the pill when the estrogen is less than 50 mcg. It is not necessary to select a pill with different progestins on this basis [2]. In other words, the profile of a woman who is obese, hypertensive, has a relevant family history, and smokes is a candidate for cardiovascular disease without the combination oral contraceptive pill. Current use of low-dose combination oral contraceptive pills is unrelated to an increased risk of myocardial infarction among nonsmokers [3]. The risk of ischemic stroke in women on combination oral contraceptive pills increases with smoking and hypertension and decreases with low dosage of estrogen. Risk is not related to the progestogen [2, 4]. The clearly established increased risk of venous thromboembolism has been reduced with pill formulations of lower than 50 mcg of estrogen [5].

The benefits of the combination oral contraceptive pill (see next section) outweighs the risks for nonsmoking, healthy women of any age. There is no increased risk of cardiovascular diseases from past use of oral hormonal contraception, and there is no relationship between atherogenic disease and the use of oral hormonal contraception [4]. Women who smoke should be helped to stop and, if they are over age 35, to find another contraceptive method.

Migraine headaches: The common migraine headache (without aura) is not a contraindication for oral hormonal contraception (unlike the classic migraine headache, with aura, which is a contraindication). Tension headaches are not contraindications [6]. Headaches should be carefully evaluated prior to and during use of oral hormonal contraception. Persistent headaches are often a precursor of cardiovascular accidents. Women on combination oral contracep-

TABLE 20-3 Relation of Side Effects to Hormone Content

	Reproductive System	Premenstrual Syndrome	General	Cardiovascular System
Estrogen Excess	Breast cystic changes Cervical extrophy Dysmenorrhea Hypermenorrhea, menorrhagia, and clotting Increase in breast size Mucorrhea Uterine enlargement Uterine fibroid growth	Bloating Dizziness, syncope Edema Headache (cyclic) Irritability Leg cramps Nausea, vomiting Visual changes (cyclic) Weight gain (cyclic)	Chloasma Chronic nasal pharyngitis Gastric influenza and varicella Hay fever and allergic rhinitis Urinary tract infection	Capillary fragility Cerebrovascular accident Deep vein thrombosis hemiparesis (unilateral weakness and numbness) Telangiectasias Thromboembolic disease
Estrogen Deficiency	Absence of withdrawal bleeding Bleeding and spotting during pill days 1 to 9 Continuous bleeding and spotting Flow decrease, hypomenorrhea Pelvic relaxation symptoms Vaginitis atrophic		Nervousness Vasomotor symptoms	
Progestin Excess	Cervicitis Flow length decrease Moniliasis		Appetite increase Depression Fatigue Hypoglycemia symptoms Libido decrease Neurodermatitis Weight gain (noncyclic)	Hypertension Leg vein dilation
Progestin Deficiency	Breakthrough bleeding and spotting during pill days 10 to 21 Delayed withdrawal bleeding Dysmenorrhea (also estrogen excess) Heavy flow and clots (also estrogen excess), hypermenorrhea, menorrhagia			
Androgen Excess			Acne Cholestatic jaundice Hirsutism Libido increase Oily skin and scalp Rash and pruritus Edema

tive pills who first develop migraine headaches while on the pill or who experience increased severity or frequency of preexisting migraine headaches should immediately stop the pill and select another method of contraception [7].

Breast cancer: A reanalysis of worldwide epidemiological evidence from 54 studies conducted in 25 countries provided strong evidence of a small increase in relative risk of having breast cancer diagnosed either while taking combination oral hormonal contraception or within the first ten years after discontinuation. After ten years there was no significant excess risk [8]. Breast self-examination by the woman and annual breast exams by the midwife are imperative. A multigenerational family study suggests that women who used formulations of combination oral hormonal contraception prior to 1975, when the estrogen dosage was considerably higher than in today's pill formulations, and have a first-degree relative (sister, mother) with breast cancer may be at particularly high risk for breast cancer [9]. These women need to be carefully monitored for early detection of breast cancer.

Other: Evidence is conflicting on whether there is an association or no association between taking combination oral hormonal contraception and other complications including cervical cancer, gallbladder disease, and hepatic neoplasms.

The midwife should be aware that laboratory test results may be altered in women on combination oral hormonal contraception, although this was seen more with the older formulations with higher dosages of the estrogen and the progestin.

Certain medications decrease the efficacy of oral hormonal contraception. Conversely, contraceptive pills decrease the efficacy of certain medications. In both cases the issue is the effect of the drug (either the oral contraceptive or the medication) on the liver (e.g., whether the drug stimulates the metabolic capacity of the liver) and the rate of clearance of the drug through the liver. There is a great deal that is speculative, anecdotal, theoretical possibility, and simply not known. Information on the effect of antibiotics on oral contraceptives falls into this category. Some medications, however, are known to affect liver metabolism and reduce the effectiveness of oral contraceptive pills. They include the following:

- rifampin (Rifamycin, Rifadin; antituberculosis drugs)
- phenytoin (Dilantin; antiseizure medication)
- primidone (Mysoline; antiseizure medication)
- carbamazepine (Tegretol; antiseizure medication)
- phenobarbital (Donnatal; antispasmodic/sedative)
- griseofulvin (Fulvicin; antifungal treatment for ringworm)

Women on the above medications should choose a different contraceptive method.

The action of the following drugs is most likely potentiated by oral hormonal contraception:

- diazepam (Valium; antianxiety medication)
- chlordiazepoxide (Librium; antianxiety/sedative)
- theophylline (Aerolate, Bronkotabs, Marax, Respbid, Theolair; bronchodilators for asthma)
- tricyclic antidepressants (Tofranil, Elavil, Norpramin)
- corticosteroids/cortisone (Cortone; anti-inflammatories)

Women on the above medications will require less of the medication to obtain the desired effect.

The action of the following drugs is most likely reduced by oral hormonal contraception:

- guanethidine (Ismelin, Esimil [with diuretic]; antihypertensive)
- metoprolol (Lopressor; antihypertensive)
- methyldopa (Aldoclor, Aldomet, Aldoril; antihypertensive)
- acetaminophen (Tylenol; analgesic)

Women on the above medications will require more of the medication to obtain the desired effect.

St. John's wort, used for depression, activates two enzyme pathways that can interfere with the use of other medications by causing them to be metabolized more quickly. Specifically, it induces cytochrome P450 drug metabolizing enzymes in the liver and affects a transport protein, P-glycoprotein, in the intestines [10]. The Food and Drug Administration recommends that persons using drugs that are metabolized by the cytochrome P450 pathway (such as oral contraceptives) not take St. John's wort. However, no formal studies exist that address the effect of St. John's wort on the efficacy of oral contraceptives. It is now thought that St. John's wort may not be as effective as previously thought [10]. Midwives need to specifically include in their history taking whether a woman is using St. John's wort and, if she is, discuss with her the possible reduction in protection from pregnancy if also using oral contraceptive pills. If studies prove that St. John's wort is actually ineffective in the treatment of depression, then the benefits of oral contraceptive pills for those who want them need to be

considered as taking precedence over the use of St. John's wort.

Benefits of Combination Oral Hormonal Contraception

There are a number of significant benefits that accrue to women who take combination oral hormonal contraceptive pills. These benefits should be weighed by the individual woman and midwife together and balanced against any risks that woman may have. This is particularly true in balancing the *possible* potential risk of breast cancer against the *known* protection of combination oral hormonal contraception against ovarian cancer and endometrial cancer.

Ovarian cancer: 40 percent reduction of risk in women who have ever used oral hormonal contraception. The protection starts within 3 to 6 months and increases with length of use; with more than 10 years of use there is an 80 percent reduction in risk. Protection continues for at least 15 years after discontinuing use of the pills. The protection is the same with different formulations of the pill including low-dose pills of 35 mcg or less of estrogen [11, 12].

Endometrial cancer: Risk is reduced by length of time taking combination oral hormonal contraception: 20 percent with 1 year of use, 40 percent with 2 years of use, and 60 percent with 4 or more years of use. Protection is the same with different formulations of monophasic pills including those with less than 50 mcg of estrogen but, as of this writing, there are no data regarding multiphasic pills. Protection continues for 15 or more years after discontinuation [11].

Benign breast disease: significant reduction of fibrocystic changes and fibroadenoma development. Protection against fibrocystic changes lasts up to 1 year after discontinuation [11].

Other: Evidence of protection against other diseases is conflicting but may possibly include pelvic inflammatory diseases [11] and colorectal cancer [13]. In addition, combination oral contraceptive pills protect against other diseases and conditions simply by virtue of the facts that pregnancy is prevented, ovulation is suppressed, and menstrual blood loss is reduced. These include the following:

1. Iron deficiency anemia
2. Ectopic pregnancy
3. Mittelschmerz
4. Dysmenorrhea
5. Menorrhagia
6. Metrorrhagia
7. Toxic shock syndrome

Combination oral hormonal contraception is sometimes used off-label as therapy for several menstrual and hormone related disorders. These include the following:

1. Dysmenorrhea (often used in conjunction with nonsteroidal anti-inflammatory drugs)
2. Menorrhagia
3. Metrorrhagia
4. Irregular menses
5. Acne
6. Hirsutism
7. Endometriosis

Finally, women can be taught to have some control over their own menstrual cycle by tricycling to reduce the number of menstrual cycles if they have premenstrual syndrome, migraine headaches with their menses, dysmenorrhea, or menorrhagia. Tricycling is achieved when the woman takes 3 consecutive packs of pills skipping the hormone-free weeks and using only the 21 active pills for a total of 63 days. She then takes no pills for 7 days after which she starts the next tricycle.

Women who want to control their menstrual periods for their own convenience (e.g., traveling, special occasions, etc.) can do this by simply extending the number of days they take active pills or by skipping the pill-free week.

Management Plan for Combination Oral Hormonal Contraception

Management of the care of the woman taking combination oral hormonal contraceptive pills consists of the following components:

1. Informing the woman of the effectiveness rates and potential side effects and complications of taking the pill and having her sign an informed consent form
2. Conducting a general history, physical and pelvic examinations, and laboratory tests
3. Screening for any deviations from normal and for any contraindications to initiating the pill
4. Selection and initiation of the pill
5. Giving the woman instructions for taking combination oral contraceptive pills
6. Scheduling and managing the return visits
7. Managing the possible side effects and complications related to the pill

The first component is self-explanatory; the second and third components have been discussed previously. It should be noted, however, that in 1993 the Food and Drug Administration approved a change in practice as reflected in the labeling on packages of oral contraceptives, which states that "physical examination may be deferred until after initiation of oral contraceptives if requested by the woman and judged appropriate by the clinician." This action was taken to address the needs of women in three particular circumstances, who otherwise might not adopt a method of contraception: (1) women whose appointment falls during their menstrual period and who would have to reschedule for a full examination, (2) adolescents who fear a pelvic examination, and (3) women who would have to wait for an available appointment time for an initial examination [14].

Selection and Initiation of the Pill

There was a time, back when the large number of available pills contained a wide range of estrogen and progestin dosages, that selection was based on a match between a woman's hormonal profile and the pill with the most appropriate hormonal potency for her profile. With today's low dosage of both the estrogen and the progestin, the differences among pills are not as profound, and this somewhat cumbersome and complicated method of selection is no longer necessary. This is not to say that you cannot do some matching of a woman's hormonal profile and hormonal components of the pill if you so choose. However, years of experience in health department clinics where the choice of pills was severely limited has taught clinicians that it is quite possible to choose from among a generic choice of two or three pills for initiating oral contraception and then switch the pill, if necessary, in accord with the adjustment/side effects an individual woman has. It is well worth a midwife's time to sit down with various sources of information on selection of a pill [5, 7, 15] and identify one or two pills to use for a generic choice of pill initiation. Tables 20-4 and 20-5 are helpful in making more individualized pill selections and include the progestin-only minipills. Table 20-4 groups the various formulations of the oral hormonal contraceptive pills by their endometrial, progestational, and androgenic activities. Table 20-5 gives pre-pill characteristics of the woman, the type of pill activity thus indicated that she needs, and the number of the pill grouping(s) from Table 20-4 with that type of activity and the names of the pills in that group.

Initiation of the pill depends on where the woman is in relation to her menstrual cycle, postabortion, postdelivery, and lactation. Oral hormonal contraception may be started immediately after a first- or second-trimester abortion. Postabortion women and women who have had a full-term delivery are *not* physiologically analogous as to hormone levels, reinstitution of ovulation, or decidual restoration. Combination oral hormonal contraception can be started in the third week postpartum for women who are not breastfeeding. Delaying until the third week postpartum avoids the increased risk of thrombophlebitis and thromboembolism during the first two postpartal weeks. Ovulation postdelivery is thought to occur rarely prior to the fourth postpartal week. However, after the sixth postpartal week it is quite possible for ovulation to have occurred and for the woman who is not breastfeeding to be pregnant if she has had unprotected sexual intercourse.

During the first 6 months postpartum, a woman is protected from pregnancy by the lactation amenorrhea method (LAM; see Chapter 17) as long as she is fully breastfeeding and has no bleeding after the first 56 days postpartum. However, if she is partially breastfeeding or plans to wean the baby, she may want to start oral hormonal contraception. Combination contraceptive pills affect the production of milk and reduce the milk supply. This is true even if the woman does not start taking the combination pills until 6 weeks postpartum and even if she takes combination pills with a low dose of estrogen [15]. For this reason it is best for the breastfeeding woman not to use combination pills until she plans to wean or after 6 months postpartum, when LAM begins to lose its effectiveness and she starts to ovulate again.

In order to prevent breakthrough bleeding and to be contraceptively effective as soon as possible, a woman should not start oral hormonal contraception any later than the tenth day in her cycle and preferably before the fifth day from the beginning of menstruation. So if a woman has her initial visit to a midwife in midcycle, she needs to wait until her next menstrual period to start the pills (either on the first day or on the Sunday after she starts to menstruate, depending on the packaging of the pill). For the interim, the midwife can give the woman a spermicidal preparation and condoms to use as her primary method until she is able to start on the pills and then as a backup method during the first cycle of pill taking. It is possible to start a woman on the pills at any point in the cycle, but this approach

TABLE 20-4 Oral Hormonal Contraceptives with Similar Endometrial, Progestational, and Androgenic Activities[a]

Group	Oral Contraceptives	Estrogen and Dose	Activity
1	Micronor Nor-QD Ovrette	No estrogen	Endometrial: low Progestational: low Androgenic: low
2	Mircette Desogen Ortho-Cept	22 mcg ethinyl estradiol (average) 30 mcg ethinyl estradiol 30 mcg ethinyl estradiol	Endometrial: intermediate Progestational: intermediate/high Androgenic: low
3	Loestrin 1/20 Estrostep* Loestrin 1.5/30	20 mcg ethinyl estradiol 30 mcg ethinyl estradiol (average) 30 mcg ethinyl estradiol	Endometrial: low Progestational: intermediate/high Androgenic: intermediate/high
4	Levlen Levora Lo/Ovral Low-Ogestrel Nordette	30 mcg ethinyl estradiol	Endometrial: intermediate Progestational: intermediate Androgenic: intermediate
5	Tri-Levlen* Triphasil* Trivora* Ovcon 35 Ortho-Cyclen Ortho Tri-Cyclen*	32 mcg ethinyl estradiol (average) 35 mcg ethinyl estradiol	Endometrial: intermediate Progestational: low Androgenic: low

TABLE 20-5 Choice of an Initial Oral Hormonal Contraceptive[a]

Characteristics	Type of OC Indicated	Suggested OC for the Initial Cycles (See Table 20-4 for OC Groups)
Regular light menses; 2 to 4 days flow; mild or no cramps	Low endometrial activity	Groups 3, 6, 8
Regular moderate menses; 4 to 6 days flow; moderate cramps	Intermediate endometrial activity	Groups 2, 4, 5, 7, 9
Regular heavy menses; 6-plus days flow; severe cramps	High endometrial activity	Group 13
Irregular and infrequent menses; hypermenorrhea when occurs; associated acne, oily skin, hirsutism	Probably polycystic ovarian syndrome; high progestational and low androgenic activity desirable	Groups 2, 6, 12
Irregular menses; hypomenorrhea when occurs; no androgen effects	If galactorrhea present, possible pituitary adenoma; skull x-ray or prolactin needed If no galactorrhea, low estrogen and low progestational activity combination OCs or multiphasic OCs may be used	Groups 1, 5, 8, barrier and spermicide methods
Smokers—ages 35 and over	Combination OCs contraindicated	Group 1, barrier and spermicide methods
Nonsmokers—ages 35 and over	Sub 35 mcg estrogen, intermediate/high progestin, combination OC	Groups 2, 3, 4
Weight less than 110 lbs	Lower estrogen and low progestin dose	Groups 5, 7, 8
Weight more than 160 lbs	High estrogen and progestin activity	Groups 9–13
Progesterone hypersensitivity: history of toxemia, strong family history of hypertension, excessive weight gain, tiredness or varicose veins during pregnancy, depression, excessive premenstrual edema	Low progestin dose and progestational activity; monitor blood pressure	Groups 1, 5, 8
Estrogen hypersensitivity: excessive nausea, edema or hypertension in pregnancy; hypertrophy of the cervix or uterus; uterine fibroids; large or fibrocystic breasts; heavy menses; migraine	Low estrogenic activity	Groups 1, 3
Conditions predisposing to cardiovascular disease, type II hyperlipidemia (hypercholesterolemia), diabetes mellitus, obesity, smoking more than 15 cigarettes per day, hypertension, varicose veins, thrombophlebitis during pregnancy, family history of cardiovascular disease before age 50	Combination pills not recommended	Group 1, barrier and spermicide methods
Surgery planned within 1 to 4 weeks	Combination pills should be stopped	Group 1, barrier and spermicide methods

[a] After the initial cycles, all patients should be switched to Group 2 through 8 OCs if possible (≤35 mcg estrogen, low androgen activity).

Source: Adapted and printed with permission from EMIS, Inc., from Managing Contraceptive Pill Patients®—10th ed., by Richard P. Dickey, MD, PhD.

practically guarantees breakthrough bleeding and offers questionable effectiveness until the pills are "in control." Most women will not tolerate this amount of trouble. It is better to synchronize the initiation of pills with the woman's natural cycle.

Regardless of when a woman starts taking the pill, she should be given a spermicidal preparation and condoms "to cover" during the first month of taking the pills. Although the pill is effective after 7 days of pill taking, "coverage" for a month provides additional protection in case of forgetfulness while the woman is establishing a regular pill-taking routine. This also enables you to teach her a second contraceptive method to use in the event she decides to discontinue the pills, she is placed on any medication that reduces the effectiveness of the contraceptive pill, or she forgets her pills in the future. She should use condoms routinely in addition to the pill if she is at risk for HIV or sexually transmitted diseases.

The Return Visit

The woman is scheduled for her first revisit after two or three complete pill cycles. This means that you need to give her or prescribe three or four packages of pills initially. She should be seen sometime in the middle of her third or fourth package of pills. You can calculate this time from the date on which you start her on the pills. During the first revisit you should evaluate the following:

1. Blood pressure
2. Weight
3. History
   - **a.** woman's or couple's satisfaction with the method
   - **b.** use of spermicidal preparation and condoms
   - **c.** description of how and when she is taking her pills
   - **d.** any medications she is taking: what, what for
   - **e.** any visits to a doctor or emergency room since starting pills: why
   - **f.** menses (compare with pre-pill menses)
     - **(1)** date
     - **(2)** length
     - **(3)** amount of flow
     - **(4)** pain
   - **g.** side effects
4. Any questions or concerns

Some midwives believe that this first revisit should be followed by a 6-month visit and then annual visits with a Pap smear thereafter. Other midwives go directly to an annual visit if all is well at the first revisit. Some clinicians believe that after 5 years of contraceptive pill use, women should have a Pap smear every 6 months.

At the annual revisit you should take the same history you obtained at the first revisit, plus a complete general screening history, physical and pelvic examinations, Pap smear, and other laboratory tests and adjunctive studies as specified in Chapter 2.

Management of Side Effects and Complications

When a woman has a side effect, the midwife should ascertain which of the following three possible courses the side effect will probably take:

1. Spontaneous remission as the woman's body adjusts to the hormonal effect of the pill. Remission is common with side effects occurring during the first three cycles of pill taking. Women are often encouraged to "wait it out" through this period of time. Spontaneous remission should have occurred by the fourth pill-taking cycle.
2. Continuation (more likely when the side effect occurs after several cycles of pill taking, but may occur with early cycles of pill taking). If the side effect appears likely to continue, you should switch the woman to a different pill or discontinue the pill and initiate another contraceptive method according to her choice.
3. Development into a dangerous complication. Some side effects are harbingers of more severe complications. If the side effect is determined to be such a harbinger, the woman should stop taking the pills immediately (see item 5 under "Instructions for Women Taking Combination Oral Contraceptive Pills," page 526).

If switching to a different pill is an option, the midwife needs to determine the following in relation to the side effect: (1) when in the menstrual cycle it occurs, (2) whether it is due to hormone excess or hormone deficiency, and (3) which hormone is involved (the estrogen or the progestin).

Table 20-3 relates symptoms or side effects to generic hormonal excess or deficiency of estrogen or progestin. After checking Table 20-3, you can consult Tables 20-1 and 20-2 to identify the biological potency and dosage of the pill a woman is taking and find a pill with more or less of the estrogen or progestin that is needed to potentially take care of the problem.

Knowing when in the woman's cycle the side effect occurs may help you diagnose the problem. For example, early cycle breakthrough bleeding is usually due to estrogen deficiency; late cycle break-

through bleeding is usually due to progestin deficiency. Thus, the pill you would switch the woman to would be quite different; a pill with higher estrogenic activity for early cycle breakthrough bleeding and a pill with a progestin with higher endometrial or progestational potency for breakthrough bleeding at any other time in the cycle.

If switching to a different pill is the method of management chosen, remember the following:

1. If the switch is to a pill with equal or greater estrogen and progestational potency, the switch can be made any time during the cycle.
2. If the switch is to a pill with less estrogen and progestational potency, the switch must be made only at the beginning of a new pill cycle, as the new pill will take a longer time to achieve hormonal menstrual control.
3. Depending on the severity of the side effect, it might be advisable to switch the pill at the beginning of a pill cycle even if the switch is one that can be made in midcycle, just to minimize confusion.
4. The woman should be counseled that her body will again be undergoing adjustment to a different hormonal balance and some temporary side effects may be experienced.

The contraceptive pill should be discontinued in the presence of the following symptoms or side effects, which should be further evaluated by the midwife and the consulting physician:

1. Headaches that are severe, persistent, of sudden onset, or qualitatively different from those the woman normally experiences
2. Visual disturbances:
   a. blurring of vision
   b. flashing lights
   c. diplopia
   d. scintillating scotomata
   e. periods of temporary blindness
3. Unexplained severe chest pain or shortness of breath
4. Unexplained severe abdominal pain
5. Severe calf or thigh pain
6. Temporary numbness or paralysis of any part of the face or body
7. Slurring of speech
8. Hemoptysis
9. Marked increase in blood pressure

The pill should also be discontinued if the woman develops any disease that contraindicates the use of the pill.

The woman should be provided with another method of family planning when she must stop taking the pill because of side effects, complications, or undesirable drug interactions.

Instructions for Women Taking Combination Oral Contraceptive Pills

General Instructions The following instructions should be given to all women taking the combination pill, regardless of whether it is the 21-day or the 28-day pill:

1. Keep your pills in a place safe from children and animals but also where you will be reminded to take them daily. It helps if you keep them with something you use in your daily routine, such as your toothbrush or toothpaste, coffee pot, or alarm clock.
2. Make your pill taking as much a routine as possible. Taking your pill at approximately the same time every day not only helps make it a routine but also ensures a consistent level of contraceptive hormone in your body.
3. It is necessary to take the pills exactly as instructed if you do not want to become pregnant.
   a. If you miss one pill during the first 3 weeks of your pill-taking cycle, you probably won't become pregnant, but you should use a backup method of contraception (for example, a spermicidal preparation and condoms) for the next 7 days. Take the forgotten pill as soon as you remember it and the next pill at the regular time (this may mean you take them both at the same time).
   b. If you miss two pills during the first 2 weeks of your pill-taking cycle, you may or may not still be protected from pregnancy. Take two pills the day you remember them and two pills the next day. This should catch you up on your pill cycle. Also, use a spermicidal preparation and condom each time you have intercourse for the next 7 days. Do not be surprised or alarmed if you have some midcycle spotting.
   c. If you miss two pills during the third week of your pill-taking cycle or if you miss three pills during any of the first 3 weeks of your pill-taking cycle, chances are good that you will start bleeding or get pregnant. Use a spermicidal preparation and condoms for the next 7 days. Throw away the remainder of your pill package and start a new package. If you have a Sunday-start type pill, continue taking an active pill every day in your old pill package until Sunday, then start a new package.

4. Be sure to keep your revisit appointment so you don't run out of pills and so you can be examined carefully for any possible side effects.
5. Call for an appointment *immediately* if you are having any of the following symptoms. Do not wait to see if they will simply go away because these are danger signs:
   a. severe headaches
   b. visual disturbances
      (1) blurring of vision
      (2) flashing lights
      (3) spots before your eyes
      (4) temporary moments of blindness
   c. severe chest pain or shortness of breath
   d. severe abdominal pain
   e. severe calf or thigh pain
   f. temporary numbness or paralysis of any part of your body
   g. slurring of speech
   h. coughing up bloody sputum
   i. severe depression
   j. if you miss two menstrual periods or think you are pregnant
6. Be sure to tell any doctor or nurse practitioner you see for any medical problems that you are taking birth control pills. Some medications can interfere with the effectiveness of the pill, and the pill can interfere with the effectiveness of some medications.
7. Do not ever take another woman's pills or allow another woman to take your pills. Most likely someone else's pills are not the same strength and hormonal makeup as your own, and such pill taking may leave you without contraceptive protection or give you side effects you otherwise would not have.
8. Remember to use a spermicidal preparation and condoms during your first cycle of pill taking. You should also use this secondary method if you run out of pills, stop taking the pill, miss pills, have diarrhea or vomiting, or need protection from HIV or sexually transmitted diseases.
9. If you want to control the timing of your menstrual periods or reduce the number of menstrual cycles you have, you can do this by continuing to take pills after the initial 21 days without stopping for hormone pill-free days for up to 3 cycles or 63 days. Then stop for 7 days for a menstrual period and start your pills again 7 days later for a minimum of 21 days.
10. It is helpful if you keep a menstrual history, noting the first and last day of each of your menstrual periods and how heavy the flow is for each day. It is not unusual for a woman's period to be short and light when she is taking the pill.
11. If you decide to stop taking the pill because you are not happy with contraceptive pills as a birth control method, be sure to call for an appointment and use a spermicidal preparation and condoms for protection from pregnancy until your appointment.
12. Call your midwife if you have plans for surgery. Depending on the nature of the surgery and the length of time you will be immobilized, you may need to stop taking the pills and use an alternative contraceptive method. Be sure to tell your surgeon that you are on birth control pills.
13. If you decide to stop taking the pills because you wish to get pregnant, stop at the end of a pill cycle and use a spermicidal preparation and condoms or other method of birth control for 3 months after stopping the pills. Waiting through three menstrual cycles prior to attempting to get pregnant allows time for your body to readjust to its own natural hormonal balance and menstrual cycles. It also enables you and your midwife to make a more accurate estimate of the date your baby will be born.

Additional Specific Instructions for Taking the 21-Day Combination Pill The instructions on the package inserts vary with the pill being taken. The following instructions apply to any of the 21-day combination pills.

1. A pill must be taken every day during the days that pills are to be taken. A missed pill equals a chance to become pregnant.
2. No pills are to be taken for 1 week (7 days).
3. Start your next package of pills 1 week (7 days) after the day you took your last pill. For example, if you take the last pill in one package on a Tuesday, you take the first pill in the next package the next Wednesday. This means that you will always be starting a new package of pills on the same day.
4. Continue taking pills in this pattern no matter what is happening with your menstrual periods. For example, continue taking pills even if
   a. spotting or bleeding occurs while you are taking the pills.
   b. your menstrual period ends before the week without the pills ends.
   c. your menstrual period is still going on when your new package of pills is to be started.

Additional Specific Instructions for Taking the 28-Day Combination Pill The only difference between the 28-day pill and the 21-day pill is that the 28-day pill

is taken every day of the month. A woman who does not take pills for a week between packages of 28-day pills is ensuring the likelihood of a pregnancy.

1. A pill must be taken every day. There is never a day on which you do not take a pill.
2. Take the first pill in a new package of pills the very next day after you take the last pill in the previous package. If you take the last pill in one package on a Wednesday, you take the first pill in the next package on the next day, Thursday.
3. Continue taking pills in this pattern no matter what is happening with your menstrual periods. For example, continue taking pills even if
   a. spotting or bleeding occurs while you are taking the pills.
   b. your menstrual period is still going on when your new package of pills is to be started.

Progestin-Only Contraceptive Pills (Minipills)

Description, Effectiveness, and User Response

Progestin-only pills contain only a low dose of a single progestin taken every day at the same time of day. The mechanism of action is primarily that of creating a hostile impenetrable cervical mucus. It may also suppress ovulation and causes a thin, atrophic endometrium that will not support implantation.

The effectiveness of the progestin-only pills is dependent on a woman adhering strictly to a regimen of taking her pill at the same time every day as the serum levels of the progestin in the pill are depleted in 24 hours. Late pills thus become as important as missed pills and accounts for the difference in effectiveness between perfect use and typical use (see Table 16-2, page 464).

Contraindications, Side Effects, and Risk of Complications

Contraindications Because the progestin-only minipills do not have estrogen and contain a low dose of progestin, they can often be used safely by women with medical conditions that contraindicate the use of estrogen-containing combination pills. The contraindications are as follows:

1. Pregnancy (known or suspected)
2. Carcinoma of the breast (known or suspected)
3. Undiagnosed abnormal genital bleeding
4. Benign or malignant liver tumor (presence or history of)
5. Acute liver disease; jaundice; hepatic failure

The one minipill specific contraindication is if a woman will not be able to reliably take her pill *at the same time every day*. The midwife should carefully evaluate the ability of a woman to be consistently reliable in complying to a rigid schedule of pill taking.

The midwife also needs to assess the woman's need for protection against sexually transmitted diseases and HIV. Progestin-only pills do *not* provide this protection.

Side Effects and Risk of Complications Menstrual irregularities with frequent and irregular bleeding are common and the reason most often given for discontinuation.

The midwife should be aware that laboratory tests for thyroxine concentrations may be decreased.

Medications that affect liver metabolism by increasing hepatic clearance of progestins and thus reduce the effectiveness of progestin-only pills include the following:

Antituberculosis drugs: rifampin (Rifamycin; Rifadin)

Anticonvulsants: phenytoin (Dilantin), carbamazepine (Tegretol)

Barbituates: phenobarbital (Donnatal)

Women on these medications should choose a different contraceptive method.

The data on the effect of broad-spectrum antibiotics on the effectiveness of progestin-only pills are sparse and contradictory. The midwife should advise a woman to use a spermicide and condoms if she is ever treated with antibiotics.

Benefits of Progestin-Only Pills

The primary benefit of progestin-only pills is that they do not contain any estrogen and thus can be used by a woman for oral hormonal contraception when she is contraindicated for the combination pill for estrogen-related reasons.

Women on progestin-only pills experience decreased menstrual blood loss and decreased dysmenorrhea.

Women have a rapid return to fertility after discontinuing the progestin-only pill.

Selection and Initiation of the Progestin-Only Pill

The management plan for progestin-only pills is the same as for combination hormonal contraception (see page 520).

There are presently three progestin-only pills on the market as noted in Group 1 in Table 20-4. Micronor and Nor-QD contain 0.35 mg of norethindrone and Ovrette contains 0.075 mg of norgestrel. Selection of a progestin-only pill is based on three critical factors for a woman who wants oral hormonal contraception:

1. Contraindicated for combination pills
2. Absolutely reliable for taking the pill at the same time every day
3. Able to tolerate menstrual bleeding irregularities

It is the pill of choice for postpartum mothers, because the lack of estrogen reduces the risk of thrombophlebitis and thromboembolic disorders, and for breastfeeding mothers, because progestin-only pills do not negatively affect milk production. This is true for the minipill even if started immediately after a full-term delivery.

In order to minimize as much as possible the irregular bleeding associated with the progestin-only pills, the woman should start the pills during her menstrual period, preferably on the first day. However, the progestin-only pill can be started at any time in the cycle as long as the midwife is sure that the woman is not pregnant. The midwife should instruct the woman on using a spermicidal preparation and condoms as a back-up method for one week.

The Return Visit

The return visit is the same as for the combination oral contraceptive pills (see page 524). The visit should emphasize a pill-taking history of consistency in the time of taking the pills every day. In addition, if the woman is breastfeeding, a history of frequency of breastfeeding and adequacy of milk production should be taken. Careful note should be made of any bleeding irregularities and the woman's ability to cope with them.

Management of Side Effects and Complications

The major side effect of irregular bleeding and spotting is managed by ruling out pregnancy and having a discussion with the woman regarding her tolerance of this side effect. If intolerant and *not contraindicated*, switch her to an oral hormonal contraceptive pill with estrogen. If she is contraindicated for the combined pill, then switch her to a nonhormonal contraceptive method.

If the woman has severe abdominal pain, evaluate her for ovarian cyst, ectopic pregnancy, and pelvic inflammatory disease. Treat or refer appropriately. If not pregnant, it is not necessary to discontinue the progestin-only pill. The woman should immediately stop taking the progestin-only contraceptive pill if she develops severe headaches (new onset or worsening of preexisting headaches) and visual disturbances (flashing lights, blurring of vision, loss of vision, scintillating scotomata). The woman should be provided with another method of contraception.

Instructions for Women Taking Progestin-Only Oral Contraceptive Pills

1. Start your pills on the first day of your menstrual period.
2. Take one pill at approximately the same time *every* day. When you finish one package of pills, start a new package of pills the next day. Never stop taking a pill every day.
   a. If you miss one pill or are more than 3 hours late in taking your pill, you are *not* protected against pregnancy. Take your missed or late pill as soon as you remember it, and take your next pill at the usual time. Also, use a spermicidal preparation and condoms for the next 7 days.
   b. If you miss two or more pills, stop taking the pills and use a nonhormonal contraceptive method such as a spermicidal preparation and condoms until you have a menstrual period or pregnancy has been ruled out. If you have had sexual intercourse during this time, consider an emergency contraception method.
3. Call for an appointment immediately if you do not have a menstrual period within 45 days of your last menstrual period. It is not unusual to have irregular or infrequent periods while taking the minipill, but if you go longer than 45 days without a period you need to know whether you are pregnant.

Emergency Postcoital Contraception

Description, Indications, and Access

Nearly half of all pregnancies in the United States are unintended [16]. The probability of getting pregnant from one random act of unprotected intercourse ranges from 2 to 5 percent [17]. The use of emergency contraception pills can reduce the risk of unintended pregnancy by 75 percent [18].

As long as contraceptive methods remain imperfect, "emergency" postcoital contraception will be necessary. Indications for emergency postcoital contraception include the following:

1. Rape/sexual assault
2. Unsuccessful use of the withdrawal method, in which the man fails to withdraw or ejaculates on the woman's external genitalia
3. Unexpected unprotected intercourse or failure to abstain when using natural family planning
4. Missing several contraceptive pills
5. Condom breaks during usage
6. Sperm leaks from the condom when the male withdraws
7. Incorrect use of a barrier method or use of a faulty barrier method
8. Expelled IUD

The urgent nature of emergency postcoital contraception takes it out of the realm of a routine contraceptive method. It should, however, be included in discussions of contraceptive methods so that women become aware of the availability of emergency postcoital contraception.

As of this writing, emergency contraception still requires a prescription. Thus, many clinicians are writing prescriptions for emergency contraception along with whatever is going to be used as the ongoing contraceptive method in case of incorrect use or method failure that ends in unprotected intercourse [5]. A concerted effort is being made through a citizen's petition to the Food and Drug Administration from more than 70 organizations for emergency contraception products to be sold over-the-counter. This effort is grounded in the facts that emergency contraception has "low toxicity, no potential for overdose or addiction, no teratogenicity, no need for medical screening, self-identification of the need, uniform dosage, and no important drug interactions" and thus meets customary criteria for over-the-counter use [19]. The American College of Nurse-Midwives

> supports removing barriers to the immediate availability of emergency contraception through increased education for consumers and professionals, advance prescription of emergency contraceptive pills, direct pharmacy access, FDA approval of over-the-counter distribution, and insurance coverage for all prescriptive methods of contraception. [20]

In the meantime, the Planned Parenthood Federation of America has endorsed prescription of emergency contraception pills by telephone which has been implemented by Planned Parenthood affiliated clinics [19]. Several state Planned Parenthoods have toll-free numbers for getting a prescription to be called to a woman's choice of pharmacy [18]. There is also a nationwide toll-free emergency contraception hotline: 1-888-NOT-2-LATE (1-888-668-2528) and Web site (http://not-2-late.com).

Methods, Side Effects, and Management

There are several ways of providing emergency contraception:

1. The two emergency contraception pill products on the market
2. The Yuzpe regimen of existing combination oral hormonal contraceptive pills
3. The use of an existing progestin-only oral hormonal contraceptive pill
4. The copper intrauterine contraceptive device
5. Off-label use of mifepristone

The two emergency contraception pill products on the market are Preven and Plan B. Preven contains 0.05 mg of ethinyl estradiol and 0.25 mg of levonorgestrel in each of 4 tablets. Two pills are taken within 72 hours (3 days) of unprotected intercourse and the other 2 pills are taken 12 hours later. Plan B contains 0.75 mg of levonorgestrel in each of 2 tablets. One pill is taken within 72 hours of unprotected intercourse and the other pill is taken 12 hours later.

In comparing these two products, levonorgestrel alone (Plan B) is more efficacious in preventing pregnancy (see first note under Table 16-2 on page 464) and has a substantially lower incidence of the side effects of nausea, vomiting, and fatigue [21].

The Yuzpe regimen calls for a total of 200 mcg of ethinyl estradiol and 2 mg of norgestrel or 1 mg of levonorgestrel to be taken in two doses, 12 hours apart, within 72 hours of unprotected intercourse. As shown in Table 20-6, there are 12 combination oral contraceptive pills that contain these hormones and, taken as noted, add up to at least this dosage (see Table 20-2). They are listed alphabetically by progestin.

In addition, Ovrette is a progestin-only contraceptive pill on the market that can be used for emergency contraception. It contains 0.075 mg of Norgestrel per pill and is prescribed as 20 pills for the initial dose as soon as possible within 72 hours after unprotected intercourse and 20 pills for the second dose 12 hours later.

TABLE 20-6 Combination Oral Contraceptive Pills That Can Be Used for Emergency Contraception

Pill[a]	Progestin	Number of Pills to Take Per Dose[b]
Alesse	Levonorgestrel	5
Levlen	Levonorgestrel	4
Levlite	Levonorgestrel	5
Levora	Levonorgestrel	4
Lo/Ovral	Levonorgestrel	4
Nordette	Levonorgestrel	4
Ovral	Levonorgestrel	2
Tri-Levlen (3rd phase yellow pills only)	Levonorgestrel	4
Triphasil (3rd phase yellow pills only)	Levonorgestrel	4
Trivora (3rd phase pink pills only)	Levonorgestrel	4
Low-Ogestrel	Norgestrel	4
Ogestrel	Norgestrel	2

[a] All emergency contraception pills contain ethinyl estradiol.
[b] Two doses: initial dose as soon as possible within 72 hours after unprotected intercourse; second dose 12 hours later.

Emergency contraception pills are most effective if taken within 12 to 24 hours of unprotected intercourse but may be taken within 72 hours (3 days) according to product information. However, if a woman is late in obtaining emergency contraception, she will still potentially benefit and should still be able to access the pills up to 120 hours (5 days) after unprotected intercourse, especially if other alternatives (e.g., copper IUD) are unacceptable [21].

All of the emergency contraception pill regimens have side effects that may last 1 to 2 days. These include abdominal pain, headache, menstrual irregularities with next menses, fatigue, dizziness, and breast tenderness. Approximately 50 percent of women who take a combination of estrogen and a progestin will have nausea and 20 percent will vomit [18]. Advise the woman to take over-the-counter meclizine hydrochloride (Dramamine) 1 hour prior to taking the initial dose. Taking the pills with food may decrease the likelihood of nausea. If the woman vomits within 1 hour of taking the pills, the dosage should be repeated.

A copper intrauterine contraceptive device (IUD) can be inserted within 5 to 7 days after the unprotected intercourse. Therefore, the copper T 380A (ParaGard) can be used when hormonal methods are no longer an option. It is advisable to perform a pregnancy test before inserting an IUD to be sure that the woman is not already pregnant.

An IUD can be used as an emergency postcoital contraceptive method only if the woman has none of the usual contraindications for insertion of an IUD. It is not a good method to use after rape because of the potential for sexually transmitted diseases and infection. While highly effective, the IUD is an extraordinarily expensive method of emergency contraception but is a particularly good choice when the woman wants an IUD for her ongoing contraceptive method.

The off-label use of mifepristone (RU 486) for emergency contraception is highly effective when taken within 120 hours (5 days) of unprotected intercourse. Side effects are significantly lower than with the Yuzpe regimen except that the next menses is more likely to be delayed. A single dose of 600 mg is used although there is now evidence that a lower dosage is equally effective and is less likely to delay the next menses [22].

Management of Care

Although it is highly likely that emergency contraception will become available over-the-counter, as of this writing a prescription is still required in most states. As a physical or pelvic examination is not needed and routine pregnancy testing is not advised and no other laboratory work is necessary, this leaves a history to be taken when a woman calls for help to access emergency contraception. This history can be taken over the telephone and includes the following:

1. The woman's menstrual cycles (this month, last month, and usual)
2. When coitus took place
3. Contraindications to either oral hormonal contraceptives or to the copper IUD
4. Past contraceptive methods

If a woman has a history of thrombophlebitis or thromboembolic disorders, then the emergency contraceptives of choice are a progestin-only regimen or copper IUD. This information also helps you in advising the woman regarding a regular contraceptive method.

Having contact with the woman gives you the opportunity to counsel her regarding the fact that emergency contraception will not work if she is pregnant. It is not an abortifacient. Also there are no negative or teratogenic effects on the fetus [19].

Emergency contraception pills are for short-term use and there are no severe long-term side effects or complications [18].

The midwife should either be available to the woman or provide her with extra pills, along with instructions, to be used in the event she vomits within 1 hour of taking the original pills. The woman should be given an appointment to be seen again in 3 to 4 weeks. At this visit the midwife should evaluate the woman's history since she used the emergency postcoital contraceptive method, noting any side effects and bleeding/menses. By this visit the woman should have had a menstrual period. If not, a pregnancy test should be done; if the test is positive, the midwife should ascertain the woman's attitude toward the pregnancy and provide counseling regarding prenatal care or abortion as indicated. The midwife should also carefully evaluate whether the woman is experiencing an ectopic pregnancy. If the woman is not pregnant, she should be provided with an ongoing contraceptive method of her choice.

Injectable Hormonal Contraception

There are two injectable forms of hormonal contraception. Since the hormonal makeup of each is very different, they will be discussed separately.

Depot Medroxyprogesterone Acetate (Depo-Provera Contraceptive Injection)

Description, Effectiveness, and User Response Depo-Provera is an aqueous suspension of depot medroxyprogesterone acetate (DMPA) microcrystals. DMPA is a derivative progesterone. The dose for contraceptive purposes is 150 mg/mL, which is injected intramuscularly every twelve weeks. It is not necessary to adjust the dosage dependent on the woman's weight. A higher dose of DMPA (400 mg/mL) is available that is used for treating cancer but has lower drug bioavailability and should not be used for contraceptive purposes.

DMPA is a progestin whose primary mechanism of action is to inhibit both the secretion of follicle stimulating hormone (FSH) and luteinizing hormone (LH) and LH surges, thereby inhibiting ovulation. If the injections are initiated within 5 days of the beginning of menstruation, the contraceptive effect is immediate, as ovulation will not occur that first month. If the injections are initiated later than 5 days after the beginning of menstruation, the woman should use a backup method of contraception for several weeks, as ovulation may not be inhibited that first month. Secondary mechanisms of action include thickening of the cervical mucus, which serves as a barrier to sperm, and alteration of the endometrium, which would make it inhospitable to a fertilized ovum (a nonissue since there is no ovulation).

The injection is effective for 14 weeks, which gives a 2-week grace period if the next injection cannot be given precisely 12 weeks (or 3 lunar months) later. As shown in Table 16-2 (page 464), Depo-Provera is one of the most effective contraceptive methods. There is no difference between perfect use and typical use, because as long as the woman shows up to get her injection there are no compliance issues involved.

DMPA is an excellent alternative for women who want highly effective long-term contraception and have medical conditions that contraindicate their use of anything with estrogen in it.

Depo-Provera has two major side effects that are positive to some women and negative to others: menstrual changes and delayed return of fertility. A negative side effect is weight gain. Many women like the method because it is totally separate from sexual activity, there is no visible evidence of use of a contraceptive method, and it is so highly effective. All women on Depo-Provera have menstrual changes, and this is the reason most commonly given for discontinuation of the method.

Contraindications, Selection, Side Effects, and Benefits

Contraindications and Selection The following are absolute contraindications to initiating Depo-Provera for a woman by a midwife:

1. Pregnancy (known or suspected)
2. History of breast cancer
3. Genital bleeding of unknown origin
4. History of cardiovascular accident or thromboembolic disease
5. History of liver dysfunction or disease
6. Known hypersensitivity to Depo-Provera

Relative contraindications the midwife should consider before initiating Depo-Provera for a woman include the following:

1. History of depression
2. History of any kind of breast disease or abnormal mammogram
3. History of migraine headaches
4. The woman's desire to become pregnant within the next year or two

5. The woman's desire to time a pregnancy within a rather narrow time range
6. Family history of osteoporosis

Although it is not a contraindication to the use of DMPA, the midwife should assess the woman's risk of exposure to HIV and sexually transmitted diseases. The woman should be fully informed that Depo-Provera does not provide protection against HIV or sexually transmitted diseases and that if she is at risk she will need to use condoms also.

In addition to its other attractive features for some women, Depo-Provera is a method that is available to women for whom other methods, especially those with estrogen, are contraindicated. The wide range of women for whom Depo-Provera is an appropriate choice includes the following:

1. Adolescents to women in their 40s
2. Nulligravidas to grand multiparas
3. Women who are breastfeeding (after 6 weeks postpartum)
4. Women with liver disease (despite what the package insert says) [23, 24]
5. Women with hemoglobinopathy
6. Women with hypertension
7. Women with a history of thromboembolism (despite what the package insert says) [23, 24]
8. Women with seizure disorders
9. Women over age 35 who smoke

Side Effects As noted earlier, there are two major side effects of DMPA that affect all women receiving the injections: menstrual changes and delayed return of fertility. The menstrual changes experienced by women on Depo-Provera start as episodes of unpredictable irregular bleeding and spotting that may last as long as 7 days or more or may be heavy during the first few months of use. These episodes gradually become less frequent and shorter until the woman has amenorrhea. Fifty percent of women experience amenorrhea after 1 year of use; with further use three-quarters of DMPA users experience amenorrhea. Menstrual changes are the most common reason women discontinue use of DMPA. The initial unpredictability puts some women on edge. Other women fear that the absence of menses is indicative of either pregnancy or disease. On the other hand, some women like having amenorrhea, which gives a certain freedom not otherwise experienced until menopause. Some clinicians treat the irregular bleeding or heavy bleeding with conjugated equine estrogen or combination oral contraceptive pills. Before doing this, however, the midwife needs to screen the woman for any contraindications to the use of estrogen. Treatment also mitigates against some of the reasons a woman may be getting DMPA injections, such as needing a progestin-only hormonal contraceptive method and not wanting any evidence around of using a contraceptive method. If taking estrogen is not a problem, give the woman a pack of combination oral contraceptive pills. Another option that some clinicians use if taking estrogen is contraindicated, is to give the woman another DMPA injection. The most effective method for helping a woman through the first 3 to 6 months of irregularity is anticipatory guidance before receiving the first injection.

Depo-Provera provides reversible contraception, but the return of fertility is delayed after discontinuation of the injections. This delay may be as long as 18 to 24 months, although 50 to 70 percent of women conceive by the end of 1 year after discontinuation. This side effect of Depo-Provera should be thoroughly discussed with the woman before the first injection. There is no relationship between the length of time the woman has been receiving injections and the length of time before fertility returns [25].

Another major side effect for some women is weight gain. The evidence on weight gain during use of DMPA is contradictory. A study with weight gains of more than 5 pounds in the first year and thereafter a progressive increase in weight of up to $16\,^1/_2$ pounds over 6 years has been reported [25] as have studies that report no problems with weight gain [24]. A woman starting use of Depo-Provera should be advised of the unsure possibility of weight gain and counseled regarding healthy lifestyle weight management. Other possible side effects include headaches, breast tenderness, abdominal bloating, mood changes, and depression.

There is a reduction of bone mineral density associated with DMPA use, which has potential for an increased risk of postmenopausal osteoporosis. The evolving evidence, however, indicates that this loss is reversible within a year or two of discontinuation and that there is no long-term effect [24].

Benefits In addition to being a safe, effective contraceptive method for a wide range of women, Depo-Provera has a number of benefits [26]. It not only provides contraceptive protection but also improves certain medical conditions:

1. Iron deficiency anemia: increased hemoglobin because of reduced menses
2. Protects against pelvic inflammatory disease

3. Sickle cell disease: decreased frequency of crises with increased red blood cell survival
4. Menorrhagia and dysmenorrhea
5. Seizure disorders: decreased frequency of seizures

Finally, all women on Depo-Provera benefit from the fact that DMPA is associated with the prevention of endometrial cancer; it contributes to a significant decrease in risk (80 percent after 1 year of use) [24] for at least 8 years after discontinuation of the injections [23].

Management of Care The majority of the education, counseling, and instruction of the woman regarding Depo-Provera comes during the process of selecting this method of contraception. Adequate premethod counseling will go a long way toward ensuring that the woman does not discontinue the method because of menstrual changes. She also needs to fully understand the delay in return of fertility. An informed consent form, detailing these two side effects of DMPA and requiring her signature, may be useful.

Although the risk of breast cancer for women on DMPA is no greater than for women on oral contraceptive pills, it was a concern that kept the FDA from approving Depo-Provera for 20 years. The World Health Organization (WHO) study that finally put this matter to rest found that the overall relative risk in women who had ever used DMPA was 1.2 [27, p. 5]. Although this risk was low enough for the FDA to approve Depo-Provera, the midwife would be prudent to ensure careful monitoring by having the woman do monthly breast self-examinations, by performing a breast examination annually, and, on women with a family history of breast cancer, by obtaining a baseline mammogram.

Initiation of DMPA injections is as follows:

Post menses: within 5 days or at any time in a woman's cycle with use of spermicide and condoms until her next menses

Post abortion: within 5 days

Post delivery (not breastfeeding): immediately or within 3 weeks postpartum unless the woman has a history of postpartum depression. Then give the first injection at 6 weeks postpartum

Post delivery (breastfeeding): immediately or at 6 weeks postpartum

The small amounts of Depo-Provera found in breast milk do not negatively affect either the breast milk or the baby.

The injection is given deep in the gluteus maximus or deltoid muscle with a 21 to 23 gauge needle. The woman is advised *not* to massage the injection site for at least several hours, to expect menstrual irregularities, and to take calcium supplements (1000 mg) daily. The midwife should also discuss with her calcium-rich foods such as milk, cheese, yogurt, sardines, and tofu.

There is one known drug interaction. Aminoglutethimide (Cytadren), an anticancer drug, may significantly reduce the efficacy of Depo-Provera. Very rarely a woman has a severe allergic reaction with anaphylaxis. For this reason the midwife may want to have a woman wait in the area for 20 minutes after the injection if she has not previously used DMPA.

The woman is given an appointment to return in 12 weeks or 3 lunar months. If she misses her appointment but returns before 14 weeks for her injection, she remains contraceptively protected. However, if more than 14 weeks have passed since the last injection, you must make sure she is not pregnant before giving her another injection. To avoid pregnancy, it helps for the woman to use a spermicide and condoms after 13 weeks or for the midwife to have given her a prescription for emergency contraception. In the event of an accidental pregnancy, the contraceptive doses of DMPA do not increase the risk of congenital anomalies.

Weight, blood pressure, dipstick urine for glucose if the woman has a history of gestational diabetes or a family history of diabetes, and a history that focuses on menstrual pattern, any other side effects, and risk for HIV and sexually transmitted diseases are taken at the routine 3-month injection visit. As long as the 3-month visits and the annual health care physical examination (see Chapter 2) reveal no contraindications, the woman may continue with Depo-Provera indefinitely.

Combination Injectable Hormonal Contraception (Lunelle)

Description, Effectiveness, and User Response Lunelle is a monthly 0.5-mL dose of aqueous suspension of 25 mg of medroxyprogesterone acetate and 5 mg of estradiol cypionate (MPA/E_2C). Its primary mechanism of action is suppression of ovulation. It may also inhibit sperm from penetrating through the thickened cervical mucus.

The injection is effective for 28 days with a 10-day window (28 ± 5 days) for repeat injection. As shown in Table 16-2 (page 464), the combination hormone injection is one of the most effective contraceptive methods. MPA/E_2C offers many of the advantages of combination oral contraceptive pills

without the daily responsibility for pill taking. This accounts for the difference in typical use between combination oral contraceptive pills and the combination hormonal injection.

The advantages of the combination injectable hormonal contraceptive to some women include regular cycles and a rapid return to fertility.

Contraindications, Selection, Side Effects, and Benefits

Contraindications and Selection Absolute contraindications are the same for combination oral contraceptive pills (see page 516) plus the following:

1. Severe hypertension
2. Diabetes with vascular involvement
3. Valvular heart disease with complications

The midwife should also assess the woman's risk of exposure to HIV and to sexually transmitted diseases. Lunelle does *not* provide protection against these diseases. The woman should be fully informed of this and instructed to use condoms if she is at risk.

Selection of Lunelle by a woman may be based on her desire for a monthly injectable over a daily pill, regular menses over the irregular bleeding of progestin-only methods, and a rapid return to fertility. Others may find monthly injections a little onerous, especially if a woman has to wait to be seen. This can be resolved with a separate patient flow system for women getting regular contraceptive injections.

Side Effects Side effects are similar to combination oral contraceptive pills. Bleeding irregularities occur primarily during the first 3 months, with most women having regular menstrual cycles after 3 months. Women who get their monthly injections at evenly spaced intervals have more predicable bleeding patterns [28].

Other side effects that occur most frequently are breast tenderness, acne, and weight gain. Weight gain is the leading cause of discontinuation and ranges from an average of 4 to 6 pounds during the first year to progressively increased amounts during the second year.

Drug interactions are the same as for combination oral contraceptive pills and for the DMPA injection. (See pages 519 and 533.)

Benefits Benefits are probably similar to combination oral contraceptive pills although as yet not studied.

Management of Care The woman is fully informed, has chosen Lunelle, and has been screened for contraindications. The initial injection is then given within the first 5 days after the onset of menstruation or completion of a first trimester abortion; or no earlier than 4 weeks postpartum if not breastfeeding and no earlier than 6 weeks postpartum if breastfeeding.

Lunelle is given as an intramuscular injection into the gluteus maximus, deltoid, or anterior thigh. Vigorously shake the vial with the solution in it just before use to ensure a uniform suspension of the drugs.

The woman should be counseled that her first menstrual period under the influence of Lunelle will be in 2 to 3 weeks; that she needs to return in 28 ± 5 days for her next injection, and that she should return for her repeat injections based on the calendar and not on when she is menstruating. If she is going to be late in returning for her next injection, she needs to know that she is vulnerable to pregnancy and that she should use a spermicide and condoms. If unprotected intercourse occurs, she should use the prescription you have given her for emergency contraception. If she is later than 33 days in returning for her next injection, you need to first rule out pregnancy.

Return visits consist of questions regarding her menses and any side effects along with administration of the injection. She should be scheduled for an annual physical and pelvic examination and routine laboratory tests.

Subdermal Implants

The Norplant System of subdermal levonorgestrel implants was approved by the Food and Drug Administration in 1990. In August 2000, the pharmaceutical company advised health care providers that Norplant insertion kits distributed after October 20, 1999, had a lower than expected release rate of hormones from several lots and recommended no longer inserting the Norplant capsules. Although Norplant is still approved by the Food and Drug Administration, which has also approved a two-rod implant originally called Norplant II (now under the trade name Jadelle), the pharmaceutical company is not marketing either one in the United States as of this writing. Norplant is still in the arms of an unknown number of women in the United States and is used, as is

Jadelle, in other countries. For these reasons, information about Norplant is retained in this edition of the book as is the removal procedure (Chapter 51). There is also a single subdermal implant called Implanon expected to be available in the United States by 2003 [29]. Biodegradable implants in the form of capsules and pellets are in development.

The Norplant System consists of six sealed capsules made of dimethylsiloxane/methylvinylsiloxane copolymer (Silastic), each of which contains 36 mg of levonorgestrel (a synthetic progestin) in crystalline form. The levonorgestrel diffuses through the capsules at an initial rate of 85 mcg per day. The diffusion rate decreases to approximately 30 mcg per day in about 9 months and remains at this level. Contraceptive levels of levonorgestrel in the body are reached within 24 to 48 hours of implantation. The implants can be left in the body for 5 years before replacement is necessary. Research in China has shown efficacy of still less than 1 percent of pregnancies up to 7 years [29]. If a woman wants to get pregnant, the implants are removed and the return of fertility is almost immediate.

The usual location for implantation is the inner aspect of the nondominant upper arm, although the implants can be located elsewhere in the body (e.g., buttocks, lower abdomen, upper leg). The inner upper arm is a protected area of the body, readily accessible for insertion and removal, not very visible to others after the initial tissue bruising has healed, but visible and accessible to the woman for postinsertion and postremoval care.

Of all the birth control methods, including sterilization (see Table 16-2, page 464), the Norplant system has the lowest percentage of women experiencing an accidental pregnancy. The capsules used in the United States are of lesser density than some of the original capsules studied in other countries. This means that U.S. women who weigh over 70 kg will benefit from the same high effectiveness of this method as women who weighed less than 50 kg in those studies of the implants. There is no difference between perfect use and typical use, because once the capsules are implanted there is nothing for the woman to do. Norplant also has the second highest continuation rate at 1 year, after sterilization.

The levonorgestrel implants have two primary mechanisms of action: (1) they render the cervical mucus hostile to sperm, and (2) they inhibit ovulation in at least 50 percent of the woman's cycles. The implants most likely also suppress the cyclic proliferation of the endometrium induced by estrogen, so the endometrium remains in a state of atrophy. The cervical mucus thickens and becomes viscous so that it serves as a barrier to sperm. The level of levonorgestrel maintained in the woman's body by The Norplant System partially suppresses the luteinizing hormone surge, limiting ovulation. Follicle stimulating hormone and luteinizing hormone secretion continues at normal levels.

Women express a high level of acceptance of and satisfaction with The Norplant System. The main reasons for discontinuing the method other than the desire to become pregnant are menstrual irregularities and headaches.

Contraindications, Selection, and Side Effects

All of the implant systems are progestin-only and are thus similar in action, contraindications, selection, and side effects to the following discussion of Norplant.

Contraindications and Selection The following are absolute contraindications to the use of Norplant:

1. Pregnancy (known or suspected)
2. Abnormal genital bleeding of unknown origin
3. Active thrombophlebitis or thromboembolism disorders
4. Acute disease of the liver; benign or malignant liver tumors
5. Known or suspected breast cancer

The contraceptive effectiveness of levonorgestrel is compromised when the woman is taking drugs for the treatment of tuberculosis (e.g., Rifampin) or seizure activity (e.g., Dilantin). Such women should use a backup contraceptive method while on these drugs and for 2 weeks after completing drug therapy.

The midwife should assess the woman's risk of exposure to HIV and sexually transmitted diseases. The woman should be fully informed that Norplant does not provide protection against HIV or sexually transmitted diseases and that if she is at risk she will need to use condoms also.

Women for whom Norplant would be an appropriate choice include the following:

1. Women who are breastfeeding (after 6 weeks postpartum)
2. Women who have had unacceptable side effects from oral contraceptive pills containing estrogen
3. Women who have difficulty remembering to take a pill or an aversion to the manipulation needed for the barrier methods

4. Women who want long-term contraception (e.g., women who are finished with childbearing but do not want sterilization)
5. Women who want to be able to time a pregnancy

Side Effects The side effects associated with Norplant are more prevalent in the first several months of use, when the level of levonorgestrel in the body is higher. Generally, a woman who is fully informed of the possible side effects before insertion and supportively monitored after insertion is more apt to continue with the method until the side effects resolve or become more tolerable as time goes on and the level of serum levonorgestrel decreases.

The two major side effects of Norplant are irregular menstrual bleeding and headaches. Irregular menstrual bleeding ranges from amenorrhea (infrequent) through unpredictable, irregular, frequent bleeding or spotting to prolonged bleeding. Most, but not all, women settle into a predictable pattern of menstrual bleeding by the end of the first year of using the implants. Menstrual changes, however, are the most frequent reason for discontinuation of The Norplant System.

Headaches are the second most frequent reason for discontinuation of the method. For many women the headaches subside as the level of levonorgestrel decreases. In the meantime they obtain relief with over-the-counter analgesics. A rare woman may have severe headaches with blurred vision and papilledema. Although these symptoms may be coincidental, discussion with your consulting physician regarding removal of the implants, referral to an ophthalmologist, and other possible diagnostic measures is indicated.

Less frequently occurring side effects include an increase in appetite and weight gain (which averages 5 lb over 5 years and is usually due to other causes), breast tenderness (bilateral; associated with fluid retention), acne (which improves after removal of implants), hair loss, nervousness, ovarian cysts (which usually regress spontaneously; investigate further if a cyst persists or becomes larger and painful), nausea (which improves after removal of implants), dizziness, and depression.

Management of Care

The majority of education, counseling, and instruction of the woman regarding The Norplant System comes during the process of selecting this method of contraception. Adequate pre-method counseling will go a long way toward ensuring that the woman does not discontinue use because of side effects.

Postinsertion instruction includes a reminder that The Norplant System does not protect the woman from HIV or sexually transmitted diseases and that she needs to use condoms if she is at risk. She should be given an appointment for her annual health care examination, and the benefits of this examination should be emphasized, as she will not have contraceptive need as motivation to keep this appointment.

Contraceptive Vaginal Ring (NuvaRing)

Description, Effectiveness, and User Response

To date, there is only one contraceptive vaginal ring on the market in the United States. Approved by the Food and Drug Administration in the fall of 2001, NuvaRing is a homogeneous design of an estrogen and a progestin surrounded by an ethylene vinyl skin, which allows for a daily release of 0.015 mg of ethinyl estradiol and 0.120 mg of etonogestrel over the course of 3 weeks (21 days). Because release of the hormones is directly into the vagina, a lower dose per day is required for cycle control. By contrast, oral contraceptive pills first have to pass through the liver leaving less bioavailability and thus requiring larger dosages. Contraceptive vaginal rings suppress ovulation with lower hormone doses [30, 31].

The ring is flexible, soft, and transparent, and approximately 4 mm ($^1/_8$ in.) thick and 54 mm (2 in.) in diameter, which is a little smaller than the smallest diaphragm. A ring is inserted by the woman for one cycle of 3 consecutive weeks of continuous ring use and then removed by the woman for 1 week without the ring during which time she has a withdrawal bleed menstrual period. She then inserts a new ring and a new cycle begins. Insertion is akin to insertion of a diaphragm except that fitting is not required. Wherever the woman places the ring inside her vagina will be correct.

NuvaRing has an effectiveness rate of 1 to 2 pregnancies in 100 women using this method [32]. User response has been positive from both women and their partners. It is convenient because the woman can easily insert it and forget it for 3 weeks. Removal is also easy. NuvaRing is usually not felt by the woman and only occasionally felt by her partner during sexual intercourse. Return to fertility is rapid and usually occurs with the first cycle after discontinuation.

Contraindications and Side Effects

Contraindications Contraindications are the same as for any combination hormonal contraceptive method (see pages 516 and 534). There is no available data on whether the lower dosages used in the vaginal ring route would mean fewer contraindications and side effects than with the oral route for combination hormonal contraception.

Side Effects Headaches are the primary side effect occurring in nearly 7 percent of users [31, 33]. Other side effects include leukorrhea (5.3 percent), nausea (2.8 percent, usually when first inserted), weight gain (2.2 percent), and device-related events (3.8 percent) such as "foreign body sensation, coital problems, and device expulsion" [31, 33]. There is minimal to no adverse or clinical effect on lipid parameters, carbohydrate metabolism, and blood pressure.

Management Plan for Contraceptive Vaginal Ring

The management plan for NuvaRing is the same as for combination oral hormonal contraception (see page 520). NuvaRing should not be used if the woman is breastfeeding.

The woman is instructed on the insertion and removal of the ring and on the use of NuvaTime, an electronic reminder alarm. The NuvaRing is first inserted during the first 5 days of the woman's menstrual cycle with instructions to also use a spermicide and condoms for seven days.

Expulsion occurs in approximately 2.6 percent of women using NuvaRing. If it is out less than 3 hours, then the ring simply should be rinsed off with cool to lukewarm water and reinserted. If it has been out more than 3 hours, then the woman may not be protected from pregnancy and needs to use a spermicide and condoms for 7 consecutive days in addition to reinserting the ring.

If the woman forgets to remove the ring for up to 4 weeks, she should then remove it for a ring-free week and then insert a new ring and start a new cycle. If the ring has not been removed for more than 4 weeks, the woman may not be protected from pregnancy and she should check to be sure she is not pregnant. If not pregnant, spermicide and condoms need to be used in addition to a new ring for 7 days in a row.

NuvaRing comes in boxes of 1 or 3. Start the woman with a box of 3 and give her an appointment for a follow-up visit in $2\,^1/_2$ months. This visit is the same as the return visit for any combination hormonal contraceptive (see page 524). If all is well at the return visit, then give the woman an appointment for her annual physical examination.

Transdermal Contraceptive Patch (Ortho Evra/Evra)

Description, Effectiveness, and User Response

To date, there is only one transdermal contraceptive patch on the market in the United States. Measuring $1\,^7/_8$ in. by $1\,^7/_8$ in., it is thin and very light, and it consists of three layers. The outer layer is a beige, flexible, protective film of polyester. The adhesive middle layer contains 6 mg norelgestromin and 0.75 mg ethinyl estradiol which, when applied to the skin, releases 150 mcg of norelgestromin and 20 mcg of ethinyl estradiol into the bloodstream daily. Norelgestromin is the primary active metabolite of norgestimate, which is a progestin used in oral contraceptive pills [34]. The third layer of clear polyester is called a release liner and protects the adhesive layer during storage. It is removed prior to use.

The contraceptive patch is applied for 7 days for 3 weeks or 21 consecutive days. This is followed by a patch-free week during which the woman has a withdrawal bleed menstrual period. She then starts the cycle over again. Four anatomical sites that result in therapeutic levels of the hormones are used: buttocks, upper outer arm, lower abdomen, or upper torso, excluding the breasts [34]. Even though the patch is to be changed every seven days, it continues to deliver the hormones for another two days which means that the woman does not have to change her patch at the exact same time every week [35].

The effectiveness of the contraceptive patch is comparable to that of combination oral contraceptive pills and is just under 1 per 100 women using this method with an overall failure of 0.88 and a method failure of 0.7. However, the patch may be less effective in women with a baseline body weight of 198 pounds or greater [36].

Studies show that 4.7 percent of patches were replaced because of partial detachment (1.8 percent) or complete detachment (2.9 percent). Adhesion is not affected by heat, humidity, and exercise. Women can carry out their usual daily activities, exercise, participate in sports, bathe, and swim while wearing the patch [37].

Compliance with the regimen of changing the patch weekly compares very favorably with compli-

ance with oral hormonal contraceptive pills. Perfect use of the patch ranged from 88.1 to 91.0 percent without significant differences between age groups [38]. These results demonstrate ease of use.

Return to fertility may be delayed and conception should be postponed until regular menstruation has resumed [39].

Contraindications and Side Effects

Contraindications Contraindications are the same as for any combination hormonal contraceptive method (see pages 516 and 534).

Side Effects Side effects are similar to those of combination oral contraceptive pills (see pages 517–520) with the addition of the nonhormonal related side effects of application site reactions. More prevalent side effects include headache, dysmenorrhea, and breast discomfort. Breast discomfort was greater than oral contraceptive pills in the first two cycles but then decreased to comparable levels [35, 40]. Reasons for the increased rate of dysmenorrhea with use of the patch (13.3 percent) have not yet been studied.

Management Plan for Contraceptive Patch

The management plan for the contraceptive patch is the same as for combination oral hormonal contraception (see page 520). The contraceptive patch should not be used if the woman is breastfeeding.

In addition to the screening done for contraindications to combination hormonal contraception, the midwife should also screen for any previous skin allergies to bandages or medicated patches and take careful note of the woman's weight. If she weighs around 198 pounds or more, then the woman needs to know the increased risk for pregnancy and be counseled about other contraceptive methods.

The woman is instructed on the removal of the contraceptive patch from its package, the sites where it can be applied, when to start using the patch, how to apply the patch, and how to track use of the patch on a calendar. She will need to also use a spermicide and condoms for the first week of her first cycle. The woman can first apply her contraceptive patch on the first day of her menstrual period or on the first Sunday after her menstrual period begins. Each new patch should be applied on the same day of the week. The woman should apply the patch in a way that her fingers never touch the medicated side of the patch. This is done by removing only half of the release liner and applying the patch to her chosen site and then removing the other half of the release liner and pressing down the rest of the patch. She should first clean and dry the site. She needs to check her patch daily by running her fingers around its edges to make sure they are not detaching.

If the patch becomes partially detached, the woman should try to reapply it, but if it does not stick, or if the patch has become completely detached, then she should use a new patch immediately and continue with this same cycle if this situation has been for less than one day. If the woman does not know how long her patch has been partially or completely detached or if it has been for longer than one day, then she is not protected from pregnancy. She should start a new patch—and a new cycle of 21 consecutive days—immediately. She will also need to use a spermicide and condoms for the first week of this new cycle. A patch should not be used if it is touched or becomes stuck to itself or to something else, and nothing else—such as tape or a wrap—should be used to try to keep the patch in place.

On the other hand, if the woman forgets to change her patch during week 2 or 3 of the cycle, and she remembers within 1 to 2 days, she should apply a new patch as soon as she remembers but continue to change the patch as was originally scheduled. If she does not remember to change her patch for more than two days, she should understand that she is not protected from pregnancy and that she should start a new 4-week cycle by putting on a new patch and use a spermicide and condoms for the first week of this new cycle. If the woman forgets to take off the patch at the beginning of the patch-free week, she should remove it as soon as she remembers within that week and start the new patch, and new 4-week cycle, as originally scheduled.

If the woman forgets to start a new 4-week cycle and apply the first patch after the patch-free week, she needs to understand that she is not protected from pregnancy and that she should start a new 4-week cycle by putting on a new patch and use a spermicide and condoms for the first week of this new cycle.

The woman should be instructed not to use creams, oils, powder, makeup, or sprays on or near her skin where she intends to place or has a patch as these may cause the patch to become loose. If the patch causes skin irritation, she should remove the patch and apply a new patch elsewhere. She should

not try to move the same patch and she should not wear two patches at the same time as this may cause nausea and vomiting.

The midwife should supply the woman with a prescription for emergency contraception and encourage her to have a spermicide and condoms on hand in the event that she did not notice that the patch had become detached or that she made an error in removing or starting a new patch on schedule.

Contraceptive patches come in a carton containing 3 patches for 1 cycle and also in cartons containing 1 patch to use as a replacement if necessary. Initially prescribe 4 cycles and make an appointment for follow-up in 3 months.

The follow-up visit is the same as the return visit for any combination hormonal contraceptive (see pages 524 and 534). If all is well at the return visit, then give the woman an appointment for her annual physical examination.

Antepartal Care

This page intentionally left blank

CHAPTER

21

Normal Pregnancy Database: Adaptations of the Mother, Development and Growth of the Embryo and the Fetus, and the Placenta

The antepartal period covers the time of pregnancy from the first day of the last normal menstrual period (LNMP) to the start of true labor, which marks the beginning of the intrapartal period. In contrast, the prenatal period covers the time of pregnancy from the first day of the last normal menstrual period to the birth of the baby, which marks the beginning of the postnatal period.

The antepartal period is divided into three trimesters, each consisting of approximately 13 weeks or 3 calendar months. This division derives from the convention of considering the duration of pregnancy to be approximately 280 days, 40 weeks, 10 lunar months, or 9 calendar months from the first day of the last menstrual period. In reality, gestation is not that long. Fertilization takes place at the time of ovulation, approximately 14 days after the last menstrual period (assuming a 28-day cycle). This makes actual gestation approximately 266 days or 38 weeks in length. Adding 14 days gives a total of 280 days from the last menstrual period. In practice, the first trimester is generally considered to be weeks 1 to 12 (12 weeks), the second trimester to be weeks 13 to 27 (15 weeks), and the third trimester to be weeks 28 to 40 (13 weeks).

The database for normal pregnancy has the following components:

1. Maternal anatomical and physiological changes
2. Maternal psychological adjustment and processes
3. Fetal growth and development
4. Placental development, circulation, and functioning

Maternal Anatomical and Physiological Changes

Information concerning maternal anatomical and physiological changes is discussed both here and throughout the chapters on antepartal care and the chapters in the skills section that pertain to antepartal care. This method of presentation was chosen in order to provide the information when it is applicable to understanding particular aspects of the antepartal period and related management of care. This approach is in accord with the principle that learning takes place best when the information is used. Anatomical and physiological changes discussed elsewhere are not necessarily repeated in this chapter. Presented here are the maternal anatomical, physiological, and hormonal changes indicative of pregnancy and an overview of the anatomical and physiological changes made throughout pregnancy.

Physiological and Hormonal Changes Indicative of Pregnancy

Knowledge of the physiology of early pregnancy is necessary for understanding the presumptive and probable signs of pregnancy. It is also important, for purposes of screening for abnormality, to know what other conditions may cause a particular sign.

Presumptive signs of pregnancy are maternal physiological changes that the woman experiences and that in most cases indicate to her that she is pregnant. *Probable signs* of pregnancy are maternal physiological and anatomical changes other than presumptive signs that are detected upon examination and documented by the examiner. *Positive signs* are those directly attributable to the fetus, as detected and documented by the examiner.

At the time of ovulation, the ovum is extruded from a mature graafian follicle in the ovary. The ruptured follicle undergoes a number of changes to become the corpus luteum of menstruation, which progressively degenerates and completely regresses during the subsequent menstruation. If the ovum is fertilized, the corpus luteum is maintained by the production of chorionic gonadotropin by the syncytiotrophoblast surrounding the blastocyst and becomes the corpus luteum of pregnancy.

The continued production of progesterone by the corpus luteum of pregnancy maintains the uterine lining for implantation and the earliest stages of pregnancy; shortly after implantation the placenta begins producing enough progesterone to take over this function. Progesterone from the corpus luteum of pregnancy also causes the mother's basal body temperature to continue at its elevated level following ovulation. With the uterine lining maintained, there is no menstruation; this usually is the first indication of pregnancy for women with regular menstrual periods. Amenorrhea, however, may also be caused by certain chronic diseases, pituitary tumors, environmental factors or changes, malnutrition, and emotional upset, such as that caused by the fear of being pregnant.

The placenta produces several hormones. These hormones cause a number of the physiological changes that aid in the diagnosis of pregnancy. The high levels of estrogen and progesterone produced by the placenta are responsible for breast changes, skin pigmentations, and uterine enlargement in the first trimester. Chorionic gonadotropin is the basis for the immunologic pregnancy tests. Chorionic somatomammotropin (human placental lactogen, or HPL) stimulates the growth of the breasts, has lactogenic properties, and effects a number of metabolic changes.

Specifically, estrogen promotes development of the ductal system of the breasts as well as mammary growth, and progesterone stimulates the development of the alveolar system of the breasts and contributes to mammary growth. Together with chorionic somatomammotropin, these hormones are responsible for the presumptive signs of breast enlargement, causing the breasts to feel tense and tingling during the first 2 months of pregnancy, enlargement of the nipples, and the presence of colostrum in the breasts, which usually can be expressed by the twelfth week of pregnancy. Hypertrophy of the mammary alveoli causes the breasts to feel nodular, starting during the first 2 months of pregnancy. Montgomery's tubercles or follicles are actually hypertrophied sebaceous glands in the areolae and are prominently noticeable by the second month of pregnancy. Excessive enlargement of the breasts causes striations. A tracing of delicate veins may be seen just beneath the skin as the breasts enlarge. Many of these breast changes are also seen in women taking oral contraceptive pills, may occur in women who have brain or ovarian tumors or who are taking certain tranquilizers, and sometimes are seen in pseudocyesis (imaginary pregnancy).

Although the cause of skin pigmentation is not certain, it is thought that estrogen and progesterone have a melanocyte-stimulating effect. This would account for the darkening of the nipple and the primary areolae (darkening of the areola around the nipple), both of which occur around the third month of pregnancy. It also would account for the secondary areolae (mottling of the skin around and beyond the primary areolae); the linea nigra (a narrow line of dark skin pigmentation in the midline of the abdomen from the symphysis pubis to the umbilicus); the striae (stretch marks) of the abdomen (striae gravidarum), excessively enlarged breasts, and occasionally the buttocks and upper thighs; and chloasma (the mask of pregnancy—irregular brownish discolorations of the forehead, nose, cheeks, and neck). All of these occur around the fifth or sixth lunar month of pregnancy. The pigmentation of the nipples and breasts varies with the woman's complexion. It is a pronounced pink in blondes, dark brown in brunettes, and black in the black race. Chloasma is most noticeable in brunettes. Although skin pigmentations are fairly common in pregnant women, they may be absent. Chloasma is seen sometimes in women taking oral

contraceptive pills. All skin pigmentations may also be associated with a variety of tumors of different origin. Most of the pigmentation changes of pregnancy regress and disappear after pregnancy has ended, with the exception of the striae, which lose their reddish brown pigmentation but remain as fine silvery white lines of glistening fibrous tissue.

Vascular spiders and palmar erythema during pregnancy possibly are due to the hyperestrogenemic state of the woman while pregnant. These conditions, which occur around the fifth to sixth lunar month of pregnancy, usually disappear after pregnancy has ended and have no clinical significance. However, palmar erythema in the first trimester indicates the possibility of hepatitis, with which it is also associated. Vascular spiders generally appear on the face, neck, upper chest, and arms and are minute reddened elevations of the skin; each has a central body from which radicles branch out. Many women do not experience either of these conditions during pregnancy.

Hormonal changes are only one of many possible explanations for the etiology of nausea and vomiting, which is so common as to be considered a presumptive sign of pregnancy. "Normal" nausea and vomiting in pregnancy rarely extend beyond the first trimester.

It is not really known what accounts for the fatigue often encountered during the first trimester. For a number of years it was thought that the basal metabolic rate (BMR) initially fell early in pregnancy, which would account for first trimester fatigue. More current thought is that the elevated progesterone(s) that initially maintain the pregnancy cause fatigue or have a sleep-inducing effect.

Hormonal Pregnancy Tests

Pregnancy tests are based on the production of human chorionic gonadotropin (hCG), which is a product of the syncytiotrophoblast, the outer layer of the trophoblast. The syncytiotrophoblast is differentiated and secretes hCG as the trophoblast invades the endometrium and implants. It is not possible to detect hCG in the maternal plasma or urine until implantation takes place. As variability in cycle length is largely due to the number of days from the beginning of menses to ovulation [1] and implantation time varies from 6 to 12 days after ovulation [2], it may or may not be possible to detect hCG when a woman misses the first days of her menstrual period. Pregnancy tests are based on the detection of hCG. Some pregnancy tests claim to be accurate down to the first day of a woman's missed menstrual period. However, as many as 10 percent of women do not implant by the first day of their missed menstrual period and therefore would register as false negative pregnancy tests if done at that time [1]. Conversely, a number of pregnancies that are detected very early also spontaneously abort very early [3].

Human chorionic gonadotropin is secreted into the maternal bloodstream where it is present in the plasma. It is then excreted in the mother's urine. The most sensitive tests, such as immunoradiometric assay, can detect hCG in either plasma or urine by the first day after implantation or 8 to 9 days after ovulation or 8 to 11 days after conception. After that point, the hCG level increases exponentially, doubling approximately every 2 days until it peaks at about $8\,^1/_2$ to 10 weeks' gestation as dated by a woman's last menstrual period (LMP) (see Figure 23-1). There is a very wide variation in normal hCG levels, which means that there are no absolute numbers for any given day or week of gestation and that a single number may not be that useful. What is informative are serial tests of hCG levels (at least two; more if indicated) and vaginal sonography. This becomes important in evaluating a threatened abortion, ectopic pregnancy, multiple gestation, hydatidiform mole, and choriocarcinoma. If such tests are conducted for whatever reason, the results may also be useful in dating a pregnancy.

Quantitative assays of hCG are of diagnostic significance in pregnancy. They are abnormally low in ectopic pregnancies and threatened abortions (also causing false-negative pregnancy tests) and abnormally high in women with multiple pregnancy, hydatidiform mole, or choriocarcinoma. Quantitative values in the serum radioimmunoassay tests are also useful in dating a pregnancy.

Human chorionic gonadotropin in the urine has been used for pregnancy tests since the late 1920s, when Aschheim and Zondek originated biological assay of its presence. The biological tests of pregnancy utilize small immature animals (mice, rats, rabbits, frogs, toads) and are based on the response of the animal's ovaries or testes after the animal is injected with either serum or urine of the woman suspected of being pregnant. These tests were supplanted by the immunologic assays of hCG. The immunologic assays utilize specific antisera obtained from animals (rabbits) in which antibody response to hCG has been stimulated. The assay is based on the fact that hCG is a protein and therefore antigenic. The antisera are mixed with

urine from the woman suspected of being pregnant which mediates the response of the antisera when mixed with either latex particles coated with hCG (latex particle agglutination inhibition tests) or with erythrocytes (from sheep) that have been sensitized to hCG (hemagglutination inhibition tests). If the woman is pregnant, her urine contains hCG, which neutralizes the antibodies in the antiserum and inhibits agglutination—a positive pregnancy test. If the woman is not pregnant, her urine does not contain hCG and agglutination will occur—a negative pregnancy test.

The companies that manufacture these pregnancy tests enclose with the necessary materials step-by-step instructions for the performance and interpretation of the test, information pertaining to the period in gestation when the test is most accurate, and data concerning the sensitivity of the test in detecting specific levels of hCG in terms of international units of hCG per liter or milliliter of urine. Because hCG is similar in structure to luteinizing hormone (LH), the antibodies of both these hormones will cross-react with each other. Therefore most tests limit their maximum quantity sensitivity in order to avoid false-positive tests caused by cross-reactivity with luteinizing hormone.

False-negative immunologic pregnancy tests occur in about 2 percent of all tests run and usually result from doing the test too early in the pregnancy (i.e., before 6 weeks since the first day of the last menstrual period) or, occasionally, too late in the pregnancy (after the middle of the pregnancy). False-positive results occur in about 5 percent of all immunologic tests. False-positive results may be caused by the woman's having massive proteinuria or may occur during the onset of menopause in middle-aged women, when the levels of pituitary gonadotropins rise while the endocrine function of the ovaries declines. False-positive pregnancy tests may also result from the cross-reaction of pituitary gonadotropins with hCG.

Overall, the immunologic pregnancy tests are as accurate as the biologic pregnancy tests (95 to 98 percent), although accuracy may vary somewhat depending on the test used and whether care is taken to ensure that the test is being done during the appropriate time of gestation. Since pregnancy tests are not 100 percent accurate, they are considered a probable sign of pregnancy, and the results should be evaluated in relation to the presence or absence of other signs of pregnancy.

Radioreceptorassay and radioimmunoassay tests are extremely sensitive tests able to detect hCG at far lower levels than previous tests could. Both require expensive equipment and trained technicians. Because the radioreceptorassay test cross-reacts with luteinizing hormone, however, it is more limited in its sensitivity than the radioimmunoassay tests.

Human chorionic gonadotropin consists of two dissimilar glycoprotein chains, designated as the alpha subunit and the beta subunit. The radioimmunoassay blood tests are designed specifically to detect the hCG beta subunit because it is distinctly different from other glycoprotein beta subunits, whereas the hCG alpha subunit is quite similar, if not identical, to other glycoprotein alpha subunits. This radioimmunoassay test is commonly called beta-preg. The laboratory will supply information about the expected levels for the particular week of gestation and the sensitivity of the test used. This is a highly accurate test, though not 100 percent perfect.

The most recent pregnancy tests use enzymes to detect the hCG beta subunit and are called enzyme-linked immunosorbent assay (ELISA) (Figure 21-1). They consist of immunosorbent assays of monoclonal antibodies to the hCG beta subunit. They have good sensitivity, are highly specific, take very little time, are not very expensive, and are easy to perform. Enzyme immunoassay is used by professionals for in-office or in-clinic testing along with the agglutination immunologic assay pregnancy tests. In addition, enzyme immunoassay is the basis for home pregnancy tests. Home tests are not as accurate in actual use as they are in the laboratory conditions of the companies that make them. Variables include correct timing of when the test is done, correct timing of when the test is read, early pregnancy loss, whether the test was properly stored prior to use, and if a woman had an hCG in-

FIGURE 21-1 Midwife discussing a woman's pregnancy test.

jection (sometimes used with assisted reproduction). If the test is negative, the instructions advise that the woman test herself again in 1 week if she still has not had her menstrual period. Toll-free telephone numbers, most of which are answered by Registered Nurses who can respond to questions/concerns, are given by the pharmaceutical companies that market the home pregnancy tests.

Anatomical Changes/Uterine Enlargement

Estrogen and perhaps progesterone are thought to be primarily responsible for uterine growth by hyperplasia (an increased number of cells) during the early months of pregnancy. This growth is not influenced by any mechanical effect of the developing embryo. The uterine wall is strengthened rather than weakened by this development, since the increased number of muscle cells are accompanied by a marked increase in elastic tissue and an accumulation of fibrous tissue. Thereafter, uterine enlargement occurs because of a combination of hypertrophy (an increase in the size of the cells) and the mechanical effect of interior pressure on the uterine wall by the growing products of conception. During the early months of gestation, there is also a marked increase in the size of the uterine blood vessels and lymphatics. The resulting vascularity, congestion, and edema most likely account for the overall softening of the uterus and, combined with hypertrophy of the cervical glands, give rise to Chadwick's, Goodell's, and Hegar's signs. Chadwick's sign is the bluish or purplish discoloration of the vulva and vaginal mucosa, including the vaginal portion of the cervix. Goodell's sign is the softening of the cervix, from a nonpregnant state of firmness similar to that of the tip of a nose to the softness of lips in the pregnant state. Hegar's sign is the softening and compressibility of the uterine isthmus. These three signs are evident by about 6 weeks' gestation.

The softness and compressibility of the uterine isthmus (Hegar's sign) have the effect of decreasing support to the enlarging body of the uterus with its increasing heaviness in the fundus. The result is exaggerated uterine anteflexion during the first 3 months of pregnancy, while the uterus is still a pelvic organ. This causes the fundus to press on the bladder, and urinary frequency ensues. Urinary frequency is relieved early in the fourth month of pregnancy as the uterus rises out of the pelvis and, therefore, no longer causes bladder pressure.

As the uterus enlarges, its shape changes from the nonpregnant pear shape to a globular form in the early months of pregnancy and becomes an ever-larger ovoid after the third month of pregnancy. (See part (b) of Figure 21-2.) As it enlarges, the uterus can no longer be contained within the pelvis, and it rises out of the pelvis to become an abdominal organ. The uterus rotates slightly to the right as it rises out of the pelvis. This dextrorotation is thought to be caused by the rectosigmoid's occupying the left side of the pelvic cavity. The uterus may enlarge at slightly different rates (one to two weeks' variation) for the primigravida and the multigravida. This variation may create some differences in early sizing and again when the uterus reaches anatomical landmarks such as the umbilicus.

Early uterine enlargement may not be symmetrical. The ovum normally implants in the upper uterine wall, more frequently on the posterior side. If the implantation is located closer to one cornual area, the cornual area where the ovum implants enlarges first in response to the embryological development taking place at that site. Such implantation may be detected during pelvic examination by the asymmetry of the uterus and a rough, irregular contour in one of the cornual areas. This uterine irregularity occurs around the eighth to tenth week of pregnancy and is called Piskacek's sign.

Uterine enlargement contributes to two other maternal signs of pregnancy. The first is Braxton Hicks contractions, which are hypothesized to result in part from the stretching of the uterine muscle cells. An increase in the concentration of actomyosin in the muscle cells is also thought to contribute to this contractility of the uterus. Braxton Hicks contractions are nonrhythmic, sporadic, painless uterine contractions that start about the sixth week of pregnancy but are not detectable during bimanual pelvic examination until the second trimester and during abdominal examination in the third trimester. They increase in frequency, duration, and intensity as well as attain some degree of rhythm and regularity close to term, at which time they are frequently misinterpreted as labor contractions. They are the major culprit in false labor.

The other sign of pregnancy brought about by uterine enlargement is abdominal enlargement. This begins at the fourth month of pregnancy as the uterus becomes an ever-larger abdominal organ, as can be seen in part (b) of Figure 21-2. The abdomen is more prominent when the woman is standing than when she is supine. Abdominal enlargement can also be more noticeable in multiparas than in primigravidas because of the loss of muscle tone of the abdominal wall, if the woman has not exercised

to get back in shape after each previous pregnancy. A pendulous abdomen results as the uterus sags forward and downward. This can cause problems during labor in extreme cases.

Uterine enlargement with progressive thinning of the uterine wall enables the fetal contributions to the diagnosis of pregnancy to become apparent. The uterus changes from an almost solid organ in the nonpregnant state, with only a narrow opening between the anterior and posterior walls, to an enlarged vessel at term with walls only 5 mm thick, a weight of approximately 2 ounces to more than 2 pounds at term, and a capacity of less than 10 mL increasing by 500 to 1000 times greater to 5000 mL or more. The combination of uterine enlargement, thinning of the uterine wall, and the uterus becoming an abdominal organ enables detection during the second trimester of a number of signs of pregnancy that were previously not able to be noticed. The precise times, however, when the fetal heart tones are heard and quickening is felt vary not only with the thinness or obesity of the individual woman but also with parity. The uterus and abdominal musculature of a multipara have hypertrophied and stretched before. They will do so again more easily, and thus the uterine wall may be thin enough to facilitate eliciting these signs of pregnancy a week or two earlier in a multipara than in a primigravida.

The fetal heart starts beating at the beginning of the fourth week postfertilization (sixth week after the LMP), but it is not until around the twentieth week following the LMP that the heartbeat can be heard with a head fetoscope during abdominal examination of the mother. However, it can be heard abdominally between the twelfth and twentieth weeks after the LMP with hand-held ultrasonic instruments, and movement of the fetal heart can be seen by 7 weeks with a transvaginal ultrasound. Fetal heart tones must be differentiated from the maternal pulse, maternal bowel sounds, fetal movement sounds, and the uterine souffle. The funic souffle (the sound of blood rushing through the umbilical arteries) is synchronous with the fetal pulse.

Similarly, weak fetal movements start in the third month of pregnancy, but it is not until around the twentieth week that they are strong enough and the uterine wall is thin enough that the movements can be felt and properly diagnosed during abdominal examination. The mother may be aware of fetal movements around the eighteenth week following her LMP. These movements increase in intensity over the weeks, from gentle flutterings to unmistakable fetal kicks. The time when the mother first feels fetal movement is called *quickening*, meaning the perception of life. Quickening may be useful as corroborative evidence in dating a pregnancy, but it is not definitively diagnostic because the early flutterings may feel to the mother like the movement of gas through the intestines.

It is not until after the twentieth week that the fetal outline can be palpated during abdominal examination. Again, this is not a definitive diagnostic sign since subserous myomas may feel like fetal parts. Ballottement can be elicited abdominally around the same time. In this sign, a sudden tap on the uterus causes the fetus to sink in the amniotic fluid and rebound to strike gently against the fingers of the examiner. Ballottement is possible at this time because there is a large volume of amniotic fluid in relation to the size of the still small fetus. This proportion grossly changes later in pregnancy, as shown in parts (b), (c), and (d) of Figure 21-2.

Positional changes of the abdominal organs and contents as the abdominal space is increasingly filled with the enlarging uterus, account for a number of the normal discomforts of pregnancy discussed in Chapter 22. Parts (c) and (d) of Figure 21-2 show the different effects on the mother's bladder, room for stomach and lung expansion, center of gravity, and spine before and after lightening, and beginning effacement, as the baby's head descends into the pelvis.

Maternal Physiological Changes

It is important to know the basic maternal physiological changes as they explain many of the discomforts of pregnancy as well as give a database from which to interpret physical and laboratory findings that would be abnormal in the nonpregnant state but are normal during pregnancy. Many of these changes are repeated elsewhere in this book when their applicability becomes important to understanding pregnancy and the management of antepartal care.

Cardiovascular/Hemodynamic Changes

Hemodynamic changes enable the mother's cardiovascular system to meet the demands of the fetus while maintaining her own cardiovascular status. They are caused by increased levels of estrogen, progesterone, and prostaglandins, and they are reversible with the end of pregnancy [4].

The mother's total blood volume increases between 30 and 50 percent in singleton pregnancies and 50 percent or above in twin pregnancies. Total blood volume is a combination of plasma volume, which accounts for 75 percent of the increase, and red blood cell volume, which increases by 33 percent from nonpregnant values. The result is hemodilution, which is reflected in a lower hematocrit, is known as the physiological anemia of pregnancy, and is most pronounced between 24 and 32 weeks' gestation. The increase in total blood volume begins early in the first trimester, becoming rapid until midpregnancy and then more slowly until 32 weeks, after which it remains relatively stable although the erythrocyte mass continues to increase [4, 5, 6].

Posture and body position of the pregnant woman affect fluid distribution and both arterial and venous pressures. A decrease in blood volume occurs after being in the supine position for an hour or more. At the same time, femoral venous pressure is rising steadily. The mechanical pressure of the pregnant uterus on the pelvic veins and on the inferior vena cava impedes the return blood flow from the legs and pelvis, which causes an increase in venous pressure, a sharp rise in hydrostatic pressure in the microcirculation, subsequent leakage of fluid from the vascular bed into the interstitium, and results in edema of the feet and ankles. It also contributes to development of leg and vulvar varicose veins and hemorrhoids and predisposes to deep-vein thrombosis. The distensibility of the veins also contributes to the decreased venous return to the heart. The lateral recumbent position relieves the mechanical pressure from the pregnant uterus, increases blood flow from the lower extremities, and returns the increased femoral venous pressure to normal. The antecubital venous pressure is not affected by the pressure of the uterus on the inferior vena cava and does not change during pregnancy [4, 6].

In late pregnancy, having a woman in the supine position may cause the now large and heavy uterus to rather quickly compress the venous return to the extent that cardiac filling may be reduced and cardiac output decreased. In about 10 percent of women, this may result in arterial hypotension, and the woman may feel faint or lose consciousness. This is readily remedied by having the woman turn on her side or sit up [6]. Arterial blood pressure may also be lowered below the level of the compression if the aorta is also compressed. This means that the pressure in the arteries below the compression is significantly lower and is not accurately reflected in the brachial artery blood pressure. This should be kept in mind when there is systemic hypotension, such as may occur with spinal analgesia, as the decrease will be greater in the uterine arterial pressure than in the arteries above the level of aortic compression [6]. Brachial artery blood pressure usually decreases until midpregnancy at which time it gradually rises again to prepregnant levels by term. The systolic decreases 8 to 10 points while the diastolic has a larger decrease of approximately 12 points [6]. This normal decrease in blood pressure should be kept in mind when evaluating blood pressure increases and screening for hypertensive disorders of pregnancy.

Cardiac output—the product of heart rate and stroke volume—increases significantly beginning in early pregnancy and remaining elevated throughout pregnancy. Factors contributing to this increase include an early increase in stroke volume, an early and progressive increase in heart rate of approximately 15 beats per minute, and decreased systemic vascular resistance. This is evidenced when measured in the lateral recumbent position because when the woman stands, cardiac output falls to nonpregnant levels [6]. As discussed in the preceding paragraph, cardiac output may decrease when the woman is in the supine position in late pregnancy due to the compression of the inferior vena cava by the uterus, which thereby impedes venous return. Obviously, cardiac output is higher when the woman is in the lateral recumbent position than when she is supine.

The heart itself is displaced upward and to the left as the diaphragm becomes progressively elevated from the growing pregnancy. This moves the apex of the heart laterally and increases the size of the cardiac silhouette on x-ray. Changes in heart sounds include the following [4, 6]:

1. Exaggerated splitting of the first heart sound with increased loudness of both components first heard between 12 and 20 weeks' gestation in 88 percent of pregnant women; best heard along the left sternal border between the third and fifth intercostal spaces.
2. A loud, easily heard third sound.
3. A short systolic murmur in 90 to 95 percent of pregnant women, which may be intensified during either inspiration or expiration; reflects the increased cardiovascular load; heard best along the left sternal border in the third intercostal space or along the lower left sternal border at the apex or aortic area.

4. A soft transient diastolic murmur in 20 percent of pregnant women.
5. Continuous murmurs arising from mammary vasculature in 10 to 14 percent of pregnant women.

Increased blood flow to the skin in pregnancy serves to dissipate excess heat generated by increased metabolism. It also enhances absorption of most transdermal and subcutaneous drugs (see Chapter 10, p. 258).

Renal Changes

There are a number of significant changes in the renal system during pregnancy that enable the mother not only to handle her own wastes and the excess brought about from the increases in blood volume and cardiac output as well as metabolic waste products but also to be the primary organ for the excretion of wastes from the fetus. In addition, the kidneys are critical in mediating sodium retention and water balance during pregnancy and maintaining arterial blood pressure through the renin-angiotensin system. All components of the renin-angiotension system produced from both maternal and fetal sources are increased in normal pregnancy, due in part to high levels of estrogen production.

Table 21-1 summarizes the changes in the renal system during pregnancy. Of particular note for midwives is the hydroureter and hydronephrosis that takes place during pregnancy. Hydroureter occurs as the uterus rises out of the pelvis into the abdomen and compresses the ureters as they cross the pelvic brim. This is more prominent on the right than on the left as the uterus dextrorotates as it comes out of the pelvis. With distention comes elongation and lateral displacement of the ureters. Hydronephrosis occurs in 80 to 90 percent of pregnant women. The increased size of the kidney and dilation of the pelves and calyces as well as the ureters all increase the risk of urinary tract infections due to urinary stasis [4, 6].

The usual daytime (diurnal) pattern of the nonpregnant woman reverses with pregnancy. The pregnant woman accumulates fluid (water and sodium) during the day in the form of dependent edema from the pressure of the uterus on the pelvic blood vessels and the inferior vena cava as discussed above and then excretes it as dilute urine at night (nocturia) via the kidneys when the woman is lying down, especially in a left lateral position.

Pulmonary Changes

It is the maternal respiratory system that delivers oxygen to and removes carbon dioxide from the fetus, and provides energy to the cells of the mother herself, the fetus, and the placenta. Factors affecting pulmonary changes include hormonal influences and mechanical changes.

Mechanical changes include the elevation of the resting position of the diaphragm by approximately 4 centimeters, an increase of 2 centimeters in the transverse diameter while the subcostal angle widens, the lower ribs flare, and the thoracic circumference increases approximately 6 centimeters [6]. These changes are all caused by the upward pressure of the enlarging uterus (see Figure 21-2). Hormonal influences include the effect of estrogen on capillary engorgement throughout the respiratory tract and the effects of progesterone on the relaxation of bronchiole smooth muscle and on the relaxation of the muscles and cartilage in the thoracic region [4].

The respiratory rate, vital capacity, and maximum breathing capacity are not affected during pregnancy but tidal volume, minute ventilatory volume, and minute oxygen uptake increase throughout pregnancy, and functional residual capacity and residual volume of air are decreased. The effect of this is physiological dyspnea or dyspnea of pregnancy, which is related to the increased tidal volume and resulting hyperventilation, and lower PCO_2. The lower PCO_2 puts the mother in respiratory alkalosis, which facilitates transfer of CO_2 from the fetus to the mother. A slight increase in blood pH facilitates the release of oxygen from the mother to the fetus [5, 6]. A 70 percent increase in alveolar ventilation related to the decreased residual volume increases particle uptake and diffusion of drugs in aerosols and bronchodilators (see Chapter 10, p. 258).

Gastrointestinal Changes

Changes in the gastrointestinal tract ensure the delivery of nutrients to meet the needs of both the mother and the fetus and are under both mechanical and hormonal influences. Of particular note for midwives is that many of these changes are responsible for a number of the discomforts of pregnancy.

Estrogen causes increased blood flow to the mouth, making the gums friable and thus contributing to gingivitis. This may also bring the mother's attention to the need for dental care, but not because of any loss of calcium to the fetus. The fetus obtains calcium from the mother's body

TABLE 21-1 Summary of Changes in the Renal System During Pregnancy

Parameter	Alteration	Significance
Renal calyces, pelvis, and ureters	Dilatation (more prominent on right) Elongation, decreased motility, and hypertonicity of ureters May last up to 3 months postpartum	Increased risk of urinary tract infection in pregnancy and postpartum Alter accuracy of 24-hour urine collections
Bladder	Decreased tone, increased capacity	Risk of infection Urinary frequency and incontinence Alteration in accuracy of 24-hour urine collections
	Displaced in late pregnancy Mucosa edematous and hyperemic Incompetence of vesicoureteral valve	Urinary frequency Risk of trauma and infection Risk of reflux and infection Alteration in accuracy of 24-hour urine collections
Renal blood flow	Increases 35–60%	Increased glomerular filtration rate Increased solutes delivered to kidney
Glomerular filtration rate	Increases 40–50%	Increased filtration and excretion of water and solutes Increased urine flow and volume Decreased serum blood urea nitrogen, creatinine, uric acid Altered renal excretion of drugs with risk of subtherapeutic blood and tissue levels
Renal tubular function	Increased reabsorption of solutes (may not always match increase in filtered load)	Maintenance of homeostasis Avoid pathological solute or fluid loss
	Increased renal excretion of glucose, protein, amino acids, urea, uric acid, water-soluble vitamins, calcium, hydrogen ions, phosphorous Net retention of sodium and water	Tendency for glycosuria, proteinuria Compensation for respiratory alkalosis Increased nutritional needs (i.e., calcium, water-soluble vitamins) Accumulation of sodium and water to meet maternal and fetal needs
Renin-angiotensin-aldosterone system	Increase in all components Resistance to pressor effects of angiotensin II	Maintain homeostasis with expanded extracellular volume Retention of water and sodium Balance forces favoring sodium excretion Maintain normal blood pressure
Arginine vasopressin and regulation of osmolarity	Retention of water	Expansion of plasma volume and other extracellular volume
	Osmostat reset	Maintenance of volume homeostasis in spite of reduction in plasma osmolarity

stores, not from her teeth. Saliva becomes more acidic but does not increase in volume [4].

The tone of the lower esophageal sphincter decreases under the influence of progesterone, causing smooth muscle relaxation. Displacement of the diaphragm and pressure from the enlarging uterus combine with loss of sphincter tone to cause reflux and heartburn. The action of progesterone on smooth muscles also causes hypotonicity of the stomach with decreased motility and prolonged emptying time. These same changes due to progesterone are true for the entire intestinal tract. The effects of progesterone become more pronounced as pregnancy advances and the progesterone levels increase. The effect of progesterone on the small intestine is to have more time for the absorption of nutrients, minerals, and drugs (see Chapter 10, p. 257). This absorption is also enhanced by hypertrophy of the duodenal villi, which increases their absorptive capacity [4]. The effect of progesterone on the large intestine contributes to constipation as the slow transit time allows for more water to be absorbed and to increased flatulence as the bowel is also displaced by the growing uterus. The appendix and liver are also displaced by the enlarging uterus. The appendix moves upward and laterally out of the lower-right quadrant and may reach as high as the right costal margin above the flank. Under the influence of estrogen on the gallbladder, there may be stasis of the bile salts (cholestasis of pregnancy), resulting in pruritus and icterus [6].

Maternal Psychological Adjustment and Processes

Pregnancy is a time of transition—spanning what life was like before having this child and what life will be like with this child. This radical change of status is considered a crisis with a defined period of time to work through the preparatory psychological processes that are normally present during pregnancy and culminate with the birth of the baby.

In general, the emotions of a pregnant woman are quite labile. She may have extreme reactions and rapidly changing mood shifts. Her emotional reactions and perceptions of the world may change. She is extremely sensitive and tends to overreact. A pregnant woman is far more open both to her internal self and to sharing her experience with others. She ruminates on her sleeping dreams, daydreams, fantasies, and the meanings of words, objects, events, and abstract concepts such as death, life, fertility, fulfillment, and happiness. She may identify with physical forms that signify childbearing or being filled with life or food.

The pregnant woman is extremely vulnerable. She fears death for both herself and her baby. She is frightened of the unknown because her body seems out of her control and her life is in the process of being changed irreversibly. This makes many women more dependent and some women more demanding. It is a time of heightened susceptibility to suggestion, as the woman searches for new support and direction in trying to imagine new role requirements, life changes that presently are vague and unknown, and what all this will mean to her.

Throughout pregnancy, there is a definable sequence of specific psychological processes that often seem to be interrelated with the biological changes taking place. These psychological events and processes are identifiable by trimester of gestation, and this division is used in the following discussion. Both the general psychological response to pregnancy just discussed and the following more specific psychological processes and events recur with each pregnancy for each woman.

First Trimester

The first trimester is often referred to as the period of adjustment. The adjustment the woman is making is to the fact that she is pregnant. The acceptance of this reality and all it means is the most important psychological task of the first trimester.

Most women are upset and ambivalent about being pregnant. Approximately 80 percent go through a period of disappointment, rejection, anxiety, depression, and unhappiness. It is doubtful that there is a single woman—even among those who have planned for and want the pregnancy or have struggled to become pregnant—who has not said to herself at least once that she wished she were not pregnant. This universality needs to be discussed with the woman, because she will tend to hide her ambivalent or negative feelings since they are in conflict with what she thinks she should be feeling. If she is not helped to understand and accept these ambivalent and negative feelings as normal for this period of pregnancy, she most likely will have overwhelming guilt feelings if the baby should subsequently either die or be deformed or abnormal. She will remember the thoughts she had during the first trimester and unless she accepts them may feel that she is the cause of any tragedy.

The woman's focus is on herself. From this self-concern arises much of her ambivalence about the pregnancy as she deals with any previous bad experience with pregnancy, the effect the pregnancy will have on her life (especially if she has a career), new or additional responsibilities she will have to assume, anxieties regarding her capability to be a mother, financial and housing concerns, and acceptance of the pregnancy by significant others. Ambivalence normally ends spontaneously as she accepts the pregnancy. This acceptance usually occurs by the end of the first trimester and is facilitated by her feeling safe enough to express the feelings that are creating conflict within her. In the meantime, some of the discomforts of the first trimester—nausea, fatigue, appetite changes, emotional irritability—may reflect her conflict and depression and at the same time serve as a reminder of her pregnancy.

Some women, especially those who planned their pregnancy or have struggled to become pregnant, are overjoyed, with an element of disbelief, and seek every shred of bodily evidence of indeed being pregnant. The first trimester is often an anxious time of waiting for the pregnancy to be "well established." This is particularly true for women who have had previous miscarriages and for female health care professionals who worry about miscarriages and teratogens. These women impatiently await the end of the first trimester as a milestone after which they can relax and believe in their pregnancy. Some couples choose to not tell others about their pregnancy until after the first trimester, thus avoiding the pain of having to tell others if a miscarriage occurs. Other couples choose to share their joy and excitement as soon as they know and consider they already have a support system in place if there is a miscarriage.

Weight has particular significance to the pregnant woman during the first trimester. It may become a part of the reality testing the woman is doing, as she looks to her body for tangible evidence of being pregnant. For many women, early weight gain may be seen as proof that the baby is growing, even though the baby is not yet physically evident. The woman sees gaining weight as being within her control and contributing to the growth of her abdomen, which means being pregnant to her. Conversely, women who are pregnant and trying to hide it (e.g., some unwed adolescents) may starve themselves to prevent "showing" while trying to cope with and make decisions to resolve some of their problems.

Validation of the pregnancy is done over and over as the woman scrutinizes any bodily change for evidence of the pregnancy. The most evident is the cessation of menses. Breast changes are repeatedly studied. This makes your sharing of pelvic findings, especially those indicative of pregnancy, very important. The woman may repeatedly examine a picture from an early ultrasound. During the first trimester, her pregnancy is her own secret to share with whomever she chooses. Her thoughts relate largely to what is happening to her, her body, her life. At this point the baby is not yet perceived as a separate being.

Women vary widely in their sexual desire during the first trimester. Although some women experience an increase in desire, generally speaking the first trimester is a time of decreased libido, and this creates the need for open and honest communication with partners. Many women feel a need for much love and loving without sex. Libido is heavily influenced by fatigue, nausea, depression, sore and enlarged breasts, worries, anxieties, and concerns—all of which may be a normal part of the first trimester.

Second Trimester

The second trimester is often referred to as the period of radiant health, a time during which the woman generally feels good and is largely free from the normal discomforts of pregnancy. However, it is also the most regressed and inward phase of pregnancy. The second trimester actually subdivides into two phases: prequickening and postquickening. Quickening heralds the fact of a separate life, thereby adding impetus to the woman's primary psychological task of the second trimester—developing her own mothering identity, distinct from that of her own mother.

Toward the end of the first trimester and during the prequickening portion of the second trimester, the woman undergoes a complete reliving and reevaluation of all aspects of her relationship with her own mother. The woman scrutinizes the total range of these feelings and relives the basis for them. All the interpersonal problems the woman and her mother may have had or may still have are analyzed. The potential that interpersonal problems can exist in the mother-child relationship is examined. With this examination comes understanding and acceptance of the qualities in her own mother that she values and respects. The other qualities of her mother, those that are negative or unwanted or do not engender respect, are rejected. This may

cause guilt and inner conflict unless the woman comes to understand the normality of this process and that rejection of specific qualities of her mother in developing her own mothering identity is not equivalent to rejection of her mother as a person.

Included in this process is the evolution of the woman from being a care receiver (from her mother) to being a caregiver (preparatory to being a mother). She may experience conflict over competing with her mother to be seen as a "good" mother. The actual resolution of all this does not occur until long after the baby is born, but the pregnant woman's preoccupation with her own mother and related processes diminishes as the transfer to her own identity as a caregiver is made. At the same time she is being a receiver, demanding attention and love which, in effect, she is storing for her baby in her role as caregiver.

With quickening comes a number of changes, as the pregnancy is unquestionably verified in the woman's mind. Her social contacts increasingly become other pregnant women or brand new mothers, and her interests and activities focus on pregnancy, childbearing, and preparation for a new role. This social shift creates the need for a certain amount of grief work, which in turn serves as a catalyst for assumption of her new role. The grief involves letting go of former relationships, attachments, and significant aspects and events of her former role that will be affected by the forthcoming baby and new role. This does not mean discarding all these relationships and ties but does involve a change in them. Sometimes a pregnant woman is in a work setting where no one understands being pregnant or her social contacts either are not pregnant or have older children and they have moved on to different concerns. In such circumstances, she may have difficulty finding other pregnant women to talk with and compare physical changes. Taking advantage of opportunities such as joining a pregnancy exercise class may give her the social contact with other pregnant women that she seeks. For a multipara, this includes a certain disengagement from established ties with her other children as she prepares her home and family for the changes a new baby will create. Much of the woman's new or changed role is tried out, developed, and refined in fantasy, imagination, and daydreaming.

Quickening enables the woman to conceptualize her baby as an individual separate from herself. This new awareness starts a change in her focus from herself to the baby. Frequently this change is manifested by dreams that someone else, usually a stranger, is being injured. These dreams generally are interpreted as expressing the mother's concern about harm to her baby. At this point, the sex of the baby is unimportant. The concern is for the baby's well-being and welcome into the family group.

Most women feel more erotic during the second trimester; approximately 80 percent of pregnant women experience a significant improvement in their sexual relationships as compared with both their first trimester and before pregnancy. The second trimester is relatively free of physical discomforts; the size of the woman's abdomen is not yet an insurmountable problem; vaginal lubrication is greater; the related anxieties, worries, and concerns causing the woman's previous ambivalence and depression have subsided; and she has shifted from seeking caretaking from her mother to seeking caretaking from her partner—all these factors contribute to an increase in libido and sexual satisfaction.

Third Trimester

The third trimester is often referred to as the period of watchful waiting. Now that the woman is aware of the baby's presence as a separate being, she becomes impatient for the baby's arrival. There is an uneasy sense that the baby could arrive at any time, a fact that places the woman on edge as she watches and waits for the signs and symptoms of labor.

The third trimester is a time of active, visible preparation for childbirth and parenthood as the woman's attention focuses on the forthcoming baby. Both fetal movement and the size of the enlarging uterus are constant reminders of the baby. People around her are now making plans for the baby and may give a baby shower. She becomes protective of the baby, avoiding crowds or anyone or anything she perceives as dangerous. She fantasizes that danger lurks in the outside world. The choosing of names for the baby is a preparatory activity for the baby's arrival. She may attend classes in preparation for childbirth and parenthood. Layettes are made or bought. Rooms are rearranged. Much thought is given to care of the baby. There is much speculation as to the baby's looks and sex.

A number of fears surface during the third trimester. The woman may fear for her own and the baby's lives; that she will have an abnormal baby; labor and delivery (pain, loss of control, the unknown); that she will not know when she is in labor; that the baby will not be able to emerge since

her abdomen is already unbelievably large; or that her own vital organs will be injured by the baby's kicking. Her dreams reflect her interests and her fears. She dreams mostly about babies, children, delivery, losing a baby, or being trapped in a small place and unable to squeeze out. She keeps busy so that she will not think of what frightens her and of all the unknowns.

She also undergoes another grief process as she anticipates the loss of attention and special prerogatives of being pregnant, the inevitable separation of her baby from her body, and the feeling of loss as her full uterus becomes a collapsed and empty vessel. Slight depression is not uncommon, and there may be further increased dependency and introversion, with a feeling of vulnerability.

Once again the woman experiences physical discomfort, which increases as the end of pregnancy nears. She may feel awkward, ugly, and sloppy, and need large and frequent doses of reassurance from her partner. By the middle of the third trimester, the heightened sexuality of the second trimester diminishes as her abdomen becomes an obstacle. Alternative positions for sexual intercourse and alternative methods of achieving sexual satisfaction may help—or may create guilt if she is not comfortable with them. The honest sharing of feelings between the couple and in their consultation with you is essential.

Fetal Growth and Development

The processes that make possible the beginning and early development of a human being involve entire fields of study. Included are the subjects of genetics, gamete maturation (spermatogenesis and oogenesis), ovum and sperm transport, sperm capacitation and acrosome reaction, fertilization, cellular division (specifically meiotic and mitotic), zygote changes and transport during the first week of life, implantation, embryology (which covers roughly the period of life from the second through the seventh week of life postfertilization), fetology (which covers from the eighth week of life after fertilization to birth), and congenital malformations and abnormalities. It is beyond the scope of this book to discuss these topics in any detail. Students interested in these subjects are encouraged to explore textbooks and courses relevant to their interests. This book zeros in on the minimal knowledge needed by the practicing midwife in the area of fetal growth and development. Basically, this includes an appreciation of the intricate and vulnerable stages of cellular differentiation, reorganization, division, and proliferation and structural beginnings occurring during the embryonic period; an ability to describe for the mother-to-be what her baby looks like during each month of the fetal period; and an understanding of the causes of congenital malformations.

First Trimester

The entire zygotic and embryonic period and the first 2 weeks of the fetal period (a total of 10 weeks of life after fertilization) are within the first 12 weeks of pregnancy (counting from the last normal menstrual period), which constitute the first trimester.

Figure 21-3 is a summary by days and weeks of the events in fetal growth and development that occur during the first trimester. The summary ends with the tenth week of age, which is equivalent with the twelfth week of gestation as calculated from the LMP. It is important to make this correlation and to check when reading other sources of literature whether they are dating fetal development from the LMP or from the assumed time of fertilization 2 weeks later. Otherwise you may be 2 weeks off in your understanding of what is happening.

Growth and development begin with the moment of fertilization and the fusing of the female and male pronuclei from the ovum and sperm, respectively. This fusion produces a single cell called a zygote. At this moment a new individual is created, with his or her own unique makeup as determined by this totally new combination of chromosomes and genes. This unique combination results because the pronucleus of each gamete, or sex cell (i.e., ovum and sperm), contains only half (23, or the haploid number) of the total number (46, or the diploid number) of chromosomes in a human being. This halving of the chromosome number is a result of gametogenesis, the process by which mature ova and sperm are developed. At the moment of fertilization, the fusion of the pronuclei of the two gametes restores the diploid number of chromosomes, which is subsequently reflected through mitotic cellular division in every cell in an individual's body except those that later undergo gametogenesis. Also determined at the moment of fertilization, as a result of this fusion and restoration of the diploid number, is the sex of this new individual. Sex is determined by the male gamete, which carries either an X or a Y chromosome. The female gamete

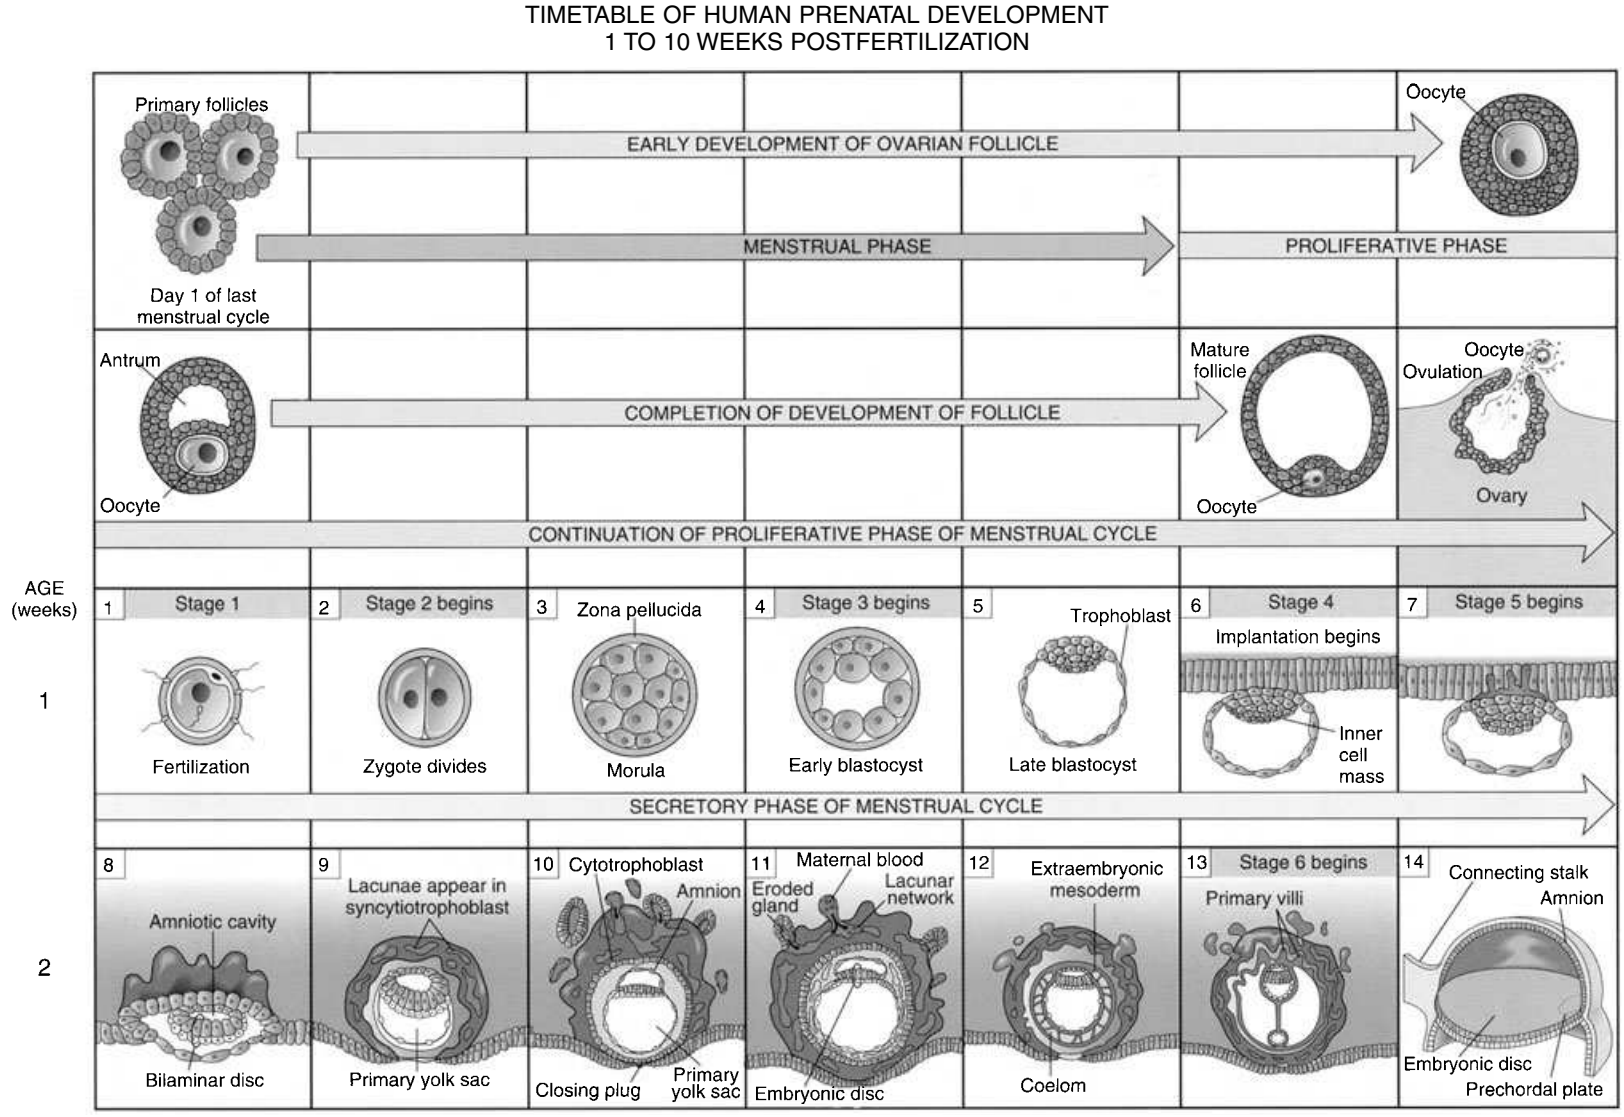

FIGURE 21-3 Early stages of development. Development of an ovarian follicle containing an oocyte, ovulation, and the phases of the menstrual cycle are illustrated. Human development begins at fertilization, about 14 days after the onset of the last menstruation. Cleavage of the zygote in the uterine tube, implantation of the blastocyst, and early development of the embryo are also shown. Beginning students should make no attempt to memorize these tables or the stages (e.g., that Stage 3 begins on day 4 and Stage 5 on day 7).

Note that the dating by weeks is based on fertilization so that the figure is 12 weeks based on the last menstrual period (LMP). The figure assumes fertilization occurs on day 14 of the menstrual cycle. Calendar months would be as follows on this figure: days 16/17 (30/31 by LMP) ends the first calendar month; days 46/47 (60/61 by LMP) ends the second calendar month; and day 77 (91/92 by LMP) would be just beginning the second trimester and ending the third calendar month. The figure actually ends at 12 weeks by LMP (10 weeks postfertilization) or three lunar (28 day) months.

carries only an X chromosome. With fusion, an XX combination normally develops into a female and an XY combination normally develops into a male.

Immediately following fertilization, the resulting zygote begins to undergo mitotic cellular division, called cleavage. Through sequential stages, the dividing cellular mass is called a morula; with cellular reorganization and the entry of fluid, the morula becomes a blastocyst. It is the blastocyst that implants in the uterine lining. By the time the process of implantation is completed on the tenth or eleventh day after fertilization, the embryonic period has begun.

At the time of implantation, the embryo is known as a bilaminar embryo because the embryonic disc arising from the inner cell mass consists of two layers of cells: (1) the epiblast, a thick layer of high columnar cells that form the floor of the amniotic cavity and eventually become the embryonic ectoderm, mesoderm, and endoderm, and (2) the hypoblast, a thin layer of small cuboidal cells that comprise the primary endoderm of the yolk sac (see Figure 21-3, postfertilization week 2, day 8) [7].

The beginning of the third postfertilization week marks the start of morphogenesis—the development of body form. This is accomplished through gastrulation, a process by which the bilaminar embryonic disc is converted into a trilaminar embryonic disc. The primitive streak forms on the surface of the epiblast and is the growth center for the embryo for approximately 2 weeks, after which it becomes insignificant and eventually disintegrates. The trilaminar embryonic disc gives rise to the three germ layers: (1) endoderm, (2) mesoderm, and (3) ectoderm [7].

Figure 21-4 specifies what each germ layer is responsible for in the makeup of the body. Toward the end of the third week, somite development begins, which will ultimately result in 42 to 44 pairs of somites. Arising from the mesoderm, the somites are responsible for most of the skeleton of the head and trunk, its related musculature, and much of the adjacent dermis of the skin [7]. The somites are useful in dating early embryos that are recovered up to approximately 30 days after fertilization. During the third week, the neural tube (rudiment of the brain and spinal cord), notochord (rudiment of the vertebrae), coelomic spaces (rudiments of the body cavities), primitive blood cells, and a primordial cardiovascular system develop.

The heart starts to beat at the beginning of the fourth postfertilization week (sixth week by LMP). It is during the fourth week that rapid growth causes both longitudinal and transverse folding of the embryonic disc. Longitudinal folding, involving a head fold and a tail fold, converts the embryo from a straight form to a curved form. Transverse folding, involving right and left transverse folds folding toward the midline, converts the embryo from a flat form to a cylindrical form. By the end of the fourth week, the embryo has assumed what is often called the salamander look and has the rudiments of ears (otic pit), arms (arm buds), legs (leg buds), and facial and neck structures (the first four branchial arches).

During the fifth postfertilization week, rapid development of the brain results in extensive growth of the head and makes it much larger in relation to the rest of the body. Development is cephalic to caudal, with the legs developing almost a week later than the arms. The eyes begin development with lens placodes (visible in the fourth week), optic cups, and retinal pigment.

The nose, mouth, and palate begin to take form during the sixth week postfertilization (eighth week by LMP) and the eye becomes visible. Arms and legs undergo extensive development and digital rays (primordial fingers) begin to develop in the hand plates. The head is much larger than the trunk.

The seventh postfertilization week marks further development of the limbs with digital rays (primordial toes) developing in the foot plates. The eyelids are formed and visible, and the auricles of the external ears are formed and visible although not yet fully developed or elevated to their proper position. The intestines are herniated into the proximal portion of the umbilical cord where there is room for them.

By the end of the eighth postfertilization week (tenth week by LMP), the embryo has human features even though the head is still disproportionately large and almost half of the total size. The limbs, especially the upper limbs, have well-differentiated regions (e.g., wrist, elbow, knee) and increased length. Ossification of bones has begun, and the neck region is established. Urogenital development has begun but differentiation is too early to ascertain the sex.

The end of the eighth postfertilization week also marks the end of the embryonic period. All essential internal and external structures are present and are undergoing further elaboration and growth, including the replacement of cartilage with bone cells. The embryonic period obviously is a critical time during which any teratogen (e.g., drugs, x-rays, viruses) may either be lethal or cause major congenital malformations (see Figure 21-5).

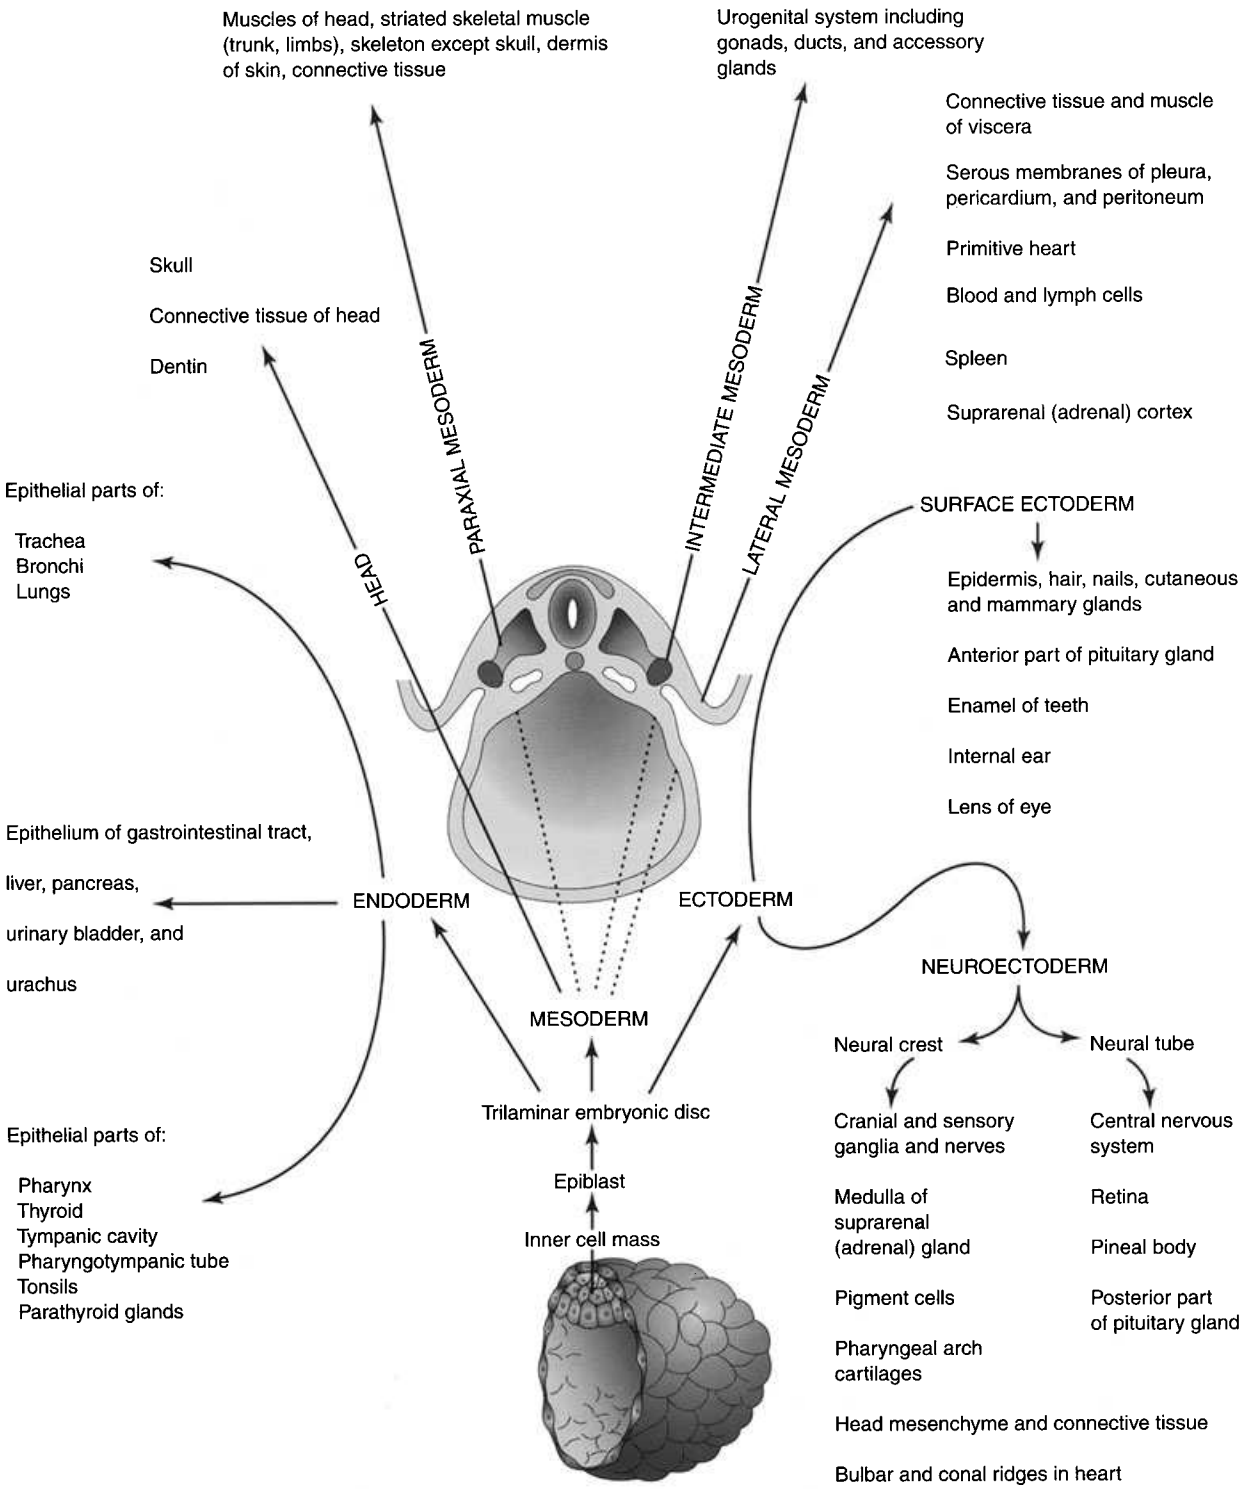

FIGURE 21-4 Schematic drawing illustrating the derivatives of the three germ layers: ectoderm, endoderm, and mesoderm. Cells from these layers make contributions to the formation of different tissues and organs; for example, the endoderm forms the epithelial lining of the gastrointestinal tract and the mesoderm gives rise to connective tissues and muscles.

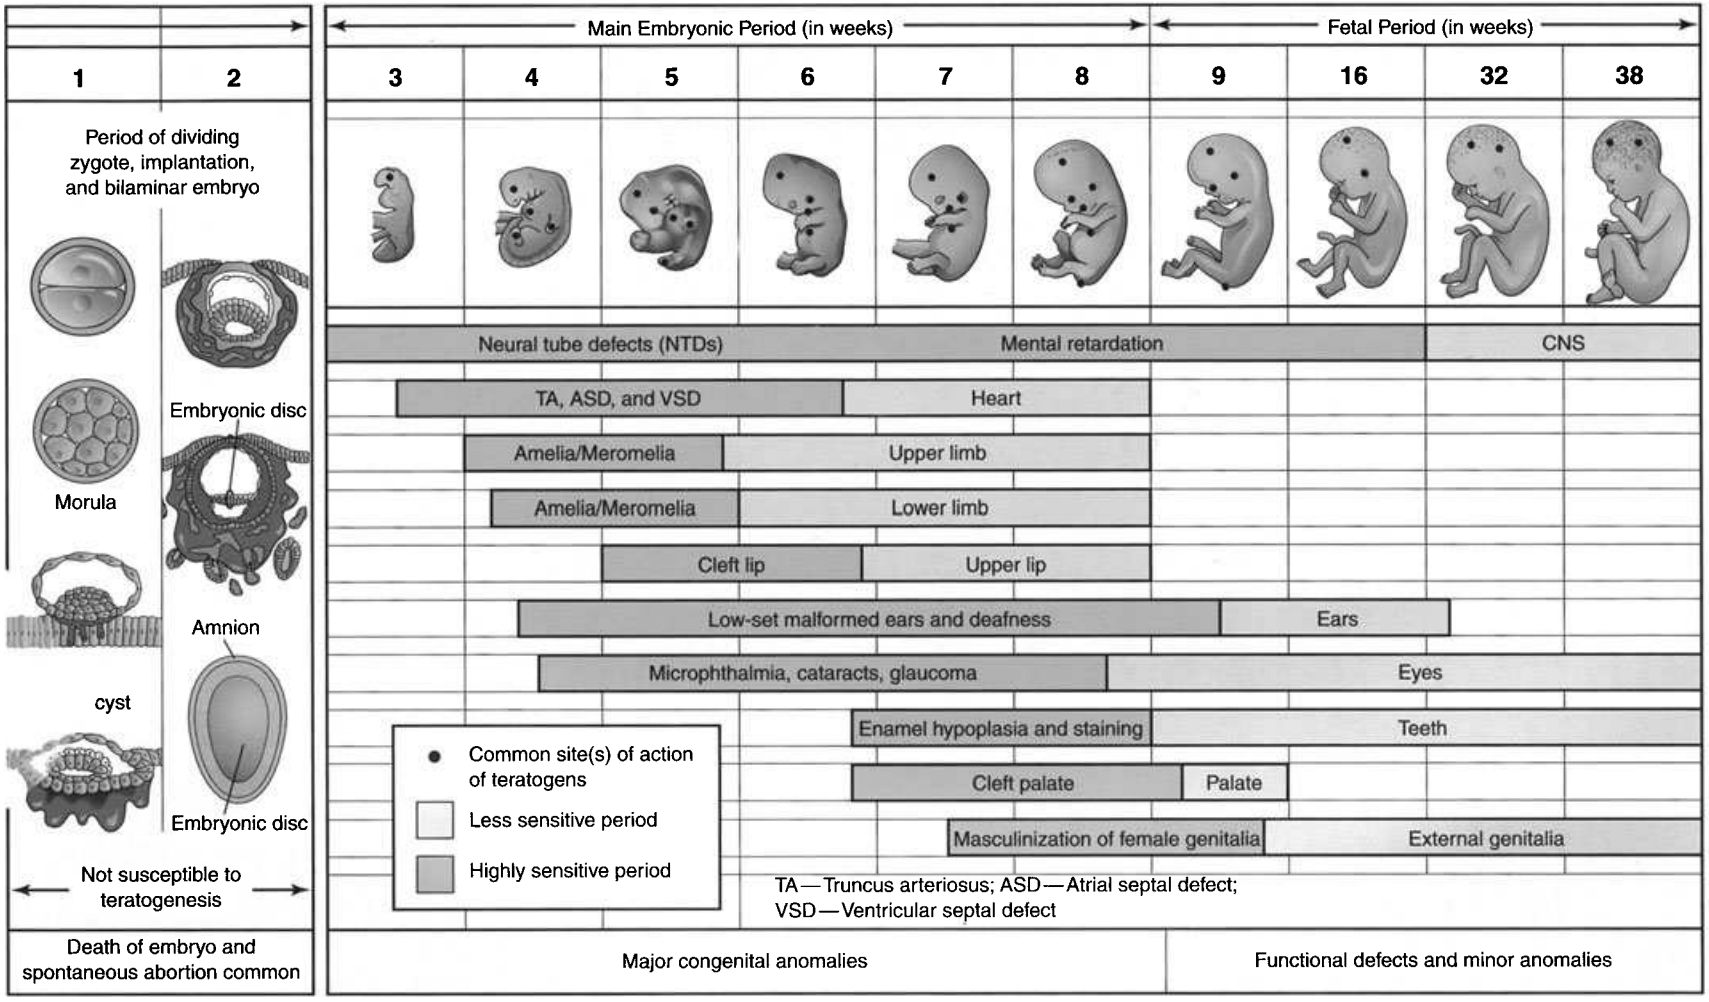

FIGURE 21-5 Schematic illustration of critical periods in human prenatal development. During the first 2 weeks of development, the embryo is usually not susceptible to teratogens; a teratogen either damages all or most of the cells, resulting in death of the embryo, or damages only a few cells, allowing the conceptus to recover and the embryo to develop without birth defects. Darker areas denote highly sensitive periods when major defects may be produced (e.g., amelia, absence of limbs). Lighter areas indicate stages that are less sensitive to teratogens when minor defects may be induced (e.g., hypoplastic thumbs).

The first trimester of pregnancy also includes the first 2 weeks of the fetal period. By the end of the tenth postfertilization week, or the twelfth gestational week calculated from the LMP, the intestines are fully into the abdomen and out of the umbilical cord, the external genitalia have male or female characteristics (though they are not yet fully formed), the anus has formed, and the facial characteristics of the fetus now look undeniably human. The fetus, now weighing approximately 0.5 to 1 ounce, can swallow, make respiratory movements, urinate, move the specific parts of the limbs, squint and frown. The mouth opens and shuts. The head is about a third of the crown-rump length, which is approximately 56 to 61 millimeters (2.2–2.4 inches).

Second and Third Trimesters

The second trimester, 15 weeks long, includes weeks 13 through 27 by gestational age based on the LMP. This is equivalent to weeks 11 through 25 by postfertilization age. The third trimester, of 13 weeks, includes weeks 28 through 40 by gestational age based on the LMP. This is equivalent to weeks 26 through 38 by postfertilization age. *Ages referred to in the following discussion are gestational ages based on the LMP*. The crown-rump lengths are given solely for the purpose of providing you with a general idea of the size of the fetus, information that may be helpful when talking with pregnant women. These measurements should not be confused with the more specific crown-rump ultrasound measurements done for dating up to the twelfth week by LMP.

Weeks 13 to 16 (Fourth Lunar Month) The eyelids are fused and head growth slows, while the ears move to a higher elevation on the sides of the head and the chin becomes evident with development of the mandible. Body growth accelerates, with the legs again growing more slowly than the arms, as the cephalic to caudal direction of growth continues. The arms but not the legs have reached their full length. Fingernails have started to develop but the toenails have not. Reflex response and muscular activity begin, although the mother cannot feel the movement because her uterus is too thick and the activity is too slight. Sex is clearly distinguishable during the fourteenth week (twelfth week after fertilization). By the sixteenth week there has been rapid progress in bone development. Centers of ossification of the skeleton are sufficiently established that they could be seen with roentgenography. The average crown-rump length is 4.5 inches and the fetus weighs between 3.5 and 4 ounces by the end of the sixteenth week.

Weeks 17 to 20 (Fifth Lunar Month) Rapid body growth continues. The legs reach their total length and toenails develop. The eyelids remain fused. The fetus moves freely in the uterus, without the confinement that later growth imposes. Stronger fetal movement and a thinner uterine wall result in the mother's experiencing quickening around the eighteenth week. When the fetus hiccups, the mother may feel this as a rhythmic series of slight jerks or jolts. By the end of the month, vernix caseosa covers the entire body. Vernix caseosa, a mixture of sebum (secretion from the sebaceous glands) and surface epithelial cells, is a thick, cheesy substance that protects the delicate skin of the fetus. The fetal heart may be heard with a fetoscope by the end of the month. By the end of the twentieth week, the average crown-rump length of the fetus is about 6.5 inches and the average weight is almost 1 pound or 500 grams.

Weeks 21 to 24 (Sixth Lunar Month) Hair growth is prominent during the sixth lunar month. The fetus is completely covered with lanugo, a fine downy hair. Eyebrows, eyelashes, and head hair are present. The head remains large compared to the rest of the body. The skin is wrinkled, translucent, and red, giving an aged appearance to the fetus, which is also thin and lean because of a lack of subcutaneous fat. Both capillary blood and the red myohemoglobin of the muscles show through the skin. Buds for the permanent teeth are present. The fetus still has room in the uterus to somersault and can make the motions of crying and sucking. The hands make fists and also grip. Brown fat, which is a source of energy, heat production, and heat regulation in the newborn, forms. By the end of the month, the average crown-rump length of the fetus is just over 8 inches and the weight is approximately 1.25 pounds.

Weeks 25 to 28 (Seventh Lunar Month) Although a little fat storage begins and the contours start to round out, the fetus still is lean and continues to look old and wrinkled during this month. A substantial weight gain makes the body better proportioned by the end of the month. Surfactant begins to

be produced in the lungs by 26 weeks. The hair on the head is longer, the sucking motions are stronger, the eyes begin to open and shut, and fingernails are present. The average crown-rump length of the fetus is approximately 9 inches and the weight is about 2.25 pounds (1000 grams) by the end of the twenty-eighth week.

Weeks 29 to 32 (Eighth Lunar Month) Subcutaneous fat deposits begin to smooth out some of the wrinkles, but the fetus has not totally lost its wrinkled, old appearance. The body is filling out and is not quite so lean. Thick vernix caseosa covers the entire fetus. The hair on the head continues to grow, and the lanugo is plentiful except on the face, from which it has now disappeared. Fingernails reach the ends of the fingers; toenails are present but do not reach the ends of the toes. The fetus has control of rhythmic breathing motions and body temperature. The eyes are open and the pupillary light reflex is present by the end of the month. The average crown-rump length is about 11 inches and weight is approximately 3.75 pounds.

Weeks 33 to 36 (Ninth Lunar Month) By the end of this month, the skin is smooth, without wrinkles, as the subcutaneous fat becomes thicker from additional deposits. The body is rounder, with the arms and legs taking on a somewhat chubby appearance. The hair is longer, the toenails have reached the ends of the toes, and the left testicle has usually descended into the scrotum. The average crown-rump length is a little over 12.5 inches and the weight is approximately 5.5 pounds (2500 grams) during the thirty-sixth week.

Weeks 37 to 40 (Tenth Lunar Month) The tenth lunar month provides the necessary finishing touches. Full growth and development are attained. The fetus is now well rounded with a prominent chest and protuberant mammary glands in both sexes. Both testes are in the scrotum by the end of the month. The lanugo has disappeared from most of the body. The nails project beyond the ends of both the fingers and the toes. The skin varies in color from white to pink to bluish-pink, regardless of race, because the melanin that colors the skin is produced only after exposure to light. The crown-rump length now averages 14 inches. The weight depends on a number of variables but averages 7.5 pounds.

Placental Development, Circulation, and Functions

Development and Circulation

The placenta is partly fetal and partly maternal in origin. The fetal contribution derives from the chorion; the maternal contribution derives from the decidua (endometrium) at the site of implantation.

The outer layer of cells forming the wall of the blastocyst is called the trophoblast. As the trophoblast begins to invade the epithelium of the endometrium, it differentiates into two layers: (1) cytotrophoblast, which is the inner layer, and (2) syncytiotrophoblast, which is the outer layer. This differentiation occurs as the trophoblast comes into contact with the endometrium.

The syncytiotrophoblast is a multinucleated protoplasmic mass without intercellular boundaries. From this mass emerge fingerlike projections, which penetrate through the endometrial epithelium into the endometrial stroma (see Figure 21-6). The endometrial stroma contains both glands and capillaries. Lacunae, or hollow spaces, form around the eighth day in the syncytiotrophoblast as it invades the stroma. As a result, the endometrial glands are eroded, and the capillaries rupture to fill

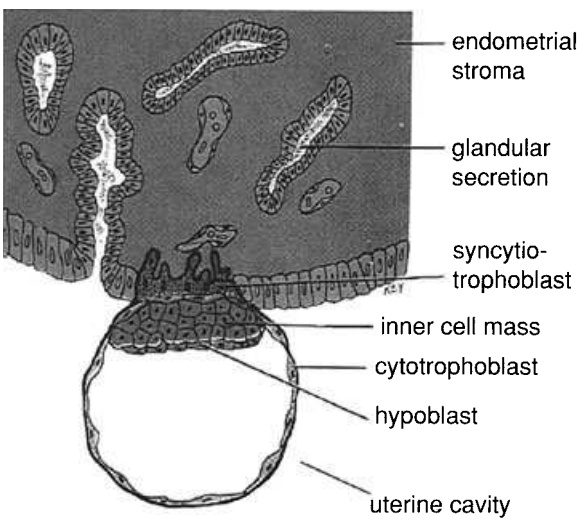

FIGURE 21-6 Early stage of implantation. The syncytiotrophoblast has penetrated the endometrial epithelium and has started to invade the endometrial stroma.

the lacunae with embryotroph. Embryotroph is a mixture of glandular secretions and maternal blood, which is nutritive to the embryo and reaches it by diffusion from the syncytiotrophoblast. It is also through the lacunae that hCG produced by the syncytiotrophoblast enters the maternal bloodstream where it can be detected by pregnancy tests.

After the embryo is completely imbedded in the endometrium, around the twelfth day after fertilization, the lacunae in the syncytiotrophoblast join together to form intercommunicating lacunar networks. These give the syncytiotrophoblast a spongelike structure. At the same time, the endometrium undergoes what is called the decidual reaction, in which the stromal cells enlarge with an accumulation of glycogen and lipid and become known as the decidual cells, and the capillaries become dilated and congested to form sinusoids. Erosion of these sinusoids by the trophoblast fills the lacunar networks with maternal blood and establishes a primitive circulatory system.

Decidua is the name for the uterine endometrium during pregnancy. It differs from the nonpregnant endometrium because of the decidual reaction, whereby, with the exception of the zona basalis, the decidua is shed after birth. The name comes from the Latin word *deciduus*, meaning "a falling off." As Moore points out, the shedding of the decidua is akin to the falling of leaves from deciduous trees in the autumn [7]. There are three areas of decidua:

1. *Decidua basalis:* the decidua beneath the site of implantation of the embryo, which becomes the maternal contribution to the placenta.
2. *Decidua capsularis:* the decidua surrounding the remainder of the embryo, which serves as a covering between the embryo and the uterine cavity. With fetal growth, the decidua capsularis bulges into the uterine cavity and fuses with the decidua parietalis. The uterine cavity is thus obliterated. This occurs by the end of the fourth lunar month of gestation.
3. *Decidua parietalis* (also called the *decidua vera*): the decidua lining the rest of the uterus.

The decidua basalis and decidua parietalis consist of three layers:

1. *Zona compacta:* the surface layer, which is compact in structure.
2. *Zona spongiosa:* the middle layer, which is spongy in structure because of the decidual cells and capillaries.
3. *Zona basalis:* the bottom or base layer, which remains to regenerate a new endometrium when the rest of the decidua is shed postpartally.

Around the fourteenth day after fertilization, chorionic villi begin to form when cytotrophoblastic cells reorganize into columns of cells extending into the core of the syncytiotrophoblast. These are known as the primary villi and form around the outer surface of the embryonic sac. Shortly thereafter, these villi branch and develop central cores of mesenchyme; at this point they are called secondary villi. The mesenchymal cells develop into blood vessels within the villi that connect with the blood vessels of the chorionic sac, also arising from the mesenchyme, and thus with the embryo via the forerunner of the umbilical cord, the connecting stalk. The villi are now called true villi or tertiary villi. Cytotrophoblastic cells at the end of the villi proliferate and extend still further into and through the syncytiotrophoblast into the endometrial stroma to firmly attach and anchor the embryonic or chorionic sac to the decidua.

Until approximately the eighth week after fertilization, the villi cover the surface of the entire chorionic sac. After that, as the sac grows, the blood supply in the area of the decidua capsularis diminishes, causing the villi in the area of the decidua capsularis to degenerate. The result is a denuded chorionic sac called the chorionic laeve or smooth chorion. At the same time, the villi in the area of the decidua basalis proliferate, branch, and enlarge in the rich blood supply there. This results in a multiple treelike or tufted structure called the chorionic frondosum or villous chorion. The chorionic frondosum is the fetal contribution to the placenta.

As the chorionic villi invade and attach to the decidua basalis, remnants of the decidua covered with trophoblast form the placental septa (see Figure 21-7). The placental septa separate, incompletely, the irregular-shaped placental cotyledons. Each placental cotyledon consists of the main stem of a chorionic villus and all its numerous branches and infinite further subbranches. There are between 15 and 30 cotyledons. The septa restrict the exchange of blood between the cotyledons in the intervillous space. This means that infarcting or pathology in one cotyledon remains a localized problem (see again Figure 21-7).

The intervillous space is an elaboration of the earlier lacunar networks. The spaces of the lacunar

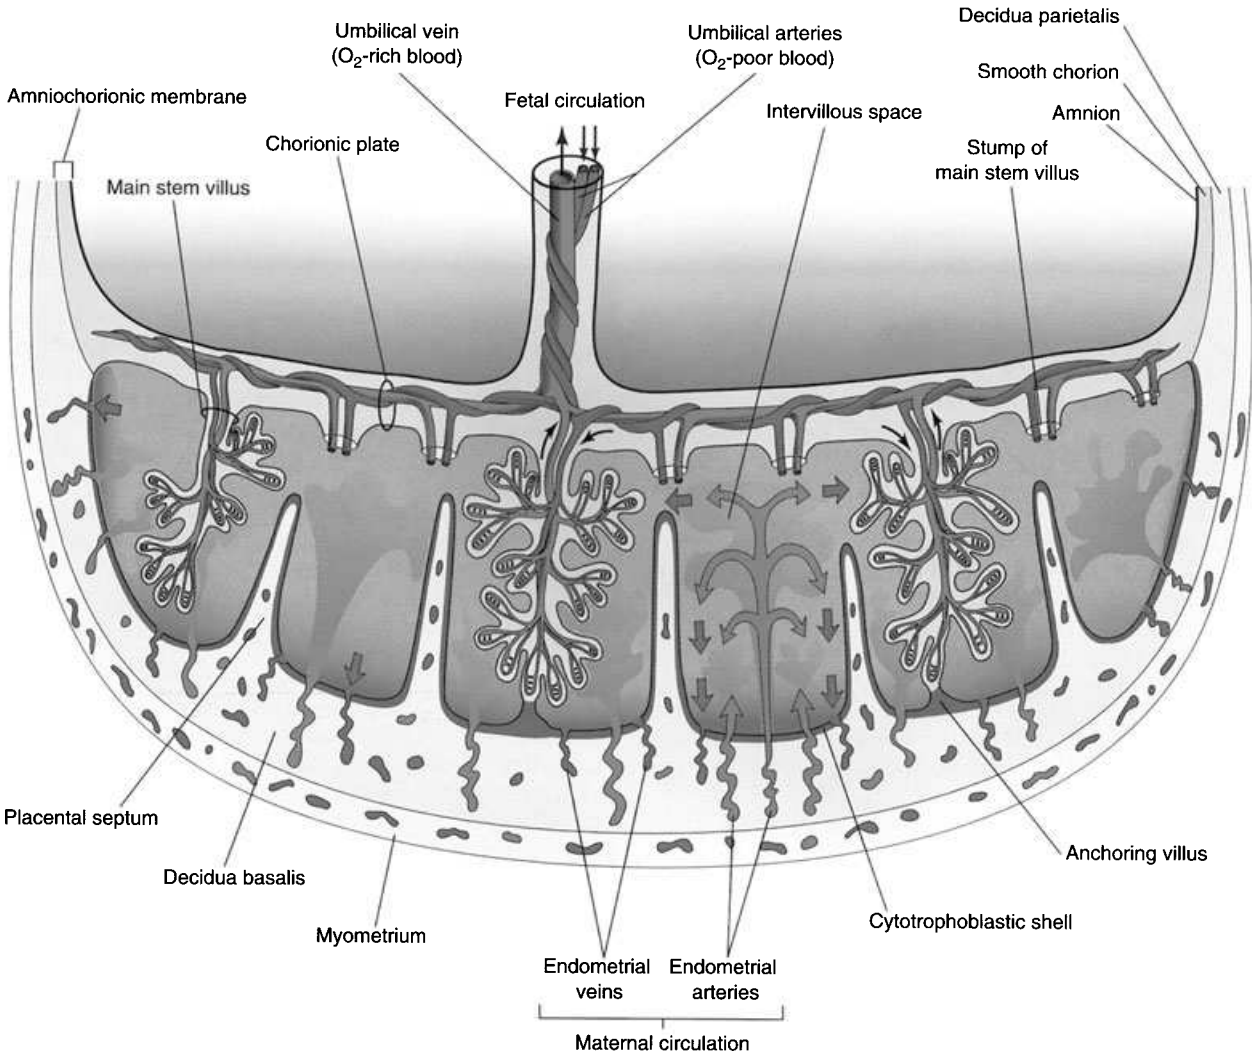

FIGURE 21-7 Schematic drawing of a transverse section through a full-term placenta, showing: (1) the relation of the villous chorion (fetal part of placenta) to the decidua basalis (maternal part of placenta), (2) the fetal placental circulation, and (3) the maternal placental circulation. Maternal blood flows into the intervillous spaces in funnel-shaped spurts from the spiral arteries, and exchanges occur with the fetal blood as the maternal blood flows around the branch villi. It is through the branch villi that the main exchange of material between the mother and embryo/fetus occurs. The inflowing arterial blood pushes venous blood out of the intervillous space into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note that the umbilical arteries carry poorly oxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. Note that the cotyledons are separated from each other by placental septa, projections of the decidua basalis. Each cotyledon consists of two or more main stem villi and their many branches. In this drawing, only one stem villus is shown in each cotyledon, but the stumps of those that have been removed are indicated.

networks enlarge with further invasion of the decidua by the trophoblast to form one large blood sinus called the intervillous space. Located between the chorionic plate on one side and the decidua basalis on the other, the intervillous space is incompletely partitioned by the placental septa that extend from the decidua but do not reach the chorionic plate. The chorionic plate consists of trophoblast externally (next to the intervillous space) and mesoderm internally. The internal mesoderm of the chorion fuses with the amnion at about the end of the first trimester. Together the amnion and chorion constitute the fetal membranes, which enclose and contain the fetus and the amniotic fluid.

Branches of the umbilical arteries and the umbilical vein run between the internal and external layers of the chorionic plate before they enter the chorionic villi that extend into the intervillous space.

Placental circulation, thus, consists of two separate circulations—fetal and maternal—with a large area for exchange of materials between the two circulations as determined by the placental membrane. The placental membrane is composed of the layers of extrafetal tissue between the circulating fetal and maternal blood. These layers are trophoblast (primarily syncytiotrophoblast), connective tissue in the chorionic villi, and the endothelium of the fetal capillaries. The placental membrane has been misnomered as the placental barrier, although most substances, including drugs, can be detected as having passed through the placental membrane. Regardless of how thin this membrane becomes as the placenta matures, neither the functions of the placental membrane nor the effectiveness of these functions changes.

Fetal circulation to the placenta comes from the two umbilical arteries, through which deoxygenated blood leaves the fetus. These arteries subdivide and branch in the chorionic plate and enter the chorionic villi, where further subdivision occurs within the branching villi to form an extensive capillary-venous network at the terminal divisions. At this point placental transfer occurs; that is, the transfer of materials between the fetal and maternal circulations takes place across the placental membrane. The return circulation to the fetus is by way of the branching of the umbilical vein, which corresponds with the branching of the umbilical arteries, to the chorionic plate and then, with further converging, into the umbilical vein through which the oxygenated blood is carried to the fetus (see Figure 21-7).

Maternal circulation in the placenta is actually outside of the maternal circulatory system. Oxygenated blood enters the intervillous space by way of spiral arteries of the endometrium; deoxygenated blood exits from the intervillous space by way of venous openings into the endometrial veins. The arterial entrances and venous exits supplying each cotyledon are randomly scattered throughout the placenta. Although different authors have cited various numbers, there may be as many as 120 spiral artery entrances into the intervillous space of the mature placenta. The blood enters the intervillous space from the spiral artery under tremendous pressure, as dictated by the maternal blood pressure. This results in a rhythmic spurting of a fountain of blood into and across the intervillous space to the chorionic plate. The blood is then dispersed laterally by this boundary and flows over the surfaces of the multitudinous branches of the chorionic villi. This flow is slow enough to allow for the exchange of materials between the fetal and maternal circulations across the placental membrane. Eventually, the now deoxygenated maternal blood exits through the venous portals (see Figure 21-7).

Functions of the Placenta

The placenta truly is an organ of life, with a number of functions designed to provide for and protect the fetus. The placenta provides the fetus with oxygen-carbon dioxide exchange, passage of essential nutrients, excretion of metabolic waste products, and needed metabolic processes. It also protects the fetus by transferring maternal antibodies to the fetus and by its synthesis of hormones essential to the maintenance and well-being of the pregnancy. The placenta thus has three functions. It acts as (1) an organ of metabolism, (2) an organ of transfer, and (3) an endocrine organ in the synthesis, production, and secretion of both protein hormones and steroid hormones.

During early pregnancy, the placenta synthesizes glycogen. This function declines as the fetal liver develops. The placenta also synthesizes cholesterol and fatty acids and has other metabolic processes that most likely provide the needed energy and allow for the other functions of transfer and endocrine biosynthesis.

There are a number of mechanisms by which the placenta transfers materials between the fetal and maternal circulations in the intervillous space across the placental membrane. These include the following:

1. *Simple diffusion:* transfer of substances across a membrane from an area of higher concentration to an area of lower concentration. Low molecular weight substances diffuse readily across the placental membrane. This probably is the mechanism involved in the transfer of oxygen, carbon dioxide, many electrolytes, water, drugs, and analgesic and anesthetic agents.
2. *Facilitated diffusion:* transfer of materials from an area of higher concentration to an area of lower concentration, facilitated across the placental membrane to allow for more rapid or more specific transfer. The placenta facilitates diffusion of substances that are essential for

rapid fetal growth but in low concentration in the maternal blood (e.g., glucose).

3. *Active transport:* transfer against usual physiological principles. This is a metabolic process requiring energy. Active transport includes the transfer from the mother to the fetus of substances that are in low concentration in the maternal blood and in high concentration in the fetal blood. Examples are the transport of iron and ascorbic acid from the mother to the fetus.
4. *Pinocytosis:* movement of a substance across the cells of the fetal membrane to the fetal bloodstream by being engulfed by the invaginations of the chorionic villi. This may be the mechanism involved in the transfer of large protein molecules with a high molecular weight such as immune gamma globulin G.
5. *Breaks between cells:* A break in the chorionic villi allows for the direct transfer of cells. The prime example of breaks is the sensitization of an Rh-negative woman from receipt of erythrocytes from her Rh-positive fetus. These breaks, or leaks, are occasional and do not negate the general truth of the statement that the circulations of the fetus and the mother are separate without gross intermingling of the blood.
6. *Placental infection:* When the placenta is infected, the lesions in the placenta caused by the infectious organisms serve as a means of access into the fetal bloodstream. Protozoal and bacterial infections are transferred this way. Viral infections may pass through the placental membrane and infect the fetus without infecting the placenta.

Substances that have been identified as being transferred across the placental membrane include the following:

1. Oxygen, from mother to fetus
2. Carbon dioxide, from fetus to mother
3. Water
4. Vitamins
5. Glucose
6. Electrolytes
7. Amino acids
8. Whole proteins
9. Lipids
10. Minerals
11. Waste products—e.g., urea, uric acid, bilirubin
12. Hormones
13. Maternal antibodies to selected diseases
14. Most drugs and pharmacologic agents
15. Selected viral, protozoal, and bacterial infections

The hormones that the placenta synthesizes, produces, and secretes include the following:

1. *Human chorionic gonadotropin (hCG):* a protein hormone produced early in the pregnancy by both the cytotrophoblast and the syncytiotrophoblast, primarily in order to maintain the corpus luteum and thus the endometrium and the pregnancy.
2. *Human placental lactogen (hPL):* a protein hormone most likely produced early in the pregnancy by both the cytotrophoblast and the syncytiotrophoblast. It is involved in lactogenic and metabolic processes. It has also been called chorionic growth hormone and chorionic somatomammotropin.
3. *Estrogens:* steroid hormones elaborated by the placenta to the extent of causing a hyperestrogenic state. The precursor for the production of these estrogens is the adrenal cortex of both the mother and the fetus, with greater emphasis on the latter.
4. *Progesterone:* a steroid hormone elaborated by the placenta, utilizing blood cholesterol as a precursor.

The effect of these hormones on the woman and their role in the diagnosis of pregnancy were discussed earlier in this chapter.

The placenta may also synthesize a thyroid-stimulating hormone (chorionic thyrotropin) and adrenocorticosteroids (human chorionic ACTH), although there is as yet no direct evidence of the latter.

CHAPTER

22

Management Plan for Normal Pregnancy

Philosophy and Scope

Care of the pregnant woman and inclusion in her care of persons significant to her are both exciting and challenging. To share in and facilitate a woman's or couple's growth as they open themselves to and explore new feelings is to be allowed to participate in one of life's great experiences. Each woman or couple and each childbearing experience is unique. Providing care for a pregnancy and the corresponding focus on how the woman and her partner are experiencing this pregnancy, therefore, must be in accord with the uniqueness of their experience.

Management of the care of the pregnant woman, like all other aspects of the childbearing cycle, incorporates basic philosophical beliefs of midwifery, as discussed in the first chapter of this book. These include facilitation of natural processes, family-centered care, continuity of care, and the woman's right to participate knowledgeably in her own childbearing experience. Thus midwives most likely subscribe to the listing of rights contained in "The Pregnant Patient's Bill of Rights," prepared by Doris Haire in 1974 and distributed by the Committee on Patients' Rights in New York City.* These are as follows:

> The Pregnant Patient has the right to participate in decisions involving her well-being and that of her unborn child, unless there is a clearcut medical emergency that prevents her participation. In addition to the rights set forth in the American Hospital Association's "Patient's Bill of Rights", (which has also been adopted by the New York City Department of Health), the Pregnant Patient, because she represents TWO patients rather than one, should be recognized as having the additional rights listed below.
>
> 1. *The Pregnant Patient has the right*, prior to the administration of any drug or procedure, to be informed by the health professional caring for her of any potential direct or indirect effects, risks, or hazards to herself or her unborn or newborn infant which may result from the use of a drug or procedure prescribed for or administered to her during pregnancy, labor, birth, or lactation.
> 2. *The Pregnant Patient has the right*, prior to the proposed therapy, to be informed, not only of the benefits, risks and hazards of the proposed therapy but also of known alternative therapy, such as available childbirth education classes which could help to prepare the Pregnant Patient physically and mentally to cope with the discomfort or stress of pregnancy and the experience of childbirth, thereby reducing or eliminating her need for drugs and obstetric intervention. She should be offered such information early in her pregnancy in order that she may make a reasoned decision.
> 3. *The Pregnant Patient has the right*, prior to the administration of any drug, to be informed by the health professional who is prescribing or

* Reprinted here in part with permission of Doris Haire.

administering the drug to her that any drug which she receives during pregnancy, labor, and birth, no matter how or when the drug is taken or administered, may adversely affect her unborn baby, directly or indirectly, and that there is no drug or chemical which has been proven safe for the unborn child.

4. *The Pregnant Patient has the right*, if cesarean section is anticipated, to be informed prior to the administration of any drug, and preferably prior to her hospitalization, that minimizing her and, in turn, her baby's intake of nonessential pre-operative medicine will benefit her baby.
5. *The Pregnant Patient has the right*, prior to the administration of a drug or procedure, to be informed of the areas of uncertainty if there is NO properly controlled follow-up research which has established the safety of the drug or procedure with regard to its direct and/or indirect effects on the physiological, mental, and neurological development of the child exposed, via the mother, to the drug or procedure during pregnancy, labor, birth, or lactation—(this would apply to virtually all drugs and the vast majority of obstetric procedures).
6. *The Pregnant Patient has the right*, prior to the administration of any drug, to be informed of the brand name and generic name of the drug in order that she may advise the health professional of any past adverse reaction to the drug.
7. *The Pregnant Patient has the right* to determine for herself, without pressure from her attendant, whether she will accept the risks inherent in the proposed therapy or refuse a drug or procedure.
8. *The Pregnant Patient has the right* to know the name and qualifications of the individual administering a medication or procedure to her during labor or birth.
9. *The Pregnant Patient has the right* to be informed, prior to the administration of any procedure, whether that procedure is being administered to her for her or her baby's benefit (medically indicated) or as an elective procedure (for convenience, teaching purposes, or research).
10. *The Pregnant Patient has the right* to be accompanied during the stress of labor and birth by someone she cares for, and to whom she looks for emotional comfort and encouragement.
11. *The Pregnant Patient has the right* after appropriate medical consultation to choose a position for labor and for birth which is least stressful to her baby and to herself.
12. *The Obstetric Patient has the right* to have her baby cared for at her bedside if her baby is normal, and to feed her baby according to her baby's needs rather than according to the hospital regimen.
13. *The Obstetric Patient has the right* to be informed in writing of the name of the person who actually delivered her baby and the professional qualifications of that person. This information should also be on the birth certificate.
14. *The Obstetric Patient has the right* to be informed if there is any known or indicated aspect of her or her baby's care or condition which may cause her or her baby later difficulty or problems.
15. *The Obstetric Patient has the right* to have her and her baby's hospital medical records complete, accurate, and legible and to have their records, including Nurses' Notes, retained by the hospital until the child reaches at least the age of majority, or, alternatively, to have the records offered to her before they are destroyed.
16. *The Obstetric Patient has the right*, both during and after her hospital stay, to have access to her complete hospital medical records, including Nurses' Notes, and to receive a copy upon payment of a reasonable fee and without incurring the expense of retaining an attorney.

It is the obstetric patient and her baby, not the health professional, who must sustain any trauma or injury resulting from the use of a drug or obstetric procedure. The observation of the rights listed above will not only permit the obstetric patient to participate in the decisions involving her and her baby's health care, but will help to protect the health professional and the hospital against litigation arising from resentment or misunderstanding on the part of the mother.

Management of the care of the woman throughout the antepartal period includes the following components:

1. Diagnosis and early management of pregnancy
2. Assessment and evaluation of the well-being of the woman

3. Assessment and evaluation of the well-being of the fetus (see Chapter 23)
4. Relief measures for the common discomforts of pregnancy
5. Nutritional intervention in pregnancy
6. Anticipatory guidance and instruction
7. Screening for maternal and fetal complications (see Chapters 24 and 25)

Diagnosis and Early Management of Care During Pregnancy

Diagnosis of Pregnancy

The diagnosis of pregnancy in the first trimester and early second trimester is based on a combination of presumptive and probable signs of pregnancy. Pregnancy is self-evident later in gestation, when the positive signs of pregnancy are readily observed.

The history, physical, pelvic, and laboratory findings that constitute the database used in making a diagnosis of pregnancy are specifically related to the presumptive, probable, and positive signs of pregnancy. These signs do not make up the midwife's total database for a particular woman, only the part needed to make a diagnosis of pregnancy.

Following is a list of all the presumptive, probable, and positive signs of pregnancy that might be observed during the history, physical examination, pelvic examination, laboratory tests, and adjunctive studies conducted and ordered by the examiner:

History

1. Abrupt cessation of menstruation (presumptive)
2. Nausea and vomiting (presumptive)
3. Tingling, tenseness, nodularity, and enlargement of the breasts and enlargement of the nipples (presumptive)
4. Increased frequency of urination (presumptive)
5. Fatigue (presumptive)
6. Color changes of the breasts—i.e., darkening of the nipples and primary and secondary areolar changes (presumptive)
7. Appearance of Montgomery's tubercles or follicles (presumptive)
8. Continued elevation of the basal body temperature in the absence of an infection (presumptive)
9. Expression of colostrum from nipples (presumptive)
10. Excessive salivation (presumptive)
11. Chadwick's sign (presumptive)
12. Quickening (presumptive)
13. Skin pigmentation and conditions—for example, chloasma, breast and abdominal striae, linea nigra, vascular spiders, palmar erythema (presumptive)

Physical examination

1. Expression of colostrum from nipples (presumptive)
2. Color changes of the breasts (presumptive)
3. Nodularity, tenseness, and enlargement of the breasts and enlargement of the nipples (presumptive)
4. Appearance of Montgomery's tubercles or follicles (presumptive)
5. Enlargement of the abdomen (probable)
6. Palpation of the fetal outline (probable)
7. Ballottement (probable)
8. Fetal movement (positive or probable; authorities vary)
9. Fetal heart tones (positive)

Pelvic examination

1. Enlargement of the uterus (probable)
2. Change in the shape of the uterus (probable)
3. Piskacek's sign (probable)
4. Hegar's sign (probable)
5. Goodell's sign (probable)
6. Palpation of Braxton Hicks contractions (probable)
7. Chadwick's sign (presumptive)

Laboratory tests and adjunctive studies

1. Positive pregnancy test (probable); see Chapter 21
2. Sonographic evidence of pregnancy (positive)

One other positive sign of pregnancy is visualization of the fetal skeleton by roentgenography (x-ray films). The fetal skeleton can first be visualized by the twelfth week of pregnancy, because centers of ossification have formed in most of the bones. The skeleton can be clearly visualized by the sixteenth week. However, because of its danger to the fetus, roentgenography is not used for diagnosis of a viable pregnancy.

It is not always appropriate to seek findings regarding all of the signs of pregnancy outlined here when examining a woman who thinks she is pregnant. This is because not all of the signs are manifested at the same time. For example, if a woman is

approximately 2 months pregnant there is no value in attempting to elicit the following signs, as they either are not yet clinically evident or have not yet occurred:

1. Expression of colostrum
2. Secondary areolae
3. Skin pigmentations
4. Enlarged abdomen
5. Palpation of a fetal outline
6. Ballottement
7. Quickening
8. Fetal movement
9. Fetal heart tones by auscultation

Note that this list includes all of the clinically elicited positive signs of pregnancy.

All of the presumptive and probable signs of pregnancy are evidences of physiological changes taking place in the woman who is pregnant. However, since the majority of these signs can be caused by other conditions, a diagnosis of pregnancy can be made only in the presence of several of these signs.

All women, regardless of the outcome of assessment for pregnancy (pregnant or not pregnant) and regardless of the choice they subsequently make, need evaluation and information, as applicable, about the use of substances (cigarettes, alcohol, over-the-counter medications, prescriptions, illicit drugs), sexually transmitted diseases, nutrition, exercise, genetic screening, HIV screening/counseling, and domestic violence. If the woman is not pregnant, she additionally needs evaluation and information regarding a family planning method and continuing health care, including preconception care (see Chapter 5).

Early Management of Care During Pregnancy

Early management of care during pregnancy includes the decision by the woman or couple about whether to continue the pregnancy. There are three alternatives: (1) continue the pregnancy and keep the baby, (2) continue the pregnancy and give the baby up for adoption, and (3) terminate the pregnancy with an abortion within the allowable time limits. The decision varies with each individual, each pregnancy, and the perception the woman or couple have of the pregnancy. For some, pregnancy brings great joy (albeit with some ambivalence, as described in Chapter 21) and is the fruition of careful planning. For others, pregnancy is a surprise that can be accepted. For still others, pregnancy is perceived as an unmitigated disaster.

The midwife cannot make assumptions about a woman's reaction to the news of her pregnancy and needs to ask her what she thinks about being pregnant. The answer to this question leads the midwife to ascertain whether the woman intends to continue the pregnancy and needs information about prenatal care or wishes to terminate the pregnancy and needs information about abortion.

Abortion The 1973 Supreme Court ruling on abortion in effect legalized abortion, although it gave each state the right to regulate abortion in the second and third trimesters. This ruling voided restrictive laws in 31 states and required revisions to laws in 15 other states [1, 2].

The issues are complex, with the central issues being the following:

1. When does life begin? At conception? Or at the point when the fetus can survive independently of the uterus? This point is much affected today by the life-sustaining technology in neonatal intensive care units.
2. Does the woman have a right to self-determination, including the right to decide whether or not to be pregnant?
3. Does the fetus, regardless of gestational age, have any rights?
4. Are there any circumstances agreed on by a public majority that might constitute grounds for abortion (e.g., rape; diagnosed genetic defects from heredity, disease, or drugs; contraceptive method failure)?

The antiabortion, or prolife, movement stresses the rights of the fetus to life. The prochoice movement, which is neither proabortion nor antiabortion or against life, stresses the right of each individual woman to make her own decision about the choices (alternatives) she has (discussed below), one of which is abortion. Like all controversial issues, especially those dealing with life, death, and the human body, the subject of abortion is heavily laden with emotion. Irrationality by the extremists on all sides of the issue can result.

All women have an emotional response to learning or having confirmed that they are pregnant, as discussed above. Being pregnant requires a number of adjustments. The first trimester is known as the trimester of adjustment, and it is likely that even the happiest woman in the happiest of circumstances has thought at least once to herself that she wished she were not pregnant. This woman, however, is quite different from the woman who seriously contemplates an abortion or imple-

ments a decision to have an abortion. How the woman feels about being pregnant can have far-reaching effects, not only in terms of abortion but also in terms of parent-child relationships if the pregnancy is fulfilled. Therefore, it is vitally important to ask *throughout* the pregnancy how the woman feels about her pregnancy in order to facilitate her coping with the demands of pregnancy and to identify indications of lack of adjustment or precursors to later child abuse.

The legalization of abortion means that every woman, upon being diagnosed as pregnant, has a choice as to whether to carry the pregnancy to its natural conclusion. The woman's decision to have an abortion is not lightly made. In many cases she will turn to the midwife for counsel, advice, and information. Every woman has the right to know her alternatives and, in the case of a first trimester infection (e.g., rubella), her chances of having an affected baby.

If you are a person who in conscience cannot provide abortion counseling, it is only fair that you tell the woman who wants abortion information that this is the situation and she should seek the desired information from someone else. Most professionals in this category will call in a colleague who will provide the information. Clinicians who are not restricted by conscience in the provision of information should be intimately familiar with the local resources for abortion counseling, the procedures for obtaining an abortion, and how to make appropriate referrals.

A recommendation from a 1990 national symposium convened by the National Abortion Federation and the American College of Obstetricians and Gynecologists proposed that midlevel practitioners perform abortions [3]. In 1992 the American College of Nurse-Midwives (ACNM) rescinded a 20-year-old clinical practice statement (1971) that prohibited nurse-midwives from doing abortions [4, 5]. The membership also voted against having prohibitive practice statements, favoring instead the individual use of the ACNM Guidelines for the Incorporation of New Procedures into Nurse-Midwifery Practice. In 1991 the American College of Nurse-Midwives published the following document on reproductive choices (updated in 1997 to include Certified Midwives) [6]:

> Certified Nurse-Midwives (CNMs) and Certified Midwives (CMs) believe that every individual has the right to safe, satisfying health care with respect for human dignity and cultural variations. We support each person's right to self-determination, to complete information, and to active participation in all aspects of care. We acknowledge that the cultural, religious, and ethnic diversity of CNMs and their clients allows for a variety of personal and professional choices. Therefore, the ACNM holds the following positions:
>
> That every woman has the right to make reproductive choices;
>
> That every woman has the right of access to factual, unbiased information about reproductive choices, in order to make an informed decision; and
>
> That women with limited means should have access to financial resources for their reproductive choices.

There are two types of first trimester abortions: (1) surgical, done by dilatation and curettage (D&C) or by dilatation and vacuum aspiration (suction curettage), and (2) medical, done with medications. The discussion here is limited to first trimester medical abortion.

Three medications are currrently in use for medical abortion: (1) mifepristone (Mifeprex), (2) methotrexate, and (3) misoprostol (Cytotec). Prior to the availability of mifepristone, medical abortion was done with off-label use of a combination of methotrexate and misoprostol or misoprostol alone. The major drawback to the combination regimen of methotrexate and misoprostol is the length of time it takes for the abortion to occur—usually approximately 14 days, but up to 15 to 20 percent of women take 4 weeks to abort after administration of the misoprostol and 3 to 7 days after the injection of methotrexate [7, 8, 9]. The effectiveness of misoprostol alone varies widely, depending on whether it is moistened before insertion into the vagina, inserted dry, or taken orally. It also has significantly higher rates of nausea, vomiting, fever and chills, and diarrhea when used alone. For these reasons the discussion here is limited to the combined use of mifepristone and misoprostol.

Mifepristone (Mifeprex) was known as RU 486 prior to its approval as a first trimester abortifacient by the U.S. Food and Drug Administration (FDA) on September 28, 2000. Mifepristone is an antiprogesterone/antiprogestin derivative of norethindrone that inhibits progesterone, the hormone that maintains normal pregnancy. The lack of progesterone alters the decidua, causes the trophoblast to separate from its implantation site, decreases se-

cretion of human chorionic gonadotrophin (hCG), and results in bleeding from the uterus. Used alone, mifepristone is approximately 80 to 85 percent effective. However, when combined with a prostaglandin analogue, effectiveness increases to approximately 96 percent [10].

Misoprostol (Cytotec) is a prostaglandin E analogue that causes contractions of the uterus, which expels the separated embryo. Both misoprostol and mifepristone also soften the cervix, which facilitates expulsion.

The FDA approved the following regimen up to 49 days' gestation by LMP (7 completed weeks):

mifepristone 600 mg po once
    followed approximately 48 hours (2 days) later with
misoprostol 400 mg po once
    with a follow-up visit in 11 days

The earlier in pregnancy the regimen is implemented, the higher the efficacy. An additional dose of misoprostol does not increase efficacy [7].

Since the FDA approval of mifepristone and the recommended regimen, there have been a number of studies researching different dosages of both mifepristone and misoprostol, different lengths of interval time between the two drugs, length of gestational age for which the regimen is effective, at-home administration of the misoprostol, and so forth. Although the regimen of mifepristone and oral misoprostol has been shown to be 80 percent effective up to 63 days (9 completed weeks' gestation based on LMP) and as high as 96 to 97 percent effective up to 63 days if the misoprostol is administered vaginally [11, 12], the American College of Obstetricians and Gynecologists *Practice Bulletin* states that surgical abortion is the preferred treatment for women who desire first trimester abortion after 49 days' gestation by LMP [7].

Five prerequisites should be in place prior to implementing the FDA regimen:

1. The woman must be pregnant and her gestational age determined. This is done by clinical evaluation of the uterus during pelvic examination combined with history and observation of presumptive and probable signs of pregnancy and a pregnancy test, or, if in doubt, vaginal sonography.
2. The woman is not contraindicated to the use of either drug. (See Table 22-1.)
3. The woman agrees to a surgical abortion if the medical abortion fails. This is imperative because misoprostol is teratogenic [7, 13].

TABLE 22-1 Contraindications to Use of Combined Mifepristone and Misoprostol Regimen

- Confirmed or suspected ectopic pregnancy
- Undiagnosed adnexal mass
- Unremoved intrauterine contraceptive device (IUD)
- Severe anemia
- Known coagulopathy or anticoagulant therapy
- Chronic adrenal failure
- Current long-term systemic corticosteroid therapy
- Severe liver, kidney, pulmonary, or cardiovascular disease
- Uncontrolled seizure disorder
- Allergy or intolerance to either drug
- Unwillingness to have surgical abortion if medical abortion is not successful
- Inability to return to office or clinic for follow-up visits

4. The woman is provided with anticipatory guidance on what to expect and when to call. Such guidance includes the following instructions and information:
    a. Expect bleeding, but call if there is too much:
        (1) more than four sanitary pads saturated in two consecutive hours
        (2) heavy bleeding for more than 24 hours
    b. If there is excessive bleeding, a surgical procedure will be required to complete the abortion, most likely suction curettage. This occurs in about 1 to 2 percent of women.
    c. Expect cramps and pain, which may be severe but will resolve after expulsion of the products of conception. Relief measures include a heating pad and medications such as acetaminophen (e.g., Tylenol, Excedrin) or ibuprofen (e.g., Motrin, Advil). Acetaminophen with codeine may be prescribed.
    d. Other possible side effects include:
        (1) nausea
        (2) vomiting
        (3) diarrhea
        (4) fever and chills
        (5) headache
        (6) dizziness

        Call if any of these lasts more than a day.
    e. Identify available support systems for information, counseling, emotional release, anxiety reduction, and any grief work.
    f. Rh-negative women with negative antibody titers should receive Rh immune globulin (e.g., RhoGAM) within 72 hours of the abortion.
5. The woman signs an informed consent.

With these five prerequisites in place, the woman is given the dose of mifepristone. Approximately 11 percent of women abort before returning to take the misoprostol. Women who have not aborted return to the office or clinic in two days and are given the misoprostol. A woman then remains in the clinic or office for approximately 4 hours during which time another approximately 50 percent of women will expel the products of conception. If she has not yet aborted, she is examined by vaginal ultrasound to determine if indeed she did unknowingly abort. She is then sent home with instructions regarding bleeding and she is asked to return in 10 to 15 days. If she has not aborted by then as determined by history, pelvic examination, and vaginal ultrasound, then surgical abortion, usually suction curettage, is done.

The follow-up visit after the abortion has several important features to it. First is to determine by history and pelvic examination that there are no complications. Second is to discuss and implement a plan for contraception. Abortion should not be considered a contraceptive method. Third is to ascertain the woman's mental health about the abortion. Fourth is all the evaluation and counseling that is part of an annual visit or preconception counseling, such as Pap smear, breast self-examination, sexually transmitted diseases, substance abuse, HIV, any form of violence, nutrition, and exercise. See Chapter 5.

Midwives who provide medical abortion but are not trained in surgical abortion need to have a collaborating physician who is trained in surgical abortion. Surgical abortion is indicated in those instances when medical abortion fails and the pregnancy continues, or when the products of conception are not completely expelled, or when there is excessive bleeding.

Assessment and Evaluation of the Well-Being of the Woman

The Initial Examination

The initial antepartal examination occurs at any point in pregnancy when the woman makes an appointment for her continuing health care. It consists of a complete history, physical and pelvic examinations, and a number of laboratory and adjunctive studies. This chapter describes the details of this examination. It is assumed that the woman's pregnancy has already been diagnosed either by prior examination and a pregnancy test (early in her pregnancy) or because it has become self-evident. The details of this initial antepartal examination are basically the same, regardless of what time in pregnancy it takes place. There are obvious differences depending on where the woman is in the pregnancy (e.g., the size of the uterus).

History In addition to collecting the woman's identifying information, past medical and primary care history, family history, menstrual history, obstetric history, gynecologic history, sexual history, contraceptive history, and douching history (outlined in Chapter 2), the midwife needs to gather a present pregnancy history. In planning the sequence in which information is to be obtained during a visit, it is often best to start with the present pregnancy history. This is what most women are interested in and expect to talk about. Your interest in the woman's first concern facilitates obtaining all the other information afterward. Emphasis also needs to be placed on obtaining the date of her last normal menstrual period, calculation of her estimated date of birth, determination of the present number of weeks' gestation, and calculation of her gravida and para status.

Gravida/Para. Gravida refers to the number of times a woman has been pregnant. It does not matter at what point during pregnancy the pregnancy was terminated. Nor does it matter how many babies were born from the pregnancy. It is the pregnancy that counts, not the number of babies. A woman who has had one pregnancy from which issued triplets would still be a Gravida 1 until pregnant again, at which time she would be a Gravida 2. A woman who is pregnant for the first time is called a primigravida. A woman pregnant for the second time is called a secundigravida. Thereafter, if pregnant again, she is called a multigravida. A woman who has never been pregnant is called a nulligravida.

Para refers to the number of pregnancies that terminated in the birth of a fetus or fetuses that reached the point of viability. This point is considered to be 20 weeks' gestation (or 500 grams), which is the cutoff for the definition of abortion. An increase in a woman's parity designation is achieved only if the pregnancy produces a fetus that has reached the point of viability. For example, a woman who has been pregnant twice and had two first trimester abortions is a Gravida 2, Para 0. Note that it is not the number of fetuses reaching

the point of viability but the number of pregnancies carried to the point of the fetus's or fetuses' reaching the point of viability that determines parity. So the woman who has had one pregnancy that resulted in 4-pound triplets is a Gravida 1, Para 1. Para is not affected by whether the fetus or fetuses are born alive or are stillbirths. The woman who has been pregnant twice with one of those pregnancies ending in a full-term stillbirth and the other in a full-term live birth would be a Gravida 2, Para 2.

A primipara is a woman who has had one pregnancy in which the fetus or fetuses reached the point of viability. Unfortunately, primipara is often used interchangeably with primigravida, but it is not possible for a primigravida to be a primipara until after the birth of a baby that reached the point of viability. A multipara is a woman who has had two or more pregnancies in which the fetus or fetuses reached the point of viability. It is possible for a multigravida not to be a multipara since, in this system, the para number can be less, but never more, than the gravida number. A woman who has not carried a pregnancy to the point of viability is called a nullipara.

Para does not provide much information about the pregnancies a woman has had. For this reason, the two-digit system of Gravida/Para is rarely used. *Instead a four- or five-digit system is used in place of para although, in practice, the digits are misnamed as para. This is confusing because this system counts each baby born rather than counting the number of pregnancies carried to viability, which is the basis for determining para.* The digits follow a precise sequence:

First digit: the number of term babies the woman has delivered. *Term* in this system refers to any baby of 36 weeks or 2500 grams or more.

Second digit: the number of premature babies the woman has delivered. *Premature* in this system refers to any baby born between 20 and 36 weeks or weighing between 500 and 2499 grams.

Third digit: the number of pregnancies ending in abortion (either spontaneous or induced). *Abortion* refers to any baby born before 20 weeks' gestation or weighing less than 500 grams.

Fourth digit: the number of children currently alive.

Fifth digit: the number of pregnancies that resulted in multiple births. The fifth digit is not commonly used but is useful when there is a history of multiple births.

The following examples illustrate the use of the four- or five-digit system:

Example 1: A Gravida 2 delivered a full-term baby with each pregnancy, both of whom are currently alive. She is a Para 2002.

Example 2: A Gravida 2 delivered a full-term baby who died at 6 months of age and aborted during her second pregnancy. She is a Para 1010.

Example 3: A Gravida 1 delivered premature twins, one of whom died. She is a Para 0201.

Example 4: A Gravida 6 delivered one full-term live birth, one full-term stillbirth, one premature live birth, and premature triplets, of whom two lived and one died, and she has had two abortions. She is a Para 2424. In this instance, it would be useful to use the fifth digit for the number of pregnancies that resulted in multiple births in order to clarify the first four numbers. With the five-digit system, she is a Para 24241.

In any of the above examples, if the woman were pregnant at the time of this summarizing of her obstetric history, her gravida number would increase by one to account for her present pregnancy. When doing the obstetric history during the initial antepartal examination, if the woman is pregnant for the first time, simply write primigravida across the space provided for this history on the chart.

Last Menstrual Period. Because the date of the first day of the last normal menstrual period (LNMP) is used as the baseline for determining gestational age and the estimated date of birth (EDB), it is important to obtain as accurate a date as possible for this event. Unfortunately, many women do not keep a record of their menstrual periods. They do, however, have a pretty good general idea of the regularity of their periods and when during the month they occur. A little detective work is often indicated. The success of your detective work will most likely depend on the questions you ask.

The first thing to determine about the date a woman gives for her LMP is whether this was a normal period for her. To do this, correlate her description of her last menstrual period with her description of her regular menstrual periods, obtained while taking her menstrual history. For example, if she says her last period was scanty and lasted 1 or 2 days and that her usual periods are moderately heavy for the first 2 days and taper off to scanty around the fourth or fifth day, then you know that her last menstrual period was not normal for her.

Therefore, ask about the period before the one she has given as her last one. If this preceding period was normal for her, then this is the one you count as her LMP. It is not uncommon for a woman to experience some spotting at the time of implantation of the blastocyst as a result of the invasive activity of the chorionic villi in the uterine lining. Since implantation in a woman with a 28-day cycle occurs close to the time she would be expecting a menstrual period (ovulation at day 14 prior to the next menstrual period; 3 to 4 days for the fertilized ovum to move down the fallopian tube to the uterus [day 17 or 18]; 3 days in the uterine cavity before implantation [day 20 or 21]; and then several days for implantation), a woman often misinterprets this spotting from implantation as a menstrual period even though it is distinctly different from her usual period. If you do not explore the normality of her last menstrual period, you may make the error of misdating the pregnancy by one month. This can cause undue concern when clinical findings and gestational age do not correlate throughout the pregnancy. Remember, LMP refers to the first day of her last *normal* menstrual period.

Occasionally you will encounter a woman who professes to have no idea of the date of her last menstrual period. To get some idea of when this might have occurred it is useful to use national holidays or other dates that might be significant to her. Such women often will remember if they had a menstrual period around a particular religious holiday, New Year's Day, Fourth of July, Halloween, Thanksgiving, their birthday, the beginning or end of school, and so forth.

At times, a woman is simply a poor historian, and accuracy in pinpointing the LMP is impossible. This should be so noted on her chart. If the last menstrual period is unknown, an estimated date of delivery is based on many parameters (see "Size-Date Discrepancy" in Chapter 25), including an ultrasound for dating.

Estimated Date of Birth. For many years, the expected date of the end of pregnancy by delivery of a full-term baby was called the estimated date of confinement (EDC). This term has been changed by a number of health care professionals to estimated date of delivery (EDD). The change was introduced because of a feeling that the word confinement connotes illness, limitation, and a passive role rather than a normal event, a healthy process, and active participation. Midwives subsequently changed estimated date of delivery to estimated date of birth (EDB), because this sounds more normal and natural and puts the focus on the mother who gives birth rather than on the practitioner who may or may not be present to "deliver" the baby. Estimated date of birth (EDB) will be used throughout this book.

The EDB is calculated by Naegele's rule, in which 7 days are added to the date of the first day of the LMP and then 3 months are subtracted from that date. Naegele's rule is easiest to calculate by substituting numbers for months and days so that the first number stands for the month and the second number stands for the day. One must be careful to use the actual number of days in the month of the LMP when crossing over to another month. This is illustrated in the following example of calculating the EDB by Naegele's rule:

```
  5/28 (LMP of May 28)
+    7 days
   6/4 (June 4–May has 31 days)
-    3 months
= 3/4 (March 4 of the next year, as 9 months have
       been added)
```

The EDB is at best a "guesstimate" because several variables may alter the actual date of delivery. First, calculation of the EDB is dependent on the woman's accurately identifying the date of the first day of her last normal menstrual period. Second, the actual period of gestation is from the time of fertilization. Since ovulation is generally considered to occur approximately 14 days before the next menstrual period, the length of a woman's menstrual cycle will affect the accuracy of the EDB. A woman with a longer menstrual cycle (more than 28 days) will actually begin her pregnancy later in relation to the LMP and will deliver at a correspondingly later date as variability in the length of the cycle is largely due to the number of days from the beginning of menses to ovulation [14]. The reverse is true for the woman with a shorter menstrual cycle. Third, not all women with 28-day menstrual cycles ovulate 14 days before the next menstrual period; this individual variation in ovulation time will affect the accuracy of the EDB. Therefore, the woman should be told she probably will not have her baby on the exact date of the EDB. The majority of women deliver within 10 to 14 days, either earlier or later, of their EDB, and this range is considered physiologically normal.

The addition of 7 days in Naegele's rule attempts to counterbalance some of the difference between the LMP and the time of fertilization. The

remaining 7 days (to total 14 in a 28-day cycle) are picked up over the 9-calendar-month period of gestation because 7 calendar months have 31 days. However, no single pregnancy would cover the period of time that would include all these 7 months.

It is useless to calculate the EDB by Naegele's rule in the presence of any of the following situations:

1. The woman had irregular menstrual periods including 1 or more months of amenorrhea.
2. Conception occurs while the mother is breastfeeding and ovulating but amenorrheic.
3. Conception occurs before regular menstruation is established after termination of a pregnancy or discontinuation of oral contraceptive pills.

In such instances, an estimated date of birth is based on clinical findings and subsequent projections and an ultrasound scan as early in pregnancy as possible, when fetal biometry is most accurate (see Table 25-2).

The same clinical measurements are used during any pregnancy to double-check the accuracy of the EDB and to detect possible intrauterine growth retardation and other complications. These measurements are discussed in detail in Chapter 25.

Determination of the weeks of gestation according to dates is done most easily and quickly by using one of the gestational calendars or calculators available from the pharmaceutical companies. However, since there is sometimes a slight inaccuracy in using these calculators to determine the EDB, most clinicians calculate the EDB from the LMP by Naegele's rule and use the resulting EDB in setting the calculator to determine the week of gestation.

Present Pregnancy History. The present pregnancy history is designed to detect complications, some of the discomforts, and any complaints about the pregnancy the woman has experienced since her LMP. You may see the woman for her initial antepartal examination at any time during the pregnancy; therefore, the present pregnancy history given here covers symptoms of possible problems in all three trimesters. The woman should be questioned about all of the following during the present pregnancy history:

1. Headaches
2. Dizziness
3. Visual disturbances
4. Syncope
5. Fever
6. Fatigue
7. Nausea
8. Vomiting
9. Heartburn
10. Breast changes
11. Leakage of colostrum
12. Shortness of breath
13. Abdominal pain
14. Back pain
15. Dyspareunia
16. Vaginal discharge
17. Vaginal bleeding
18. Dysuria
19. Urinary frequency
20. Constipation
21. Hemorrhoids
22. Leg cramps
23. Varicosities
24. Edema (ankle, pretibial, face, hands)
25. Infections (e.g., measles, flu, other viruses)
26. Drugs and medications
27. Street drugs, alcohol, and smoking
28. Roentgenography (exposure to x-rays)
29. Accidents
30. Relationship status: support from significant other for pregnancy; presence or history of domestic violence and emotional, physical, or sexual abuse
31. Sexual satisfaction: sexual changes and the feelings of both partners toward any changes
32. Feelings about her pregnancy: effect on her life and her body image, feelings about the baby
33. Quickening (date of)
34. Any complaints, discomforts, or concerns other than those already discussed

A positive response to any of items 1 through 30 requires further exploratory history taking to ascertain the following:

1. When during the pregnancy this occurred; duration; recurrences
2. Specific location (if applicable)
3. Severity (if applicable)
4. Associated symptoms
5. Factors influencing the problem, either aggravating or relieving
6. Medical help (whom); diagnosis and treatment (if applicable)
7. Treatment or relief measures (self or medically initiated) and their effectiveness

The use of drugs and medications during pregnancy is particularly complex, and the midwife needs to review each drug and balance the reason for its use against the risk it carries when used during pregnancy. (See Chapter 10.) In 1980 the Food and Drug Administration published pregnancy risk categories for drugs in the *Federal Register* (see Table 10-5). All drugs are now identified as being in one of the pregnancy risk categories.

Of particular concern is to identify women who are being subjected to violence through physical, sexual, and psychological abuse. This abuse often starts or increases during pregnancy, more in the third trimester, and violent death may be the end result.

All pregnant women should be screened by history, physical, and pelvic examination. Observation of bruises, teeth marks, burns, mutilation; fear of partner; or partner possessiveness and controlling behaviors should not go unexplored. Even without obvious signs, privacy for just the midwife and the woman to talk, without children or partner present, must be created at some point in time during the visit. The midwife can begin with a preamble such as the following: "I always want some time alone with each of the women I see because I have learned that often a woman has concerns she does not want to talk about in front of others. We know that violence in the home often starts or increases during pregnancy and I want to make sure that every woman I see is able to talk about any abuse that is happening to her and develop plans for her safety." You can then ask if she is being abused (hurt) physically (hit, punched, slapped, cut, kicked), sexually (forced to have unwanted sex), or psychologically (called derogatory names, threatened with a weapon, belittled). A positive response requires further history taking to determine frequency, how long she has been a victim of violence, prior injuries (a body map for her to indicate where she has been hurt is useful), and if she is afraid; validation of the abuse to her; a plan for safety including her thinking through the details of an escape route; and providing her with information about possible resources.

Physical Examination A complete screening physical examination is done during the initial antepartal examination in order to ascertain whether the woman has any medical abnormalities or disease. This physical examination was outlined in Chapter 2. Breast examination is detailed in Chapter 52, and variations in findings during breast examination of the pregnant woman were discussed in Chapters 21 and 52. The obstetric abdominal examination is detailed in Chapter 53.

In addition to the physical examination outlined in Chapter 2, the midwife should perform an abdominal examination of the pregnant woman. The following is included in such an examination:

1. Observation of any scars or bruises and inquiry to obtain explanation of them
2. Observation of linea nigra
3. Observation of abdominal striae
4. Determination of the lie, presentation, position, and variety of the fetus
5. Measurement of fundal height
6. Gross evaluation of amniotic fluid volume
7. Auscultation of fetal heart tones
8. Estimation of fetal weight
9. Observation or palpation of fetal movement

Each of these items provides informative data that are useful either in diagnosis of pregnancy, in evaluation of fetal well-being and growth, or as indicators of possible problems.

Any scars or bruises on the abdomen must be noted and their reason for being there explored. The scar of a previous cesarean section is of particular importance. It is useful to know if the woman has had an appendectomy so that appendicitis can be ruled out in the event of right-sided abdominal pain during the pregnancy. The midwife should note any bruises in the woman's chart and discuss their origin with the woman, paying particular attention to the possibility of domestic violence and abuse.

Observations of linea nigra and abdominal striae are presumptive signs of pregnancy. Observation or palpation of fetal movement and hearing the fetal heart tones (FHT) are positive signs of pregnancy. The normal range of fetal heart tones is 120 to 160 per minute. Whether the FHT are in the lower or upper end of this range is *not* an indication of whether the baby will be a boy or a girl.

The importance of determining the lie, presentation, position, and variety of the fetus varies with the length of pregnancy. Prior to the twentieth week it is nearly impossible to ascertain this information because of a combination of the small size of the fetus, the thickness of the uterus, and the still high ratio of amniotic fluid to baby in the amniotic sac. The baby will continue to turn and somersault in the amniotic sac until the bulk of the baby's body is far

greater than the amount of amniotic fluid and there is no longer room for the fetus to turn easily. Consequently, information about fetal placement in the uterus has little meaning for labor and delivery management until around the thirty-sixth week of gestation. By this time most babies have settled into what will be their lie and presentation for the intrapartal period. This is not absolute, however, as some babies will turn again. Malpresentation prior to thirty-six weeks' gestation is not cause for concern because the baby is still turning. Malpresentation after this time, however, may be cause for concern and possible intervention. In planning the management of the intrapartal period, the midwife should determine carefully at the beginning of labor if the problem still exists. Data on lie, presentation, position, and variety are obtained from doing Leopold's maneuvers of abdominal examination by palpation. The procedure for doing Leopold's maneuvers is presented in Chapter 53.

Fundal height is of greatest value when it is measured the same way by the same examiner throughout pregnancy. It provides information regarding the progressive growth of the fetus and serves as a gross screening tool for detection of problems related to a fundal height that is too large or too small for the presumed gestational age by dates (see Chapter 25). A fundal height that is not increasing but remains the same over a period of time is ominous. Signs and symptoms of possible intrauterine fetal growth restriction or fetal death must be looked for and these possibilities ruled out.

There are four major ways of measuring fundal height. These are described in Chapter 53 and the norms for different points in pregnancy are given.

Determining estimated fetal weight (EFW) requires concentrated practice on the part of the examiner in order to develop enough accuracy for the EFW to have any meaning. EFW is important in the intrapartal period, when this figure is compared with the clinical evaluation of the pelvis to ascertain the adequacy of a given mother's pelvis for the size baby she will be delivering. During the antepartal period, EFW is used as one clinical measurement in evaluating gestational age and progressive fetal growth.

Learning to evaluate EFW accurately is difficult, because there is no precise measuring tool for checking the accuracy of your estimate during the antepartal period. Neither experienced hands nor sonogram is necessarily more accurate than the other but both can be used to develop your own accuracy. Combining the ultrasound measurements of abdominal circumference, head circumference, and femur length enables calculation of an EFW that becomes increasingly inaccurate the larger the baby grows. However, it will give the learner some idea of EFW, and it is worthwhile if the student palpates the woman's abdomen prior to a scheduled ultrasound and compares the resulting EFW with that subsequently determined by ultrasound. You also can ask an experienced clinician to give you an EFW on your patient, but the accuracy of even seasoned clinicians is highly variable. The literature describes the inaccuracy of EFW by clinicians, especially for the smaller and larger babies but reports greater accuracy for the middle range of average-sized babies. It is important to feel as much of the fetus as possible, to ascertain accurately what proportion of the fetus you have felt, and to envision the remainder mentally. The following suggestions will help you learn how to translate what you feel into an estimated weight:

1. Palpate as many women in the labor and delivery unit as possible. Compare your EFW with the actual weight of the baby at birth.
2. Undress, put into the fetal position, and palpate as many babies in the normal newborn nursery as possible. (Get the mothers' permission first.) Compare your estimated weight of the baby to the actual weight of the baby. Remember to redress and, if necessary, calm any crying babies you palpate—for the sake of the baby and the mother and to be fair to and maintain good relationships with the nursery staff.
3. Visualize and study the size of premature newborns in relation to their weights.
4. Visualize and study the size and corresponding weights of fetal specimens at different gestational ages.

The only additional information to be obtained from the physical examination other than that outlined in Chapter 2 for the initial antepartal examination, is the woman's prepregnant weight and height at the time of her last menstrual period as well as a measurement of her weight at the time of this examination.

Pelvic Examination A complete pelvic examination is done during the initial antepartal examination. This includes not only the speculum, bimanual, and rectovaginal examination (see Chapter 56) but also evaluation of the bony pelvis by clinical pelvimetry (see Chapter 61).

You may occasionally see a woman who refuses to have a pelvic examination. Such women are usu-

ally either young adolescents who are primigravidas with minimal sexual experience, women who have had traumatic experiences during pelvic examinations in the past, women who have been raped or who have a history of sexual abuse, or women who are victims of current, on-going sexual abuse. These women are quite frightened and will be hurt both mentally and physically if an examination is forced on them. This problem is rarely encountered in women who have had at least one vaginal delivery. Understanding and patience are required on the part of the examiner. Venting of frustration and anger on the woman should be scrupulously avoided. Exploration of the meaning of the woman's behavior to her is mandatory so that you can identify the problem in order to begin working through it. Why is she objecting to this procedure? If she is fearful, precisely what is she afraid of? It may be necessary to arrange for this woman to be examined by someone who is skilled in working with such women and known to be especially gentle in doing pelvic examinations. It may take several antepartal visits before the woman is willing to be examined.

Time is on your side, inasmuch as the pelvic ligaments relax as pregnancy progresses. (The cause of this pelvic relaxation is unknown, although it has been attributed in the past to the hormone relaxin. However, since a pure substance has not been isolated for definitive study, it cannot be said that relaxin is the causative factor.) The relaxation of the pelvic ligaments makes it easier to do a pelvic examination around the thirty-sixth week of gestation than during the first or second trimester. The value of earlier examinations must be weighed against trauma to the woman and a potential breakdown of trust and cooperation, which could affect all other aspects of her pregnancy. In the absence of clinical symptoms requiring a diagnostic pelvic examination, the pelvic can be delayed until later in pregnancy when you need to do clinical pelvimetry.

Laboratory Tests and Adjunctive Studies The laboratory tests and adjunctive studies ordered during the initial antepartal examination vary, depending on policies established in a particular clinical setting. Some tests and studies also vary with the gestational age of the fetus at the time of the examination and with the woman's history. Exactly which tests are used to obtain the same information also varies from setting to setting. The following list encompasses the most common variations; these tests, unless otherwise noted, are routine for all pregnant women. Additional laboratory tests would be done in the event of pathological findings; these tests, which would be specific to the woman and not routine for all, are covered in the discussion of complications in Chapter 24 and are not included in this list.

1. Pap smear (done during speculum examination; see Chapter 57)
2. Gonococcal (GC) and chlamydia testing specimens collected during speculum examination; see Chapter 58
3. Blood type (ABO)
4. Rh factor
5. Antibody screen/antibody titer
6. Sickle cell prep or hemoglobin electrophoresis; done routinely in an increasing number of clinical settings
7. Tuberculin test (PPD) for women in high-risk groups except for those with a known previous positive test (see Chapter 24); done in all public health department settings
8. Venereal Disease Research Laboratory (VDRL), rapid plasma reagin (RPR), or other serology test for syphilis
9. Hepatitis B surface antigen
10. Rubella titer
11. Varicella antibody screen if woman has not had disease or vaccine
12. Hemoglobin and hematocrit; some settings order a broader spectrum of blood counts and tests such as those included in an SMA-4, SMA-12, or CBC (e.g., WBC, RBC, differential); the hemoglobin and hematocrit, however, are minimal in all settings
13. Urinalysis for protein, glucose, and routine microscopic examination; some clinical settings also routinely order a urine culture
14. Diabetes screening at 28 weeks' gestation
15. Screening for vaginal and rectal group B streptococcus (GBS) colonization at 35 to 37 weeks' gestation

In addition, all women should be offered the following:

1. HIV testing
2. Maternal serum alpha-fetoprotein (MSAFP) or triple screen testing (to be done between 15 and 18 weeks' gestation)

In some settings, it may be the midwife's responsibility to draw or otherwise obtain the blood needed for tests. These procedures are described in Chapters 46 and 47.

The procedure for collecting specimens for culture of GBS is to swab the lower vagina at the in-

troitus without a speculum and then, either using the same swab or a second swab, swab the rectum by inserting the swab through the anal sphincter. One or both swabs are placed into the same container of transport medium. Clearly labeled specimens should also identify if the woman is allergic to penicillin and specify susceptibility testing for clindamycin and erythromycin if GBS is isolated [15].

A case study of antepartal management based on the database obtained during an initial antepartal examination is given after the next section on the antepartal revisit. The case study follows the woman through an antepartal revisit.

The Revisit

The antepartal revisits are the return visits the woman makes, after her initial antepartal examination, for prenatal care throughout the remainder of her pregnancy until her entry into true labor. Each revisit consists of a chart review, a history and physical examination geared toward evaluation of the well-being of the mother and the fetus, speculum and/or pelvic examination when indicated, laboratory and adjunctive studies when indicated, and explanations and teaching appropriate to the woman's needs and her baby's gestational age.

Chart Review Immediately before seeing the woman, the midwife should review her chart for the following information:

1. Name
2. Age
3. Parity
4. Weeks of gestation by dates
5. Any significant finding from
   a. obstetrical history
   b. past medical and primary care history
   c. family history
   d. present pregnancy history
   e. initial physical examination
   f. initial pelvic examination
6. Any previously identified problems, treatment, and evaluation of the effectiveness of the treatment
7. Any particular concerns and desires, plans made, and instruction provided
8. Specific medications, treatments, and dietary requirements for which the woman is presently responsible
9. Laboratory reports:
   a. normality of results
   b. need to repeat any lab tests
   c. need for further investigation and lab tests

This comprehensive chart review serves the purposes of (1) reacquainting the midwife with the findings, problems, concerns, and unique aspects related to this individual woman, (2) evaluating the thoroughness of the database, and (3) evaluating the thoroughness and effectiveness of the preceding management.

History The basic revisit history is designed to detect any symptoms or subjective indications of complications or discomforts that the woman may have experienced since her last visit. The woman is thus questioned about the following:

1. Any concerns, complaints, questions, or problems she has
2. Headaches
3. Visual disturbances
4. Dizziness
5. Fever/chills
6. Nausea/vomiting
7. Fetal movement
8. Abdominal pain/contractions
9. Back pain
10. Dysuria
11. Vaginal discharge/leaking fluid
12. Vaginal bleeding
13. Constipation/hemorrhoids
14. Varicosities/leg ache
15. Leg cramps
16. Edema (ankle, pretibial, face, hands)
17. Exposure to any infectious diseases
18. Use of any medicines other than those prescribed (e.g., aspirin)
19. Any relationship changes, such as an increase in or initiation of abuse
20. Any medical care since last visit (e.g., doctor, emergency room); reason, diagnosis, treatment, continuing care

In addition, the woman is questioned about possible discomforts, concerns, and desire for information regarding the weeks' gestation at the time of the revisit (e.g., discomforts and concerns common during this trimester, development of the baby during this month), as well as any plans she may have to attend classes on preparation for childbirth and parenthood (including breastfeeding). The midwife should also inquire about any significant findings identified during the chart review.

Physical Examination At each antepartal revisit the following physical examination is done to detect any signs of complications and to evaluate fetal well-being:

1. Blood pressure (compare with baseline blood pressure obtained at the time of the initial visit; note blood pressure readings throughout pregnancy to date)
2. Weight (compare with prepregnant weight; note the number of pounds for the number of weeks since the last visit; note weight gain pattern)
3. Abdominal examination for
   a. lie, presentation, position, and variety
   b. engagement
   c. measurement of fundal height (compare with measurement at the preceding visit; note pattern of uterine growth)
   d. gross evaluation of amniotic fluid volume
   e. observation or palpation of fetal movement
   f. estimated fetal weight (compare with estimated weight at preceding visit)
   g. fetal heart tones (note rate and location) (see Chapter 53)
4. CVA tenderness (see Chapter 54)
5. Examination of the upper extremities for finger edema (note if any rings are tight and ask if they are tighter than usual; also ask if woman is not wearing any rings that she used to wear because they became too tight, or if she has changed the fingers on which she is wearing her rings)
6. Examination of the lower extremities for
   a. ankle and pretibial edema
   b. quadriceps (knee-jerk) deep tendon reflexes (see Chapter 55)
   c. varicosities and Homans' sign, when indicated

After the initial physical examination, a breast examination for adequate support and for any crusting of leakage should be conducted approximately once a month. If the woman plans to breastfeed, her nipples need to be reevaluated at the thirty-sixth week of gestation to ascertain the need for measures to help bring out flat or inverted nipples.

Pelvic Examination After the initial examination, the midwife performs some or all of the following components of a pelvic examination, as indicated:

1. A speculum examination if the woman complains of vaginal discharge.
   a. Look for visual signs of vaginal infection, and obtain material for a diagnostic wet smear slide; obtain specimen for GC and chlamydia diagnostic testing.
   b. Evaluate treatment for vaginal infection (test of cure) if symptomatic; not necessary if the woman is now asymptomatic (see Table 15-3).
   c. Repeat Pap smear, if needed.
   d. Repeat GC and chlamydia diagnostic testing in the third trimester.
   e. Rule out or confirm premature rupture of membranes (see Chapter 29).
2. Clinical pelvimetry late in the third trimester if the pelvis needs to be reevaluated or if it was not possible to obtain this information during the initial examination because the woman refused to be examined (see the discussion earlier in this chapter).
3. A vaginal examination if the woman has any signs/symptoms of preterm labor to assess
   a. cervical consistency
   b. effacement
   c. dilatation
   d. status of membranes
   e. engagement/station
   f. presenting part

   Some midwives also do a vaginal exam routinely at the fortieth week of gestation by dates and thereafter to determine cervical "ripeness" (readiness) for labor.

Many, although not all, midwives believe in performing a 36-week pelvic evaluation, including a repeat of clinical pelvimetry; obtaining specimens for diagnostic testing of GC, chlamydia, and GBS; and evaluation of cervical status. They view this as part of a total reevaluation of the woman at this time. This total reevaluation also includes evaluation of any laboratory tests.

Laboratory Tests and Adjunctive Studies A voided urine specimen is obtained at each revisit; a dipstick test for the presence of protein and glucose. Laboratory tests and adjunctive studies ordered during the initial antepartal examination are reviewed for results. All women should be screened for diabetes at 28 weeks and for group B streptococcus at 35 to 37 weeks. Practice and institutional policies vary about routinely repeating laboratory tests obtained at the initial visit or repeating them only if indicated by history, physical, and pelvic findings. This includes hemoglobin and hematocrit, VDRL, gonorrhea, chlamydia, and antibody titers

for Rh-negative women prior to receiving prophylactic RhoGAM at 28 weeks (see Chapter 24). Other laboratory tests and adjunctive studies are done if the findings of the history, physical and pelvic examinations, and laboratory studies suggest a need for further diagnostic workup.

Management

Collection of the database through history, physical and pelvic examinations, and laboratory and adjunctive studies is the first step in the management process (see Chapter 2). The remaining steps of the management process depend on the database and its interpretation. Interpretation of the database (step 2 in the management process) includes the following:

1. Determining normality
2. Differentiating between common discomforts of pregnancy and a possible complication
3. Identifying signs and symptoms of possible deviations from normal or complications
4. Identifying areas of possible learning needs

Anticipation of related potential problems (step 3) is important in the development of a comprehensive plan of care. Evaluation of the need for immediate midwife or physician intervention and/or for consultation or collaborative management with other health care team members (step 4) becomes necessary only when there is deviation from normal, with or without an emergency situation.

Development of a comprehensive plan of care includes the following components:

1. Determination of need for laboratory tests or adjunctive studies to rule out, confirm, or differentiate between possible complications
2. Determination of need for consultation with the physician
3. Determination of need for dietary reevaluation and intervention
4. Determination of instructional measures for meeting learning needs
5. Determination of need for any discomfort relief or treatment measures
6. Determination of need for medication or other measures for treatment of minor complications (e.g., vaginitis, asymptomatic bacteriuria, initial urinary tract infection, borderline anemia)
7. Determination of need for consultations with or referrals to other health professionals (e.g., nutritionist, social worker, public health nurse)
8. Determination of need for more active inclusion of significant others
9. Determination of need for specific counseling or anticipatory guidance
10. Determination of need for HIV counseling (if you are not doing it yourself)
11. Scheduling of the next revisit. Revisits for a woman who is progressing normally through her pregnancy are usually scheduled as follows:
    a. up to 28 weeks' gestation, every 4 weeks
    b. between 28 and 36 weeks' gestation, every 2 weeks
    c. between 36 weeks' gestation and delivery, every week

    For a woman who has her first antepartal visit at 8 weeks' gestation, following this schedule will total 14 visits.

    However, the U.S. Public Health Service Expert Panel on the Content of Prenatal Care in their 1989 Report [16] recommended a reduction in the number of visits for women with normal pregnancies and no medical problems. They proposed a total of eight visits for nulliparas and six visits for multiparas for 40 weeks of gestation. Another visit at 41 weeks was added for pregnancies going beyond 40 weeks.

    Reaction was varied and included the following: (1) concern that outcomes would be negatively affected—especially the number of preterm deliveries and the number of women with preeclampsia and their respective sequella; (2) concerns that there would not be enough time and sufficient contact to adequately address the psychosocial issues of women; and (3) questions about cost effectiveness if women instead used the emergency room for pregnancy discomforts (a situation that would be circumvented with more frequent antepartal visits and related instruction). The Expert Panel recommendation was based in part on the practice in England of a lower number of scheduled visits. There was some concern expressed about superimposing a system of antepartal visits predicated on a system of health care that has provided previous health care, such as England has, onto the system in the United States where for many women prenatal care is their first exposure to the health care system.

    Although most clinicians continue with the traditional schedule of visits, some have experimented with different schedules with a reduced number of visits, ranging from six to ten for nulliparas [17, 18, 19, 20]. The findings indicate that clinical outcomes (obstetric and neonatal) are no different for this selected population. Women with a history of obstetric complications or who later develop them, as well as women who have medical problems, have more frequent visits as dictated by their condition.

The revisit appointment data are indicated on the woman's chart with the notation "RTC _____ weeks." (*RTC*, for *return to clinic*, is an abbreviation universally used to mean the return appointment time, even though the visits may not be to a clinic per se.)

12. Determination of approach to providing antepartal care. An alternative option is Centering Pregnancy [21], a group approach to the provision of antepartal care after the initial visit that breaks with both the traditional individual examination room visit with separate childbirth education classes and the traditional schedule of visits. Groups of 8 to 12 women/couples at approximately the same gestational age are formed between 12 to 16 weeks. They meet monthly for 4 months or sessions, and then biweekly, and once for an early postpartum session for a total of ten 90-minute sessions. A session includes individual risk assessment with self-care components, discussion and education periods, and support activities. Additional individual examination room visits are scheduled if necessary. Further information can be obtained at www.centeringpregnancy.com.

Case Study

The following case study is designed to illustrate how management is based on interpretation of the database starting with the findings obtained during an initial examination and continuing during the subsequent revisit. Because the case study is being presented for a specific purpose, parts of the database that would normally be detailed will instead be either omitted as insignificant for this woman or summarized as "within normal limits (WNL)" so that the parts of the database that will be used will be obvious. The first part of Chapter 2, which discusses the first five steps of the management process, should be reviewed, because those steps are utilized in this presentation. After reading the database, you are encouraged to write down your interpretation of the database, anticipation of related potential problems, and management plan before reading this part of the case study.

Initial Antepartal Examination (February 22)

Step 1. Database Ms. Oceana is a 21-year-old African American, Gravida 1 Para 0 at 24 weeks' gestation by dates, with an LMP of September 5 and an EDB of June 12.

Present Pregnancy History. Experienced quickening in mid-January. This is a planned pregnancy both she and her husband are happy about. They desire natural childbirth. Body changes are seen as evidence of the pregnancy and welcomed. Have continued sexual intercourse without problems. Has been having occasional right-sided pain for the past month, complains of a recurrent malodorous vaginal discharge, and has also felt tired throughout her pregnancy although this has not affected her activities. Otherwise her pregnancy has been uneventful. She is not taking any drugs or medications.

Past Medical History. UCHD. Had both rubeola and rubella as a child. Appendectomy at age 17; no blood transfusion. Otherwise insignificant.

Family History. Paternal grandmother is a diabetic controlled by diet and oral medication. Maternal aunt and uncle are twins. Otherwise insignificant.

Obstetric History. Primigravida.

Menstrual History. Menarche at age 11, every 28 days × 5 days with a heavy flow for the first 3 days. No dysmenorrhea.

Sexual, Contraceptive, and Douching History. Successful and satisfied with use of a diaphragm for past two years without any side effects; douches in connection with removal of the diaphragm, has also douched two to three times a week during her pregnancy because of recurrent malodorous vaginal discharge; sexual frequency is twice a week with no problems.

Social History. High school graduate; working as a secretary in an insurance office. Husband in final year of college; living in married student housing with high population of children and pets (dogs and cats) although they have no pets of their own. Does not drink or smoke. Out of town past 3 months caring for parents in noncontagious health care crisis; both are OK now, but was reason for delay in starting prenatal care. Woman states relationship is stable; denies abuse; husband supportive of pregnancy.

Physical Examination

Temperature: 98.6°F, pulse: 84, respirations: 16
Blood pressure: 120/80
Height: 5'6"
Weight: prepregnant, 150 lb; present, 164 lb
General: woman appears her age, well nourished, and in good physical and emotional health

Hair and skin: WNL
HEENT: WNL
Neck: WNL
Breasts: WNL; nipples erect; plans to breastfeed
Heart and lungs: WNL
Abdomen: WNL; scar in right lower abdomen from appendectomy
Area of right-sided pain identified as being in the right lower quadrant of the abdomen and into the right inguinal region
Fundal height: 26 cm
? breech presentation
FHT: 132 RLQ
EFW: 700 grams
No CVAT
Extremities: WNL

Pelvic Examination. Thick, white, malodorous discharge with plaques on the vaginal walls and cervix; wet smear slide shows branching hyphae and budding spores; otherwise WNL

Clinical pelvimetry:
Inlet:
diagonal conjugate—more than 11.5 cm
forepelvis—slightly narrowed
Midplane:
ischial spines—prominent
sciatic notch—quite wide, 3–4 fb
sidewalls—parallel
sacrum—flat, posterior inclination, and long
Outlet:
intertuberous diameter—more than 8 cm
pubic arch—tight 2 fb
coccyx—movable

Laboratory. Urine negative for protein, 2+ glucose by dipstick (no immediate possible explanation). All other labs negative.

Step 2. Interpretation of the Database The basis (information from the database) for each interpretation will be given.

1. Monilial vaginal infection. *Basis:*
   - **a.** complaint of a malodorous vaginal discharge
   - **b.** history of douching during pregnancy because of a malodorous vaginal discharge
   - **c.** speculum examination revealing thick, white, malodorous discharge and plaques on the vaginal walls and cervix
   - **d.** visualization of branching hyphae and budding spores on a wet smear slide
2. Need for diabetic screening to rule out diabetes. *Basis:*
   - **a.** family history shows paternal grandmother is a diabetic controlled by diet and oral medication
   - **b.** history of recurrent malodorous vaginal discharge during this pregnancy; known diagnosis of monilia at this time, and most likely the previous episodes were also monilial
   - **c.** glycosuria: 2+ glucose by dipstick not related to dietary intake (would have to have occurred twice to be the only basis for screening)
3. Right-sided round ligament pain. *Basis:*
   - **a.** complaint of occasional right-sided pain for the past month
   - **b.** area of pain identified as the right lower quadrant of the abdomen and into the right inguinal region; no s/s of preterm labor
   - **c.** had appendectomy at age 17
4. Borderline pelvis with anthropoid tendency. *Basis:*
   - **a.** clinical pelvimetry findings
     - **(1)** slightly narrow forepelvis
     - **(2)** prominent ischial spines
     - **(3)** wide sciatic notch
     - **(4)** sacrum long and flat with posterior inclination
     - **(5)** pubic arch a tight 2 fb
5. ? breech presentation. *Basis:* abdominal examination of a ? breech presentation; this has no significance at this time
6. Teaching needs:
   - **a.** Re douching, to discontinue this practice. *Basis:* patient history of douching two to three times a week during her pregnancy because of a malodorous vaginal discharge
   - **b.** Re breast care and plans for breast preparation. *Basis:* plans to breastfeed
   - **c.** Re relationship between cats and toxoplasmosis and the need to avoid care or handling of cats and any contact with their excrement. *Basis:* lives in a housing complex with a high population of cats
   - **d.** Re rest periods and positioning while resting, during the day and while at work. *Basis:* works as a secretary in an insurance office
   - **e.** Re relief measures for her right-sided round ligament pain. *Basis:* see 3 above
   - **f.** Re use of the vaginal medication prescribed for treatment of her monilial infection. *Basis:* see 1 above and Step 5, item 13

g. Re classes for preparation for childbirth and parenthood and the La Leche League. *Basis:* desires natural childbirth, plans to breastfeed
h. Re diabetic screening (why and how). *Basis:* see 2 above
i. Re pelvic measurements and question of pelvic adequacy. *Basis:* see 4 above and Step 3

Step 3. Anticipation of Related Potential Problems Possible cephalopelvic disproportion (CPD) yielding possible cesarean section. *Basis:* borderline pelvis with anthropoid tendency

Step 4. Need for Immediate Intervention or Consultation Neither is indicated at this visit.

Step 5. Management Plan Each item in the management plan will be correlated with the related interpretation of the database and subsequent anticipated problems, or marked with an asterisk (*) to denote that this is a routine item of management of the woman at the initial antepartal visit.

*1. Pap smear (done during pelvic examination)
*2. Specimen for GC and chlamydia testing (done during pelvic examination)
3. PPD test for tuberculosis (risk factors: married student housing; African American)
*4. ABO and Rh
*5. Antibody screen/antibody titers
6. Sickle cell prep or hemoglobin electrophoresis (risk factor: African American)
*7. Rubella titer
8. Varicella antibody screen (no history of disease or vaccine)
*9. VDRL or RPR
*10. Hepatitis B surface antigen
*11. Hemoglobin and hematocrit
*12. Urinalysis and urine culture
13. Monistat cream; one applicatorful intravaginally hs × 7 days (treatment of monilial vaginal infection; correlates with interpretations 1 and 6f)
14. Schedule and instruct for a 1-hour glucose challenge test (see Chapter 24) (diabetic diagnostic screening test that correlates with interpretations 2 and 6h)
15. Reevaluate pelvis upon entry into labor in relation to estimated size of the baby (correlates with interpretation 4 and anticipated potential problem of CPD)
16. Teaching about the following (correlates with interpretation 6):
    a. not douching
    b. breast care and plans for breast preparation in her last month of pregnancy
    c. cats and toxoplasmosis
    d. rest periods and positioning
    e. round ligament pain relief measures
    f. how to insert and use the Monistat vaginal cream
    g. names and telephone numbers for teachers of classes in preparation for childbirth and parenthood and for La Leche League
    h. diabetic screening and test instructions
    i. pelvic measurements, pelvic adequacy, CPD, and possible C-section
*17. RTC for dietary history and calculation of nutritional intervention in 1 week
*18. RTC for antepartal revisit in 4 weeks

First Antepartal Revisit (March 22)

Step 1. Database

Chart Review. See initial antepartal examination for name; age; parity; significant findings; identified problems and treatment; desires and plans of the woman, and teaching done; medications; and dietary requirements determined at her nutritional visit on March 1.

Results from the laboratory tests and adjunctive studies ordered at the initial visit are as follows:

1. Pap smear: class 1
2. GC testing: no *Neisseria gonorrhoeae* seen
3. Chlamydia testing: negative
4. PPD: negative
5. Blood group: O, Rh positive
6. Antibody screen: negative
7. Rubella titer: more than 1:30 (immune)
8. Varicella antibody screen: negative
9. Hemoglobin electrophoresis:
   Hemoglobin A_1 98%
   Hemoglobin A_2 2%
10. VDRL: negative
11. HBsAg: negative
12. Hemoglobin: 9.8 milligrams; hematocrit: 29%
13. Microscopic urinalysis: negative; urine culture: less than 50,000 colony count
14. 1-hour 50-gram glucose challenge test: 120 milligrams/deciliter

Today Ms. Oceana is 28 weeks' gestation by dates.

History

Basic revisit history (see earlier in this chapter) is negative.

Accuracy of LMP and EDB reconfirmed with Ms. Oceana.
Complains of continuing fatigue. Is resting midmorning, noon, and midafternoon at work, and when she first arrives home after work, as discussed at her last visit.
Relief measures for round ligament pain have been helpful and this is not keeping her awake any more.
Used full regimen of Monistat cream and is no longer having malodorous vaginal discharge.
Has not douched since her last visit.
Is avoiding cats and wears gloves for gardening.
Has contacted both a teacher of Lamaze classes and a local member of the La Leche League. She and her husband attended their first Lamaze class last night and enjoyed it. Is realistic, but hopeful, re vaginal birth.
No problems with her dietary requirements; appetite good.

Physical Examination
Blood pressure: 130/84
Weight: 167 pounds
Breasts: adequate support, no crusts on nipples
Abdominal examination:
vertex presentation; ? position; not engaged
fundal height: 32 centimeters
fetal heart tones: 132 RLQ
estimated fetal weight: 1600 grams
many small parts easily felt
abdomen soft
No CVAT
No edema of the upper or lower extremities
Knee-jerk reflexes: 2+

Pelvic Examination. Speculum examination for TOC not necessary if the woman is asymptomatic.

Laboratory. Urine negative for protein and glucose

Step 2. Interpretation of the Database The basis (information from the database) for each interpretation will be given.

1. Monilial infection cured. *Basis:* no further complaint of malodorous vaginal discharge
2. Not diabetic. *Basis:* 1-hour glucose challenge test result within normal limits.
3. Measures for round ligament pain effective. *Basis:* statement of effectiveness during history
4. Anemia. ? iron deficiency anemia. *Basis:*
   a. hemoglobin 9.8 milligrams
   b. hematocrit 29%
   c. fatigue throughout pregnancy (from initial and revisit history)
   d. heavy menstrual periods (from initial history)
   e. hemoglobin electrophoresis normal, thus ruling out sickle cell anemia and other abnormalities of hemoglobin
5. Need to rule out multiple gestation or a single large-for-dates fetus. *Basis:*
   a. fundal height of 32 centimeters is greater than expected for 28 weeks' gestation
   b. fundal height of 26 centimeters at 24 weeks' gestation (early sign of trend?)
   c. estimated fetal weight in accord with 31 to 32 weeks' gestation rather than 28 weeks' gestation
   d. many small parts easily felt; indicative of multiple gestation if not a posterior position
   e. unsure of fetal position; indicative of multiple gestation
   f. soft abdomen and ease in feeling small parts rule out polyhydramnios as a possible explanation of the discrepancy between gestational age by dates and by clinical findings
   g. LMP and EDB confirmed, which rules out inaccuracy in determining gestational age by dates
   h. only one fetal heart heard, which is indicative of a single large-for-dates fetus
   i. family history of fraternal twins on maternal side

Step 3. Anticipation of Related Potential Problems Need diagnoses before further potential problems can be identified.

Step 4. Need for Immediate Intervention or Consultation Neither of these is indicated at this time. Consultation/collaboration with your consulting physician may be indicated later in this visit, or at the next visit, depending on the ultrasonography findings and the anemia work-up test results.

Step 5. Management Plan Each item in the management plan will be correlated with the related interpretation of the database.

1. Interpretation 1: share conclusion with Ms. Oceana.
2. Interpretation 2: share results of diabetic screening test with Ms. Oceana.
3. Interpretation 4:
   a. complete blood count with differential

   b. reticulocyte count
   c. serum iron
   d. serum ferritin
   e. total iron-binding capacity (TIBC)
   f. platelet count
   g. iron prescription: ferrous sulfate 65 mg of elemental iron po BID; ensure adequate supply
   h. increase dietary iron enhanced with vitamin C in orange juice
   i. prescribe vitamin C 250 mg po BID to be taken with meals
   j. discuss with Ms. Oceana findings, concerns, probable reason for her fatigue, need to recover from her caretaking of her parents, possible need for further tests, and faithful adherence to medication regimen
4. Interpretation 5:
   a. ultrasound scan to rule out multiple gestation and to determine fetal position
   b. discuss with Ms. Oceana findings, possible reasons for discrepancy between gestational age by dates, clinical findings, and ultrasound
5. RTC in 2 weeks

Common Discomforts of Pregnancy and Their Relief Measures

Not all women experience all of the following common discomforts of pregnancy, but many women experience a few to a great number of them. Relief from these discomforts can make a significant difference in how a woman views her pregnancy experience. The physiological, anatomical, and psychological bases for each discomfort (if known) are given to stimulate your thinking about further possible relief measures. Relief measures are predicated on the causes of the discomfort and are geared toward symptomatic management. Not all relief measures work for all women. The more relief measures you know for each discomfort—or can dream up on the basis of your knowledge and understanding of the cause of the discomfort—the better the chance that at least one of them will be helpful.

Nausea

Nausea, with or without vomiting, is erroneously called morning sickness but most often occurs during the day or evening or all day long. It is more apt to occur when the stomach is empty, so it is usually worse in the morning. The cause of morning sickness is not really known, although a number of ideas have been advanced. These include hormonal changes of pregnancy, low blood sugar (perhaps caused by not eating, thereby creating a vicious cycle), gastric overloading, slowed peristalsis, and emotional factors. About half of women with nausea and vomiting are over it by 14 weeks' gestation and 90 percent by 22 weeks [22]. Women with a multiple gestation often have longer-lasting and more severe nausea and vomiting [23]. Nausea is a common problem occurring in over half to three-quarters of pregnant women—so common, in fact, that it is a presumptive sign of pregnancy. The peak prevalence of nausea and vomiting in pregnant women is at 11 weeks' gestation, with the average time of onset between 5 to 6 weeks [22]. Fortunately, nausea and vomiting are limited discomforts. There is little support for the idea that nausea and vomiting of pregnancy, especially severe nausea and vomiting, reflects the transformation of psychological distress into physical symptoms [24]. Rather, it is more likely that biological, psychological, and sociocultural factors have an intricate relationship in nausea and vomiting that is poorly understood but for some women is amenable to hypnosis [24]. Persistent and severe nausea and vomiting beyond the first trimester may indicate hyperemesis gravidarum or hydatidiform mole (see Chapter 24).

The relief measures for morning sickness are numerous. One or all or any combination or none may be effective for a particular individual. It gives most women some comfort and relief just to be trying something to ease the problem. The following suggestions can be made:

1. Eat small, frequent meals, even as often as every 2 hours, as these are more apt to be retained than three large meals a day.
2. Eat dry crackers or toast before getting up in the morning.
3. Do not brush your teeth immediately after eating to avoid stimulating the gag reflex.
4. Drink carbonated beverages—especially ginger ale.
5. Avoid foods with strong or offensive odors.
6. Restrict fats in your diet.
7. Try acupressure wristbands.
8. Keep in mind that nausea will most likely end sometime during the second trimester.
9. Rest.

10. Use medication. There are two issues with the use of drugs: (1) teratogenicity and (2) effectiveness. The overriding concern is possible teratogenic effects of a drug on the embryo or fetus during this period of time (see Figure 21-5). Midwives are cautious when it comes to the use of drugs that have not been extensively studied for teratogenic effects.

    The anti-nausea drug known as Bendectin in the United States, which contained pyridoxine (vitamin B_6) and doxylamine, is safe for use in the first trimester. However, it was removed from the market because of litigation brought against the manufacturer that claimed congenital malformations resulting from use of the drug. This legal action was taken despite 19 epidemiologic studies that showed no increased risk of congenital malformations [23, 25]. This has led to use of medications about which less is known. Although antihistamines have been shown to have some effectiveness and are generally considered to be safe during pregnancy, no major epidemiological studies, with the exception of doxylamine, have been done to look for possible adverse effects on the fetus [23].

    Nonpharmacologic therapies are the first line of treatment for nausea and vomiting. If these measures are not effective and the woman is miserable, losing time at her job, or otherwise unable to keep up with her daily routine, the midwife can recommend the use of pyridoxine (vitamin B_6) either 25 mg QID or 50 mg BID, available over-the-counter. If the woman still has a problem with nausea and vomiting, even if a reduced problem, add the other effective ingredient that was in Bendectin, which was doxylamine [25]. Doxylamine, an antihistamine, is sold over-the-counter in 25 mg tablets as the hypnotic drug Unisom. Possible dosages include 50 mg of pyridoxine and 1 Unisom tablet at bedtime in addition to 25 mg pyridoxine BID; or, 25 mg pyridoxine and one-half of a Unisom tablet TID with a warning to the woman about possible drowsiness.

In addition, communicate to the woman's significant others to provide her with considerate, understanding, loving treatment with special attention to the little things that are important to her.

Ptyalism (Excessive Salivation)

Ptyalism is an unusual condition that may be caused either by increased acidity in the mouth or by the intake of starch, stimulating the salivary glands in women susceptible to excessive secretion. Women who have ptyalism frequently are also nauseated. Their condition becomes cyclic, for not only does the excessive saliva intensify the nausea but also the desire to avoid nausea causes the patient to swallow less, thus increasing the amount of saliva in the mouth.

Fatigue

Fatigue occurs during the first trimester for no known reason. One idea is that it results from the initial fall in the basic metabolic rate early in the pregnancy, but why this happens is not clear. Another idea is that the increase in progesterone has a sleep-inducing effect. Fortunately, it is a limited discomfort, usually disappearing by the end of the first trimester. It can have the effect of increasing the intensity of the psychological responses the woman is having during this time.

The relief measures are to reassure the woman of the normality of fatigue and its spontaneous remission by the second trimester. It will help her to have frequent rest periods if possible during the day until this passes. Mild exercise and good nutrition also combat fatigue.

Upper Backache (Nonpathological)

Upper backache develops during the first trimester because of the increase in size and resulting heaviness of the breasts, which is one of the presumptive signs of pregnancy. This enlargement may produce muscular strain if the breasts are not adequately supported.

The relief measure, then, is a well-fitting and supportive brassiere. The characteristics of a good bra are listed later in this chapter in the discussion of instruction and anticipatory guidance. By decreasing breast mobility, a snug, supportive bra also reduces the discomfort of breast tenderness resulting from enlargement.

Leukorrhea

Leukorrhea is a profuse, thin or thick vaginal secretion that begins during the first trimester. The secretion is acidic because of the conversion of an increased amount of glycogen in the vaginal epithelial cells into lactic acid by Döderlein's bacilli. Although this serves the function of protecting the mother and fetus against possible harmful infection, it does provide a medium that fosters the growth of the organisms responsible for vaginitis. The productivity of the cervical glands in secreting an increased amount of mucus at this time to form the cervical mucus plug may also contribute to leukorrhea. Relief measures are close attention to bodily

cleanliness in the area and frequent changes of cotton-crotch panties. The woman should not douche or use feminine hygiene sprays.

Urinary Frequency (Nonpathological)

Urinary frequency as a nonpathological discomfort of pregnancy often occurs at two different times during the antepartal period. Frequency during the first trimester is due to the increased weight in the fundus of the uterus, with the softening of the isthmus (Hegar's sign) causing increased anteflexion of the enlarging uterus, which exerts direct pressure on the bladder. This pressure lessens as the uterus continues to enlarge and rises out of the pelvis to become an abdominal organ while the bladder remains a pelvic organ. Urinary frequency during the third trimester occurs most often in primigravidas, after lightening has occurred. The effect of lightening is that the presenting part descends into the pelvis and causes direct pressure against the bladder. The pressure makes the woman feel the need to urinate. The enlarging uterus or the presenting part also takes up space in the pelvic cavity, thereby allowing less room for distention of the bladder before the woman feels the need to urinate. Also to be remembered is the reversal of the usual diurnal pattern to nocturia as dependent edema accumulated during the day is excreted (see the discussion of maternal physiological changes in Chapter 21).

The only relief measures are an explanation of why this is happening and a decrease in fluid intake before bedtime so that the woman need not make many trips to the bathroom when she is trying to sleep.

Heartburn

Heartburn—a discomfort that may start toward the end of the second trimester and extend through the third trimester—is another word for regurgitation, or the reflux, of acidic gastric contents into the lower esophagus by reversed peristalsis. The gastric contents are acidic by virtue of the hydrochloric acid in the stomach. This acidity causes the material to burn the throat and taste bad. The causes of heartburn are thought to be as follows:

1. Relaxation of the cardiac sphincter of the stomach due to the effects of increased amounts of progesterone
2. Decreased gastrointestinal motility resulting from smooth muscle relaxation, which is probably due to increased amounts of progesterone and uterine pressure
3. Lack of functional room for the stomach because of its displacement and compression by the enlarging uterus

There are numerous relief measures for heartburn. Finding the combination that will help an individual woman is largely a matter of trial and error. The following suggestions can be made:

1. Eat small, frequent meals, to avoid overloading of your stomach.
2. Maintain good posture, to give more room for your stomach to function; slumped posture only adds to the problem by allowing further pressure on your stomach.
3. Stretch your arms high over your head, to give room for your stomach to function.
4. Avoid fats with meals; fat depresses both motility of the stomach and the secretion of gastric juices needed for digestion.
5. Avoid beverages with meals, since liquids tend to inhibit gastric juices; a dry diet without breadstuffs has helped some women.
6. Avoid very cold foods with meals.
7. Avoid spicy foods or other foods causing indigestion.
8. Drink cultured milk rather than sweet milk; this has helped some women.
9. Drink skim milk and/or eat low-fat ice cream; this has helped some women.
10. Avoid heavy foods or a full meal just before bedtime.
11. Use antacid preparations with aluminum hydroxide, magnesium hydroxide, or magnesium trisilicate (e.g., Maalox, Mylanta, Gaviscon, Gelusil), Amphojel, and milk of magnesia. Sodium bicarbonate (Alka-Seltzer) should be avoided as sodium could increase edema [17].

Flatulence

Increased flatulence is thought to be due to decreased gastrointestinal motility. This probably results both from the effect of increased progesterone on relaxing smooth muscle and from the displacement of and pressure on the intestines by the enlarging uterus.

The only relief measures are a regular pattern of daily bowel movements and avoidance of gas-forming foods. The knee-chest position will help with discomfort from unexpelled gas.

Constipation

Women previously without a problem of constipation may develop this problem during the second or

third trimester. Constipation is thought to result from decreased peristalsis caused by relaxation of the smooth muscle of the large bowel in the presence of increased amounts of progesterone. The displacement and compression of the bowel by the enlarging uterus or presenting part may also contribute to decreased motility in the gastrointestinal tract and thus to constipation. One of the common side effects of iron medication is constipation; this compounds the problem for a large percentage of pregnant women.

The following relief measures for constipation are most effective when all are used in combination. Medication should be used only if the natural methods are not sufficient.

1. An adequate fluid intake, defined as a minimum of eight glasses (drinking-glass size) per day
2. Prunes or prune juice; prunes are a natural mild laxative
3. Adequate rest; this may require rest periods during the day
4. Warm liquids (e.g., water, tea) on rising, to stimulate peristalsis
5. Foods that contain roughage, bulk, and natural fiber (e.g., lettuce, celery, bran)
6. Establishment of regular and good bowel habits; this includes establishing a regular time of day for having a bowel movement and being conscious of not ignoring the "urge" or delaying having a bowel movement
7. General exercise, a daily walk, good posture, good body mechanics, and daily exercise of contracting the lower abdominal muscles; all of these measures facilitate venous circulation, thereby preventing congestion in the large intestines
8. Mild laxatives, stool softeners, and/or glycerin suppositories if indicated

Hemorrhoids

Hemorrhoids often are preceded by constipation. Therefore, all the causes of constipation have the potential of leading to the development of hemorrhoids. Progesterone also causes relaxation of the vein walls and of the large bowel. In addition, the enlarging uterus causes increasing pressure—specifically in the hemorrhoidal veins as well as generally; the pressure interferes with venous circulation and causes congestion in the pelvic veins.

There are a number of relief measures for hemorrhoids. Some solely give comfort; others both numb and reduce the hemorrhoids. The latter are noted in the following listing of relief measures for hemorrhoids:

1. Avoidance of constipation—prevention is the most effective measure
2. Avoidance of straining during defecation
3. Sitz baths; the heat of the water not only gives comfort but also increases circulation
4. Witch hazel compresses (for reduction)
5. Ice bag (for reduction)
6. Epsom salt compresses (for reduction)
7. Reinsertion of the hemorrhoids into the rectum (using lubrication) in conjunction with perineal tightening (Kegel) exercises
8. Bedrest with hips and lower extremities elevated
9. Analgesic ointments and/or topical anesthetics
10. Preparation H

Leg Cramps

The physiological basis for leg cramps is not clear. For a number of years, leg cramps were thought to be caused by inadequate or impaired calcium intake or an imbalance in the calcium-phosphorous ratio in the body, but these causes are no longer stated in current literature. Another school of thought is that the enlarged uterus exerts pressure either on the pelvic blood vessels, thereby impairing circulation, or on the nerves as they course through the obturator foramen on their way to the lower extremities. Relief measures are as follows:

1. Have the woman straighten her affected leg and point her heel (i.e., dorsiflex her foot). If the woman is in bed, she needs strong, steady pressure against the bottom of her foot, either someone's hand or the footboard of the bed, to push against; if she is standing, the floor serves this function. This measure is nearly guaranteed to instantly alleviate an acute leg cramp.
2. Encourage general exercise and a habit of good body mechanics to improve circulation.
3. Recommend leg elevation periodically throughout the day.
4. Recommend a diet that includes both calcium and phosphorous.

Dependent Edema

Dependent pedal edema is the result of impaired venous circulation and increased venous pressure in the lower extremities. These circulatory disturbances are caused by pressure of the enlarging

uterus on the pelvic veins when the woman is sitting or standing and on the inferior vena cava when she is supine. Any constrictive clothing that inhibits venous return from the lower extremities adds to the problem. Dependent edema is generally evidenced in the ankles and feet and must be carefully differentiated from edema associated with preeclampsia/eclampsia (see Chapter 24). Relief measures include the following:

1. Avoidance of constrictive clothing
2. Elevation of the legs periodically throughout the day
3. Positioning on the side when lying down
4. A maternity abdominal support or girdle, which may take the pressure off the pelvic veins

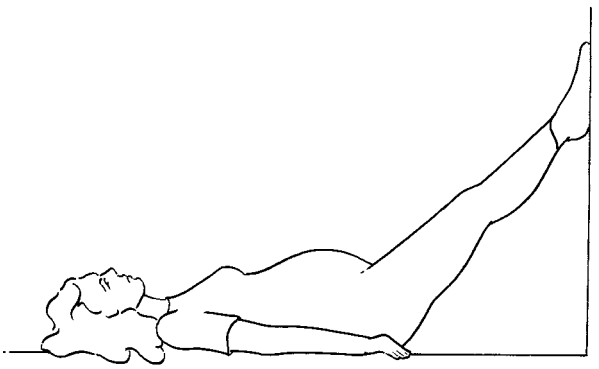

FIGURE 22-1 Right-angle position.

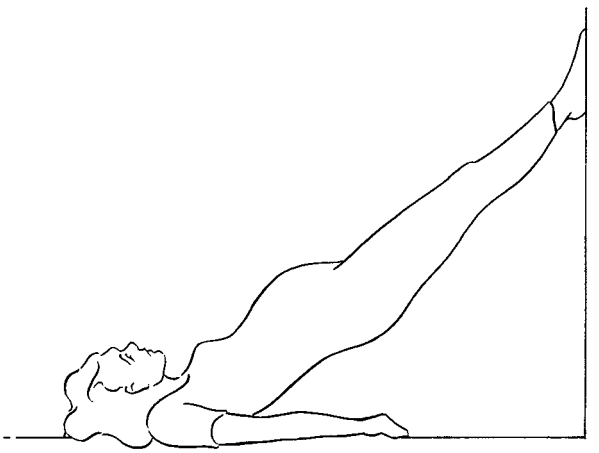

FIGURE 22-2 Incline position.

Varicosities

A number of factors may contribute to the development of varicosities during pregnancy. Varicose veins are more apt to occur in women who have a familial tendency or congenital predisposition. Varicosities may result from impaired venous circulation and increased venous pressure in the lower extremities; these changes are caused by pressure of the enlarging uterus on the pelvic veins when the woman is sitting or standing and on the inferior vena cava when she is supine. Any constrictive clothing inhibiting venous return from the lower extremities or prolonged periods of standing add to the problem. Progesterone-induced relaxation of the vein walls and valves and surrounding smooth muscle also contributes to the development of varicosities.

Varicosities during pregnancy are most pronounced in the legs and/or vulva. Relief measures specific to vulvar varicosities are so noted in the following list of suggestions to a woman:

1. Use support hose, Ace bandages, or elastic stockings; whichever is used should be put on after elevating your legs and before arising.
2. Avoid constrictive clothing (e.g., knee-high or ankle hose, round garters).
3. Avoid long periods of standing.
4. Have rest periods, with your legs elevated, periodically throughout the day.
5. Lie in the right-angle position several times daily (Figure 22-1).
6. Assume the incline position several times daily (for vulvar varicosities) (Figure 22-2).
7. Keep your legs uncrossed when sitting.
8. Sit whenever possible, preferably with your legs elevated, rather than standing.
9. Maintain good posture and good body mechanics.
10. Engage in mild exercise and walking, to facilitate increased circulation.
11. Provide physical support for vulvar varicosities with a foam-rubber pad held in place with a sanitary belt.
12. Wear a maternity abdominal support or girdle, to relieve pressure on your pelvic veins.
13. Do Kegel exercises for vulvar varicosities or hemorrhoids, to increase circulation.
14. Take warm, soothing baths.

Dyspareunia

Pain during sexual intercourse may stem from a number of causes during pregnancy. Physiological changes may be responsible, such as pelvic/vaginal congestion resulting from impaired circulation

caused by pressure of the enlarging uterus or the presenting part. Physical problems may be posed by an enlarged abdomen or may be encountered in late pregnancy when the presenting part descends into the true pelvis. Psychological factors may cause dyspareunia because of misconceptions and fears of hurting the baby when there is no basis for this concern unless there is vaginal bleeding or the membranes have ruptured. Appropriate relief measures depend on the causes.

1. Positional changes will alleviate problems that are caused by an enlarged abdomen or pain from deep penetration.
2. Ice may reduce accessible congestion but imposes its own discomforts.
3. Discussion of misconceptions and fears and the provision of facts may reassure the woman.
4. Both partners may welcome information on alternative ways of sexually satisfying each other.

Nocturia

In addition to the urinary frequency of the first trimester and possibly the third trimester discussed earlier, nocturia is thought to have a physiological basis. Venous return from the extremities is facilitated when the woman lies in a recumbent lateral position, since the uterus is no longer pressing against the pelvic vessels and inferior vena cava. When the woman lies in this position while sleeping at night, the result is a reversed diurnal pattern, which yields increased urinary output. The only relief measures consist of whatever comfort she derives from an explanation of why this is happening and reduction of fluids after the evening meal so her intake during this time does not add to the problem.

Insomnia

Insomnia in both pregnant and nonpregnant women may be due to any number of causes such as concerns, anxieties, or excited anticipation of an event the next day. The pregnant woman, however, has additional, physical reasons for insomnia. These include the discomfort of the enlarged uterus, other discomforts of pregnancy, and fetal movement, especially if the fetus is active. The time-honored relief measures for insomnia may or may not be effective. For many women they are at least something to do.

1. Warm baths
2. Warm drink (milk, decaffeinated tea with milk) before going to bed
3. Nonstimulating activity prior to going to bed
4. Use relaxation positions (e.g., Figure 22-3)
5. Use the technique of progressive relaxation

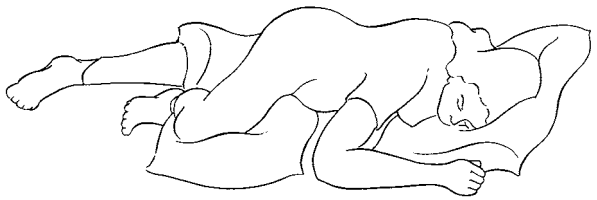

FIGURE 22-3 Side-lying relaxation position.

Round Ligament Pain

The round ligaments attach on either side of the uterus just below and in front of the insertion of the fallopian tubes; they then cross the broad ligament in a fold of peritoneum, pass through the inguinal canal, and insert in the anterior (upper) portion of the labia majora on either side of the perineum. The ligaments are composed largely of smooth muscle that is continuous with the smooth muscle of the uterus. This muscle tissue enables the round ligaments to hypertrophy during pregnancy and, in essence, stretch as the uterus enlarges. It is anatomically mandatory that the round ligaments be able to increase in length as the uterus rises high into the abdomen. Round ligament pain is thought to result from this stretching and possibly from the pressure of the increasingly heavy uterus on the ligaments. It is a common discomfort that must be differentiated from gastrointestinal tract and abdominal organ disease (e.g., appendicitis, gallbladder inflammation, and peptic ulcer). One feature that aids in this differentiation is the extension of pain into the inguinal area, which, among the conditions mentioned, is peculiar only to round ligament pain.

Relief measures are few and not always effective. Round ligament pain is one of the discomforts that a pregnant woman simply has to put up with. Explanations of why she is having pain will at least alleviate anxieties or fears and may help her to cope. Additional measures include the following:

1. Flexing her knees onto her abdomen
2. Bending toward the pain to ease the stretch on the ligament
3. Pelvic tilt
4. Taking warm baths
5. Applying a heating pad to the area; this relief measure should be used only if you are sure the pain is not caused by any medical complication such as appendicitis

6. Supporting the uterus with a pillow under it and a pillow between her knees when lying on her side (Figure 22-3)
7. Wearing a maternity abdominal support or girdle

Low Back Pain (Nonpathological)

Low back pain is backache in the lumbosacral region. The pain usually increases in intensity as the pregnancy progresses, because it results from a shift in the woman's center of gravity and thus in her posture; these changes are produced by the weight of the enlarging uterus. Unless the woman pays deliberate attention to her posture, she will walk with a swayback from increasing lordosis. This curvature strains the back muscles and causes the ache or pain. It has been suggested that students who have not experienced pregnancy should tie a 10-pound bag of sugar or flour around their waists and walk around with it to get an idea of what this localized weight does to the back.

The problem is exaggerated if the woman's abdominal muscles are lax; they fail to give any support to the heavy enlarged uterus. Without support the uterus sags, a condition that increases the curvature of the back still further. Weakness of the abdominal muscles is more common in grand multiparas who have not exercised and regained their abdominal muscle tone after each pregnancy. Primigravidas usually have excellent muscle tone, because their muscles have not been stretched before. Low back pain, thus, generally increases in severity with parity.

Backache may also result from excessive bending, walking without rest periods, and lifting, especially if any or all of these are done when the woman is tired. Such activities add strain to the back. Proper body mechanics for lifting are essential to avoid this type of muscular strain. There are two principles to be followed:

1. Stoop, rather than bend, to lift anything (e.g., toddler, groceries) so that the legs (thighs), rather than the back, bear the weight and strain.
2. Spread the feet apart and place one foot slightly in front of the other when stooping so there is a broad base for balance when rising from the stooped position (Figure 22-4).

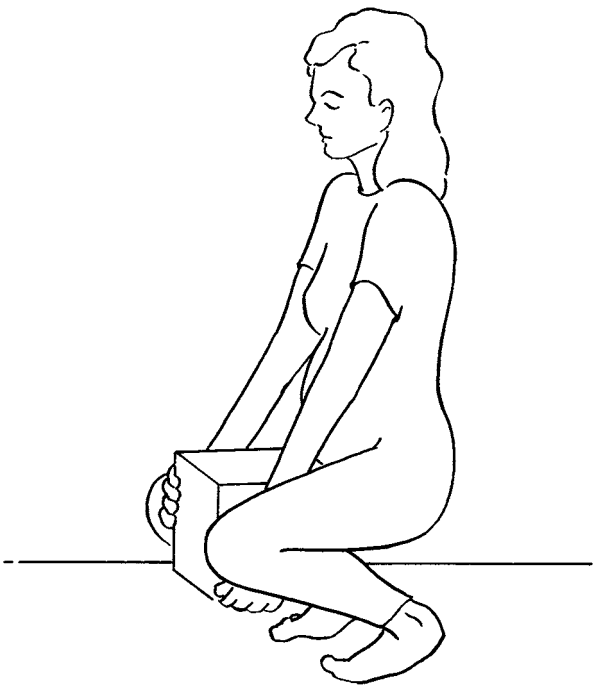

FIGURE 22-4 Proper position for lifting.

Relief measures for low back pain are as follows:

1. Good posture
2. Proper body mechanics for lifting
3. Avoidance of excessive bending, lifting, or walking without rest periods
4. Pelvic rock/pelvic tilt
5. Supportive low-heeled shoes; high heels are unstable and further exaggerate the problem of the center of gravity and lordosis
6. If the problem is severe, external abdominal support is advisable (e.g., a maternity girdle or supportive elastic "Belly Band")
7. Warmth (not too hot) on the back (e.g., heating pad, warm bath, sitting in a warm shower)
8. Ice packs on the back
9. Massage/back rub
10. For resting or sleeping:
    a. a supportive mattress
    b. positioning with pillows to straighten the back and alleviate pulling and strain

Hyperventilation and Shortness of Breath (Nonpathological)

It is thought that the increased amount of progesterone during pregnancy acts directly on the respiratory center to lower the carbon dioxide levels and increase the oxygen levels. Increased oxygen levels benefit the fetus. The increased metabolic activity that occurs with pregnancy causes an increase in carbon dioxide levels; hyperventilation lowers car-

bon dioxide levels. Women may experience this effect of progesterone early in the second trimester. (See the section on maternal physiological changes in Chapter 21.)

Shortness of breath is largely a discomfort of the third trimester. During this time, the uterus has enlarged to the point of pressing on the diaphragm. In addition, the diaphragm elevates approximately 4 centimeters during pregnancy. Although there is some widening of the transverse diameter of the thoracic cage, it is not sufficient to compensate for the elevation of the diaphragm, and a decrease in both the functional residual capacity and the residual volume of air results. This combined with the pressure being exerted on the diaphragm (possibly decreasing still further the functional residual volume) causes a feeling or awareness of slight difficulty in breathing and shortness of breath. Many women tend to respond to this by hyperventilating.

The midwife can offer the following relief measures for hyperventilation:

1. Explain the physiological basis of the problem.
2. Encourage the woman to deliberately regulate the speed and depth of her respirations at normal rates when she is aware of hyperventilating.
3. Teach the woman how to alleviate shortness of breath as a causative factor (described below).

The relief measures for shortness of breath are geared toward providing more room for abdominal contents, thereby reducing the pressure on the diaphragm and facilitating lung functioning. These are as follows:

1. Have the woman periodically stand up and s—t—r—e—t—c—h her arms above her head and take a deep breath.
2. Encourage good posture; no slumping of shoulders.
3. Teach the woman to do intercostal breathing.
4. Instruct her to do the same stretching when in bed as when standing.
5. Explain the reasons for shortness of breath; alleviation of anxieties or fears will reduce a response of hyperventilation.

Tingling and Numbness of Fingers

The change in the center of gravity resulting from the enlarged and heavy uterus may cause the woman to assume a posture in which her shoulders are too far back and her head is anteflexed in an effort to counterbalance her heavy front and curved back. This posture is thought to cause compression of the median and ulnar nerves in the arm, which would cause tingling and numbness of the fingers. Hyperventilation may also cause finger tingling and numbness, but most women do not hyperventilate enough as a result of pregnancy to have this effect. Relief measures include an explanation of the probable cause and encouraging scrupulous attention to good posture. Some women obtain relief simply by lying down.

Another possible explanation for finger tingling and numbness is carpal tunnel syndrome. Edema reduces the available space in the carpal tunnel through which the median nerve passes (see Chapter 7). Compression of the nerve causes these symptoms, which are usually bilateral, vary in severity, and at times become distressingly painful. Starting in the second or third trimester, the symptoms usually occur at night and resolve themselves by two weeks postpartum. Treatment is designed to alleviate symptoms and consists of wrist splints that keep the wrist in a neutral position and are worn while sleeping.

Supine Hypotensive Syndrome

Supine hypotensive syndrome causes the woman to feel faint; she may pass out if the problem is not immediately alleviated. Supine hypotensive syndrome occurs when the woman lies in a supine position (such as for sleep or on an examining table), because the full weight of the enlarged uterus and its contents is on the inferior vena cava and other vessels of the venous system. Venous return from the lower half of the body is inhibited, which in turn reduces the amount of blood filling the heart and subsequently lowers cardiac output. Supine hypotensive syndrome is actually obvious arterial hypotension. In addition, the weight of the enlarged uterus compresses the aorta, which also results in deleterious changes in arterial pressure.

Supine hypotensive syndrome is alleviated immediately by simply having the woman either turn on her side or sit up. Reassurance and explanation are essential, since she is likely to be frightened.

Nutritional Intervention in Pregnancy

Importance of Nutrition

The quality of life is inseparably bound not only to prenatal care in general but also to prenatal and

postnatal nutrition and environmental influences specifically. If prenatal nutrition has been inadequate, scrupulous attention to postnatal nutrition is like locking the barn door after the horse has been stolen—it is at best merely salvaging what remains.

The genetic design for fetal growth and development is determined by the genetic constitution of the individual fetus; however, it is influenced by maternal factors. Maternal factors cannot improve the genetic design, but some factors prohibit fulfillment of the design. Prohibitive factors include prenatal malnutrition, smoking, and maternal disease.

Birth weight is used as the standard evaluative measurement of a newborn all over the world, inasmuch as it is the most accurate and routinely obtained measurement. The importance of the newborn's birth weight and the importance of the factors that influence the birth weight have been identified and enumerated in a number of studies [26–35].

Maternal disease may affect the fetus in a number of ways. Maternal disease may lead to either a small-for-gestational-age infant (e.g., as a result of preeclampsia) or a large-for-gestational-age infant (e.g., as a result of gestational diabetes). Because smoking interferes with metabolic processes, it has been correlated with babies that are significantly smaller by birth weight than the babies of nonsmoking mothers.

Many studies focus on the effect of malnutrition on pregnancy outcome. This is because nutrition is a factor in all pregnancies, whereas smoking and maternal disease affect only the babies of mothers who smoke or are ill. Therefore, when these two factors (smoking and maternal disease) are controlled, differences in birth weight are directly related to nutrition during pregnancy. Maternal nutritional factors that have been shown to relate to birth weight are (1) prepregnancy weight and (2) weight gain during pregnancy.

One other factor that has an obvious direct correlation with birth weight is gestational age. As the length of gestation increases, there is an increase in birth weight (see Chapter 21). It has also been shown that male babies weigh more than female babies by an average of approximately 144 grams (5 ounces) and that birth weight increases with parity.

Other maternal factors have been studied but do not correlate with birth weight when prepregnancy weight, weight gain during pregnancy, maternal disease, and smoking are controlled. Maternal factors that do *not* correlate with birth weight include age, height, marital status, and income.

Whether it results from prematurity or from the baby's being small for gestational age, low birth weight has been shown to correlate with an increased incidence of the following:

1. Perinatal mortality (stillbirth, neonatal death)
2. Small head circumference
3. Mental retardation
4. Cerebral palsy
5. Learning problems/disabilities
6. Visual and hearing defects
7. Neurologic defects
8. Poor infant growth (stunted) and development

Conversely, a high maternal weight gain has been shown to be associated with an increased birth weight and, therefore, with the following:

1. Reduction in the rate of prematurity
2. Better postnatal growth (height and weight) as measured at 8 months and better performance (neurological, motor, and mental) as measured at 12 months in the Collaborative Study of Cerebral Palsy [28]
3. Decreased incidence of the detrimental outcomes associated with low birth weight

Furthermore, brain growth may be directly affected by maternal nutrition. There are two types of cellular growth: (1) hyperplasia, in which there is an increase in the number of cells by cell division, and (2) hypertrophy, in which there is an increase in the size of the existing cells. Malnutrition during either type of cellular growth results in a smaller organ. If the fetus suffers malnutrition during hyperplastic growth, the damage is irreversible, since the smaller size of the brain is due to a reduced number of cells. If the fetus suffers malnutrition during hypertrophic growth, the damage is reversible at any time with improved nutrition, since the smaller size of the brain results from a lack of increase in the size of the cells. Although the details of human brain growth are not known, it is generally thought that the bulk of cellular growth of the brain is from 15 weeks gestation to 2 years of age, with a peak from 28 weeks gestation to 6 months after birth. Most likely this peak period of brain growth reflects the second of the sequential three phases of growth: (1) hyperplasia only, (2) combination of hyperplasia and hypertrophy, and (3) hypertrophy only.

Thus the profound effect of malnutrition during gestation becomes obvious. However, the impact of malnutrition becomes even greater when the

causes of intrauterine growth failure are considered. Two causes have been identified: (1) uteroplacental insufficiency and (2) malnutrition or, specifically, maternal protein deficiency. With uteroplacental insufficiency, fetal growth retardation is asymmetric; that is, the body and body organs are small but the brain is of normal size with its full complement of cells. With malnutrition, fetal growth retardation is symmetric; that is, the body, body organs, and brain are all reduced both in size and in the number of cells by approximately the same percentage amount. Studies of rats show that prenatal malnutrition results in a 15 percent reduction in the number of fetal brain cells, that postnatal malnutrition results in a 15 percent reduction in the number of brain cells, and that a combination of prenatal and postnatal malnutrition results not in a 30 percent but in a 60 percent reduction in the number of brain cells [28].

The meaning of low birth weight in relation to malnutrition needs to be redefined. The traditional definition of prematurity is birth weight below 2500 grams (5 pounds 8 ounces). However, babies between 2500 and 2999 grams (5 pounds 8 ounces and 6 pounds 10 ounces) should also be considered at risk by virtue of low birth weight. Considerable focus has been concentrated on newborns that weigh less than 2500 grams, and miraculous reduction of mortality has been achieved with the technology to be found in neonatal intensive care units. The high perinatal mortality rate for newborns weighing less than 2500 grams at birth certainly warrants this attention. But the group of babies weighing between 2500 and 3000 grams at birth gets lost in the shuffle. Although this group shows much less perinatal mortality than the under-2500 gram group, its mortality rate is still three times higher than the rate for babies weighing between 3000 and 3500 grams (6 pounds 10 ounces and 7 pounds 12 ounces) at birth. Babies in the 2500 to 2999 gram weight group also show an increased incidence of the detrimental conditions listed earlier for low-birth-weight babies. Thus, 3000 grams, or approximately $6\,^1/_2$ pounds, seems to be another critical cutoff point, as is $5\,^1/_2$ pounds [31, 34, 36].

The statistics improve considerably for babies in the 3000 to 3499 gram (6 pounds 10 ounces to 7 pounds 12 ounces) group. However, the optimum birth weight seems to be between 3500 and 4000 grams (7 pounds 12 ounces to 8 pounds 14 ounces); studies show this group to have an increased incidence of higher intelligence and a decreased incidence of physical disabilities. This weight range also represents the upper end of a continuum reflecting steadily better pregnancy outcome.

As little as 120 grams (4 ounces) in birth weight can make a very real difference in pregnancy outcome. In two separate studies (one comparing private and clinic populations, the other comparing whites and blacks), a 120-gram difference in average birth weight accounted for twice as much perinatal mortality and twice the incidence of low birth weight in the clinic babies and in the black babies. Proper prenatal nutrition eradicates the differences in outcome in these populations [37].

Genetic design not only determines fetal growth potential but also appears to limit fetal growth after that potential has been attained. In other words, increased maternal caloric and nutrient (protein) intake will not result in obese, oversized babies incapable of being delivered vaginally if this is not the genetic design. The pregnancy outcome cannot surpass the potential, but it can fall considerably short. For all babies, the determinant of whether that potential is met seems to be nutrition. Some babies suffer from exposure to additional factors such as maternal disease and smoking. Even for such babies, good maternal nutrition can help ameliorate the effects of these factors.

The tragedy thus lies with the 2500 to 3000 gram (5 pounds 8 ounces to 6 pounds 10 ounces) group of babies, whose mortality is much lower than the below-2500 gram babies but who are more likely not to have met their genetic potential. Mental retardation and physical disabilities are more common in this group than in neonates weighing over 3000 grams. Although the ideal is to strive for birth weights between 3500 and 4000 grams, it is probably more realistic, and certainly a worthy goal, to strive for birth weights above 3000 grams (6 pounds 10 ounces).

It is estimated that approximately 10 percent of the population of the United States is born with mental or physical handicaps or both. Since these deficits are often directly related to prenatal malnutrition, improving maternal nutrition to the point of raising birth weights to over 3000 grams would have a profound effect on individual and societal quality of life. Its economic effect would also be felt nationally. One need only compare the cost of providing supplementary food, when needed, to a pregnant woman and the estimated economic savings if just one individual is prevented from being severely

mentally retarded. The costs of programs for the mentally retarded mount into billions of dollars each year. Between the cost for an optimal outcome and the cost of caring for the severely mentally retarded is the cost to society of those individuals who are not severely mentally retarded but who are functioning mentally and/or physically at a lower level than they would have been had their genetic potential been met. Their potential contribution to society is forever lost. And finally, there are the emotional and economic costs borne by the families of those born with mental and/or physical handicaps.

Nutritional Needs

Given the foregoing information, it suffices to say that nutrition of the mother is a prime concern in prenatal care. The woman requires specific instruction regarding certain aspects of maternal nutritional needs: calories, protein, iron, folic acid, and vitamin C.

Caloric and protein needs go hand-in-hand. This is true because the body needs calories to "protect" the protein so that it is not burned for energy. When caloric intake is insufficient, it is possible for a woman to have protein deficiency even when protein intake is adequate, because the protein will be used for meeting the metabolic energy requirements of the mother. A measurement of positive nitrogen balance indicates protein storage. If 90 to 100 percent of the protein intake is being utilized, only a small amount is being stored. The result is a smaller baby. If there is a 30 percent utilization of the protein intake, the remainder is stored and a larger baby will result. A positive nitrogen balance depends on both the calorie and the protein intake and indicates protein storage. Further, if both calorie and protein intake are so inadequate that fat is catabolized to meet the maternal metabolic energy requirements, maternal acetonuria will occur. This may result in neurological damage of the fetus.

The Recommended Daily Dietary Allowances (RDA) of the Food and Nutrition Board of the National Academy of Sciences–National Research Council indicate that in general a pregnant woman should take in 300 calories in addition to the 2200 calories recommended for nonpregnant women and 60 grams of protein, which is 10 grams per day over the 50 grams of protein recommended for nonpregnant women [38]. These numbers are based on the results of a number of studies, which have been analyzed and reanalyzed; most have some type of design or statistical flaw(s). The usual protein intake of pregnant women in the United States is in excess of the RDA, but many are below the RDA for calories [37]. The number of calories in the RDA is too generalized to assure adequate caloric intake by the *individual woman*. Further, the RDA for protein is less than the amount advocated by those researchers and clinicians who recommend 85 to 90 grams of protein per day, with calories to cover, and even more for the pregnant adolescent because of concurrent maternal growth needs. The obvious conclusion is that caloric and protein intake needs to be calculated for each individual to ensure the optimal pregnancy outcome. This calculation is described later in this chapter. Dietary restrictions, nagging and scolding the woman for weight gain, calculations of ideal weight gains based on the weight by trimester of the products of conception and pregnancy components, and reducing diets for maternal obesity should be banished forever.

The adage that protein intake indicates the adequacy of the diet in general is based on the fact that foods that are good sources of protein are also good sources of other nutrients. In other words, if the protein intake is adequate, most of the other necessary dietary nutrients are also adequate. The exceptions to this generalization during pregnancy are the inadequate intake of minerals—iron, zinc, calcium, and magnesium—and of vitamins—D, E, B_6, and folate—when compared to the RDA [37, pp. 260–263, 384]. The conclusion of experts, however, is that the RDA includes a wide margin of safety and the finding that the average nutrient intake of these minerals and vitamins is below the RDA does not warrant routine supplementation except in nutritional high risk populations, special circumstances, and for iron [37, pp. 16–18].

Nutritional high-risk populations are defined as women who use tobacco, alcohol, caffeine or coffee, marijuana, or cocaine [37, pp. 16–18]. Special circumstances include lactose intolerance (especially in black and Hispanic populations), multiple gestation, and strict vegetarianism. The concern is that these women may not consume enough vitamin D and calcium, which are usually obtained through vitamin D–fortified milk.

It is generally accepted that all pregnant women (except women who have a medical contraindication, e.g., hemochromatosis) should receive iron supplementation in the form of ferrous iron 30 milligrams daily (150 milligrams ferrous sulfate, 300 milligrams ferrous gluconate, or 100 milligrams ferrous fumarate) during the second and third trimesters [37, p. 20]. This supplementation is to

meet the demand for both maternal and fetal hemoglobin synthesis during pregnancy and to compensate for blood loss at the time of delivery. Most women do not have iron stores adequate to meet these demands, and their dietary intake is insufficient to do so. Supplemental iron reduces the incidence of iron deficiency anemia. If a woman becomes anemic, then a higher dosage is indicated. Nonheme iron comprises the vast majority of dietary iron. Meat and ascorbic acid–rich fruits and vegetables enhance absorption of nonheme iron. Tea, coffee, and milk, on the other hand, reduce absorption of nonheme iron [37, p. 281]. The pregnant woman is thus best counseled to take her iron pill between meals with orange juice. However, the need for iron supplementation in well-nourished healthy pregnant women has been questioned and some professionals have expressed concern about possible excessive iron intake, related increased blood viscosity, and stored iron as a risk factor for myocardial infarction [39].

Folic acid supplementation in the amount of an additional 200 to 400 micrograms, or a total of 0.4 to 0.8 milligrams daily, reduces considerably the incidence of megaloblastic anemia and should be used in conjunction with iron when a woman shows indications of anemia. The use of 400 micrograms of folic acid to reduce the risk of having a baby with spina bifida or other neural tube defects is effective only prior to conception and during the first 6 to 8 weeks of pregnancy.

Vitamin C, 250 milligrams daily taken with meals, enhances absorption of nonheme iron from dietary sources. Vitamin C may also enhance iron absorption from iron supplements and may be prophylactic for postpartal hemorrhage.

The long-standing practice of routinely restricting sodium intake during pregnancy or as part of the treatment for preeclampsia has been severely questioned and is considered passé. Restriction of sodium intake combined with the use of diuretics is potentially dangerous. Such practice is not considered safe management of a pregnant woman unless the woman has medical complications when she is *not* pregnant that require the restriction of sodium intake as part of the treatment regimen. During pregnancy, the body establishes a compensatory mechanism in order to conserve sodium, which would otherwise be excessively lost (with resulting electrolyte imbalance) because of a 50 percent increase in glomerular filtration rate. If a system that is trying to conserve sodium from normal physiological processes is further insulted by dietary restriction, the mechanism is compromised through overwork.

When a woman is overweight, her diet must be analyzed to ascertain if the overweight is due to edema only, fat only, or a combination of the two. Overweight due to fat is caused by the intake of too many calories. Overweight as a result of edema most likely is due to inadequate protein and caloric intake. It may well be that increased protein and calories will reduce the incidence of preeclampsia and eclampsia.

Assessment of Weight and Weight Gain

The Institute of Medicine's Subcommittee on Nutritional Status and Weight Gain During Pregnancy proposed that gestational weight gain be predicated on a woman's prepregnancy body mass index (BMI, or "weight for height"). Body mass index is defined as weight divided by height squared (kilograms/meter^2 or pounds/inches^2) multiplied by 100. Note that if height is measured in centimeters, then the result of the formula must be multiplied by 100 again to obtain the BMI. The subcommittee used metric units to make their calculations, created weight-for-height categories, and made recommendations for each category of the total weight gain during pregnancy. As shown in Table 22-2 and its notes, there are four categories of BMI—low (underweight), normal, high (overweight), and obese. The first three of these categories roughly correspond to 90, 120, and 135 percent of the

TABLE 22-2 Recommended Total Weight Gain Ranges for Pregnant Women,[a] by Prepregnancy Body Mass Index (BMI)[b]

	Recommended Total Gain	
Weight-for-Height Category	*kg*	*lb*
Low (BMI < 19.8)	12.5–18	28–40
Normal (BMI of 19.8 to 26.0)	11.5–16	25–35
High[c] (BMI > 26.0 to 29.0)	7.0–11.5	15–25

[a] Young adolescents and black women should strive for gains at the upper end of the recommended range. Short women (< 157 cm, or 62 in.) should strive for gains at the lower end of the range.

[b] BMI is calculated using metric units.

[c] The recommended target weight gain for obese women (BMI > 29.0) is at least 6.0 kg (15 lb).

Metropolitan Life Insurance Company's 1959 weight-for-height charts, which have been and are the most commonly used standards in the United States [37, pp. 5–12].

The methodology for determining optimum weight gain during pregnancy is first to ascertain the woman's prepregnancy BMI. Table 22-3 provides weight, height, and metric BMI figures. The shaded area and staircase lines indicate the cutoff values for obese, high, normal, and low BMI. Height and weight should be measured when the woman is not wearing shoes. Height is determined with the woman's heels, buttocks, and back against a flat vertical surface. The recommended range of total weight gain during pregnancy is then determined by the prepregnancy BMI, as shown in Table 22-2. The woman and the health care provider should agree on a weight gain goal (preferably a range rather than a single number). The woman should achieve at least the lower limit of the weight gain specified by her BMI.

Intervention Methodology*

The method presented here is known as the *Higgins Intervention Method for Nutritional Rehabilitation During Pregnancy*. Its usability has been demonstrated by the staff of the Montreal Diet Dispensary and by others who have been taught the method [35, 40, 41]. Its effectiveness has been clearly shown in studies of the pregnancy outcomes of those receiving the services of the Montreal Diet Dispensary, both at the Diet Dispensary and at the Royal Victoria Hospital Maternity Clinics in Montreal [31, 34, 36].

The Higgins Intervention Method uses the 1948 Canadian Dietary Standard (CDS), approved by the Canadian Council on Nutrition, as a baseline for establishing what the client's nonpregnant calorie and protein intake should be (Table 22-4). The CDS determines calorie and protein intake on the basis of (1) ideal body weight and (2) individual activity level. This method of establishing the recommended intake is more specific than the U.S. RDA and has a profound effect on calorie and protein levels. When the pregnancy allowance is added to the CDS values, the resulting total amounts of calories and protein vary much more than those of the U.S. RDA and are more in accord with women. Ideal body weight is determined by using the actuarial tables of the Metropolitan Life Insurance Company for desirable weights of women, based on height and body frame (Table 22-5). Individual activity level is a subjective evaluation.

Determination of Calorie and Protein Requirements

Calorie and protein requirements according to the Higgins Intervention Method consist of the normal requirements plus additional corrective allowances. The method is applied as follows:

1. Collection of baseline data:
   - a. age
   - b. height
   - c. body frame
   - d. nonpregnant weight
   - e. weeks' gestation
   - f. present weight
   - g. activity level
   - h. present dietary intake
   - i. existence of any of the following conditions:
     - (1) pernicious vomiting
     - (2) pregnancy spacing less than 1 year apart
     - (3) poor obstetrical history (stillbirths, spontaneous abortions, preterm babies)
     - (4) failure to gain 10 pounds by the twentieth week of gestation
     - (5) serious emotional upset or problems
2. Determination of normal requirements:
   - a. For a mother 20 years of age or more:
     - (1) Locate the client's height and body frame on the Table of Desirable Weights for Women (Table 22-5).* Determine the ideal weight based on these data.
     - (2) Locate the client's ideal weight, as determined in (1), and her activity level on the Canadian Dietary Standard (Table 22-4); and ascertain the woman's nonpregnant calorie and protein requirements.
     - (3) After 20 weeks' gestation, add 500 calories and 25 grams of protein to the woman's daily nonpregnant calorie and protein requirements, as determined

* This method is presented with the permission of the late Mrs. Agnes Higgins, former Executive Director of the Montreal Diet Dispensary, Montreal, Canada.

* In using this table, be sure to use the height figure 2 inches taller than your client measures in her stocking feet, since the heights in the table include shoes with 2-inch heels. For example, if your client measures 5'4" in her stocking feet, use the row of figures for 5'6" in the table.

[a] Use of table: The intersection of the woman's weight (row) and height (column) is her metric BMI.

Calculations:

BMI (metric) = $(kg/m^2) \times 100$; BMI (English) = $(lb/in.^2) \times 100$.

BMI (metric) $\times$ 0.142 = BMI (English); BMI (English) $\times$ 7 = BMI (metric).

= obese = normal

= overweight = underweight

[a]1959 Actuarial Tables. Courtesy of the Metropolitan Life Insurance Company.

above. These now become her normal pregnancy calorie and protein requirements. If the pregnancy is a multiple gestation, add 500 calories and 25 grams of protein for each fetus.

b. For a mother 19 years of age or less:

(1) Locate the client's age on Table 22-6, taken from the 1958 U.S. RDA. (Both the calorie and protein allowances for these ages, or any ages, were higher in 1958 than in any subsequent RDA.) This determines the woman's nonpregnant calorie and protein requirements. This use of higher nonpregnant calorie and protein requirements as the baseline for adolescent pregnancy is in keeping with the fact that the dietary require-

TABLE 22-6 Calorie and Protein Requirements for Women under 19, U.S. RDA

Age	Calories	Protein
13–15	2600	80 g
16–19	2400	75 g

Source: From the Food and Nutrition Board, National Academy of Sciences–National Research Council, 1958.

ments for pregnancy are superimposed on the adolescent's own dietary requirements for this period of growth in her life. The nonpregnant adolescent would normally be gaining weight as a reflection of her own growth; the averages are shown in Table 22-7. Therefore, weight gain during and after the adolescent's pregnancy must be evaluated in view of what she normally would gain if she were not pregnant.

(2) After 20 weeks' gestation, add 500 calories and 25 grams of protein to the woman's daily nonpregnant requirements, as determined above. These now become her normal pregnancy calorie and protein requirements. If the pregnancy is a multiple gestation, 500 calories and 25 grams of protein are added for each fetus.

3. Determine additional corrective allowances: Additional corrective allowances of calories and protein are given for three categories of identifiable nutritional conditions that may adversely affect pregnancy outcome if not considered: (1) undernutrition, (2) underweight, (3) nutritional stress. Each requires a separate addition to the daily normal pregnancy requirements for protein and calories.

a. Undernutrition assessment and corrective allowance: Undernutrition is defined as a deficit in protein between the normal pregnancy protein requirements for an individual woman and her actual dietary intake of protein, as determined by calculations performed on the data collected from a diet history, described later in this section. The corrective allowance is as follows:

(1) *protein*—the number of grams of protein deficit is added to the daily normal pregnancy requirements for protein

(2) *calories*—for each gram of protein deficit, 10 calories are added to the daily normal pregnancy requirements for calories (i.e., 10 calories × the number of grams of protein deficit = the total calorie addition)

b. Underweight assessment and corrective allowance: Underweight is defined as the mother's prepregnant weight being 5 percent or more under the ideal weight as determined from Table 22-5, the Table of Desirable Weights. The corrective allowance is as follows:

(1) *protein*—20 grams per day

(2) *calories*—500 calories per day

Both the protein and calorie corrections are added to the daily normal pregnancy requirements for protein and calories. This corrective allowance of protein and calories will permit an additional weight gain of 1 pound per week and should be continued for the number of weeks equivalent to the number of pounds the mother was underweight prior to conception. The allowance may be cut in half if needed for a weight gain of $^1/_2$ pound per week or increased to a maximum addition of 1000 calories and 40 grams protein daily if a weight gain of 2 pounds per week is needed in order to make up the deficit by the time of delivery.

c. Nutritional stress assessment and corrective allowance: Nutritional stress is defined as the existence of one or more of the following conditions:

(1) pernicious vomiting

(2) pregnancy spacing less than 1 year apart

(3) poor obstetrical history

(4) failure to gain 10 pounds by the twentieth week of gestation

(5) serious emotional upset or problems

The corrective allowance is an additional 200 calories and 20 grams protein for each stress condition present (up to a maximum allowance of 400 calories and 40 grams protein) to be added to the daily normal pregnancy requirements for protein and calories.

4. The foregoing calculations may be summarized as in Table 22-8 for ease in totaling the woman's daily caloric and protein requirements.

TABLE 22-7 Average Nonpregnant Adolescent Female Weight Gain

Age	Average Weight Gain per Year
11–13	11 lb
13–15	8 lb
15–17	3 lb
17–19	1 lb

TABLE 22-8 Summary Format for Calculating Calorie and Protein Requirements During Pregnancy

	Calories	Protein (g)
Nonpregnant requirements	_____	_____
Addition for pregnancy (after 20th week)	500	25
Undernutrition corrective allowance	_____	_____
Underweight corrective allowance	_____	_____
Nutritional stress corrective allowance	_____	_____
TOTAL	_____	_____

Evaluation of Dietary Adequacy; Nutrition Counseling To evaluate dietary adequacy, the midwife takes a 24-hour recall diet history. This is cross-checked against the client's responses to a list of common foods and food categories (e.g., citrus fruits) and, if necessary, further checked by questioning the woman about food purchasing (i.e., what foods she purchases and in what amounts for how many people). The daily number of calories and grams of protein in the woman's diet is then determined by calculations based on the information obtained from a standard food composition table. These figures are then used to compare the woman's usual actual calorie and protein intake against her requirements.

Nutrition counseling is most effective when the woman's dietary patterns and eating habits are changed as little as possible. Milk primarily is used to make up any deficiency between the woman's intake and her calorie and protein requirements. Peanut butter, cheese, bread, and eggs can also be used to meet calorie and protein requirements. Nutrition counseling includes attempting to motivate the woman to follow her diet. Telling her that she is drinking the supplementary milk to "feed her baby" is helpful in overcoming any negative feelings she might have about drinking milk (and also in discouraging her from giving the milk to other children in the family instead if she obtained the milk through WIC).

Mrs. Higgins suggests that a mother-to-be mark milk cartons with *B* for baby. This reinforces the idea of feeding her baby. The mother knows the baby is fed milk after being born, so it usually makes sense to her that her baby needs milk before being born as well. Mrs. Higgins has been quite successful in motivating clients at the Montreal Diet Dispensary by promoting the concept of the mother's having "a blue-ribbon baby." The nutritionists at the Montreal Diet Dispensary make a home visit to each client to establish a friendly contact, to evaluate the food storage and preparation facilities in the home (e.g., refrigerator, stove, running water), and to ascertain the response of other family members to the pregnancy.

After the initial visit and calculations, the woman's diet is periodically reviewed utilizing a 24-hour recall diet history. The midwife should completely reevaluate the woman nutritionally at critical nutritional points during the pregnancy. For example, a woman first seen during the first trimester should have a nutritional reevaluation as follows:

1. *At 20 weeks' gestation:* The diet is recalculated at this time so the pregnancy allowance of 500 calories and 25 grams protein can be added.
2. *At 28 weeks:* The peak in cellular growth of the brain begins at this time.
3. *At 36 weeks:* Encouragement should be offered through the last critical month of pregnancy and a contribution made to a total evaluation of the woman's well-being (since she is also being reevaluated obstetrically at this time).

Instruction and Anticipatory Guidance

Anticipatory guidance and instruction during the antepartal period relate largely to the activities of daily life, the common discomforts of pregnancy and their relief measures, nutrition preparation for childbirth and parenthood, the danger signs, an understanding of the physical and psychological changes taking place, and the basics of fetal growth and development. The section below outlines these topics, with the exception of the common discomforts of pregnancy and their relief measures, and nutritional intervention in pregnancy, which were discussed above.

This material is presented in topical outline with only occasional further notations for several reasons: (1) most nurse-midwifery students will have taught this material as student nurses or in nursing practice, (2) some of the material appears elsewhere in this book, and (3) there are innumerable pamphlets, booklets, books, and textbooks that detail this instruction. Those who are unfamil-

iar with this teaching can use the topical outline to identify areas in which they need instruction, refer to the literature, and observe classes and discussion groups dealing with the information.

Principles of Antepartal Teaching

As in any teaching, be sure you have an audience in your potential learner before talking. Otherwise, you may be wasting her time and your time. Common mistakes are trying to teach too much at one time and trying to teach at the end of an exhausting day for her in the clinic or office. An interested learner at such a time would be rare. Some information is mandatory to communicate—danger signs of critical complications; the avoidance of over-the-counter drugs; the potential dangers of cat care; and so forth. Joyce Roberts [42] advocates using the following priority ranking in giving information:

1. Information given in response to specific questions, problems, or experiences of a woman at the particular time in her pregnancy
2. Information that is essential for a woman to have for her own or her baby's health and safety
3. Anticipatory guidance that will facilitate a woman's efforts to deal realistically with the pregnancy and with issues or aspects of childbirth that she is likely to encounter
4. Additional information regarding pregnancy progress, childbirth, or institutional policies that may be helpful but is not related to the immediate needs of the woman

Not all women have learning needs for all of the instruction and anticipatory guidance you have to give. You should avoid making unvalidated assumptions regarding a woman's learning needs. Find out first if she wants the information you have to share with her on a given topic. Be especially alert not to make assumptions about what pregnant health care professionals (e.g., nurse-midwives, nurses, midwives, physicians, physician assistants) want and need to know. Most such women do not want to rely on themselves or to feel they should act as though they know it all—they may know for other women, but this is their own experience, which is new and fraught with its unique set of anxieties and joys.

Antepartal Teaching Outline

1. Interpretation of physical findings and laboratory results
2. Value of keeping appointments for antepartal revisits
3. Signs and symptoms of complications that indicate a need to call the midwife immediately:
   - **a.** vaginal bleeding
   - **b.** facial or hand edema
   - **c.** prolonged nausea and vomiting
   - **d.** fever, chills
   - **e.** sudden, sharp, continuing abdominal pain
   - **f.** sudden gush of fluid from the vagina
   - **g.** continuing severe headache
   - **h.** visual changes (e.g., blurring of vision, dizziness, spots before eyes)
   - **i.** any change from normal urination
4. Perineal and vaginal care
   - **a.** direction of wiping (front to back)
   - **b.** cotton-crotch panties
   - **c.** frequent change of underwear
   - **d.** no douching
5. Breast care
   - **a.** daily cleansing with warm water and a soft, clean cloth followed by careful drying
   - **b.** if colostrum is crusted on the nipple, softening with an application of nipple cream or lanolin before trying to remove
   - **c.** gentle handling
   - **d.** good breast support (see 6, below)
   - **e.** preparation for breastfeeding in the ninth month of pregnancy (see Chapter 62)
6. Breast support. A good brassiere is essential for preventing or alleviating upper backache; it gives comfort for tender enlarged breasts and provides alignment for facilitating ductile functioning. There is little change in breast size during the remainder of the antepartal period after the fourth to fifth lunar month of gestation. A good bra has the following characteristics:
   - **a.** supportive, porous, soft, washable material
   - **b.** shaped to avoid compression and irritation of the breasts and nipples, while giving snug support
   - **c.** wide, adjustable shoulder straps
   - **d.** wide back band with a number of available fastening adjustments
   - **e.** support is from below upward and from the sides inward
7. Abdominal support
   - **a.** abdominal muscle tightening exercises (e.g., chin-chest, controlled breathing, sit-ups)
   - **b.** maternity girdle, if needed
   - **c.** maternity abdominal support or binder, if needed

8. Clothing
   a. supportive, washable, loose-fitting (never binding or constrictive of circulation), mood-lifting
   b. adjustable
   c. comfortable shoes with a broad base; avoidance of high heels, which are unstable and increase any problem with lordosis
   d. maternity clothes (usually not needed until around the fifth calendar month of pregnancy)
9. Fetal growth and development appropriate for the period of gestation now and until the next antepartal revisit
10. Bodily and psychological changes appropriate for the period of gestation now and until the next antepartal revisit
11. Possible discomforts for the period of gestation now and until the next antepartal revisit
12. Explanation of relief measures for any present discomforts
13. Dental care
   a. appointment with dentist
   b. cleaning of teeth after meals
   c. gum care; explanation that gums will tend to bleed because of hyperemia by midpregnancy
14. Avoidance of cats; explanation of toxoplasmosis
15. Avoidance of alcohol; explanation of fetal alcohol syndrome (see Chapter 12)
16. Smoking: If the woman smokes, she should be encouraged to stop or at least reduce smoking; women who smoke have an increased risk for perinatal mortality, fetal wastage, preterm labor and delivery, and small-for-gestational-age babies (see Chapter 12).
17. Avoidance of all medicines and drugs, including aspirin and BC powder, except those prescribed by the midwife or physician working with the midwife. The woman should be told to consult with the midwife before taking over-the-counter drugs or any prescription obtained from any other physician for any other condition.
18. Immunizations: At the time of this writing, the most recent recommendations available from the American College of Obstetricians and Gynecologists regarding specific immunizations during pregnancy were those prepared in 1991 [43]. They are reproduced as Appendix A to this chapter with additional information from Travelers' Health document issued by the National Center for Infectious Diseases at the Centers for Disease Control and Prevention 2002 [44]. "The use of immunobiologic agents during pregnancy should be limited to a few well-defined situations" [43, p. 3]. Factors to be considered include risk of exposure to the disease in question, risk of morbidity or mortality if the woman contracts the disease, and risk from the immunobiologic agent, especially if from live virus or live bacteria.
19. Nutrition
20. Food cravings/pica: Food cravings (e.g., pickles and ice cream) are usually transient and are of no concern as long as the diet is otherwise nutritionally adequate. Pica, a craving for clay or dirt (or ice shavings or laundry starch if the former are not available), is basically sociocultural in origin and is best indulged in limited quantities, if possible, in order to not interfere with a nutritious diet.
21. Rest: In addition to whatever amount of sleep she needs, the woman should have periodic rest periods during the day, preferably with her feet elevated. She should avoid sitting or standing for prolonged periods of time.
22. Exercise and activity: The woman should do whatever she is *accustomed to*, stopping short of fatigue—exercise should never be excessive. No other limits are needed if the woman is experienced in whatever form of exercise she wishes to pursue. Pregnancy is not the time, however, to be learning new strenuous sports (e.g., skiing, skydiving). Daily exercise such as walking outdoors is good for mental health, relaxation, bowels, and muscle conditioning (see Chapter 9).
23. Work: The decision as to whether to continue working should be left to the woman's discretion, within the following limits:
   a. A rest period should be taken approximately every 2 hours (this is equivalent to taking a lunch period and a morning and afternoon break during an eight-hour workday).
   b. Fatigue should be avoided.
   c. Severe physical strain should be avoided.
   d. The decision to work should be reassessed in the event any complications develop.
24. Body mechanics
   a. posture
   b. lifting (see the section on low back pain earlier in this chapter)
   c. getting up from a supine position:
      (1) bend knees
      (2) turn to side
      (3) push up with arms to a sitting position

25. Bathing
- **a.** no hot baths (exhausting)
- **b.** no cold baths (chilling)
- **c.** choice between shower and tub bath a matter of personal preference
- **d.** later in pregnancy a shower may be safer than a tub bath because of awkwardness arising from a change of center of gravity and balance; be sure tub bottom and shower floor are nonskid

26. Sexual intercourse
- **a.** changes in position to accommodate enlarged abdomen
- **b.** alternative methods of satisfying male and female sexual needs
- **c.** alleviation of any unnecessary concerns or fears regarding harming the baby with sexual intercourse
- **d.** abstinence if necessary (e.g., suspected premature rupture of membranes, bleeding, bleeding and cramps in first trimester, preterm labor)

27. Travel: If the pregnancy is progressing normally, the woman may travel as desired, keeping in mind
- **a.** the need to walk periodically (every two hours) to encourage circulation and avoid venous stasis
- **b.** if close to term, the need for alternative plans for giving birth at her destination and for any emergencies en route

28. Domestic violence
- **a.** Statistics and facts
  - **(1)** Twenty-three percent of pregnant women seeking routine prenatal care are battered women [45].
  - **(2)** Battering may be initiated or become more acute during pregnancy.
- **b.** risk factors in staying in or leaving the abusive situation, with an emphasis on safety
- **c.** resources available to the woman
- **d.** components of an emergency plan of action

29. Preparation for childbirth and parenthood (varies according to anticipated site of birth): The woman should be encouraged to attend classes (Figure 22-5); general areas of content may include the following:
- **a.** reproductive anatomy; bodily changes during pregnancy and related discomforts and relief measures
- **b.** exercises to promote relaxation (Figure 22-6), condition specific muscle groups, relieve discomforts, use during labor; positioning; breathing exercises for working with contractions; posture; body mechanics
- **c.** nutrition
- **d.** substance abuse
- **e.** fetal growth and development
- **f.** signs of impending labor; process and progress of labor; comfort measures; what to do, what to expect
- **g.** preparation for breastfeeding
- **h.** preparations for baby in the home; what to bring to the hospital or birth center for taking the baby home; basics of baby care

FIGURE 22-5 Childbirth education class.

FIGURE 22-6 Helping a couple with relaxation exercise.

- **i.** general hygiene (e.g., breast care, perineal care, bowel habits)
- **j.** potential problems: danger signs, what to do, prevention; use of medications
- **k.** postpartal course: what to expect in the hospital (individualized to the hospital) if birth occurs in this setting, sibling rivalry, 2-week and 4–6-week checkup
- **l.** antepartal/postpartal adjustments in relationships, especially between the woman and her partner
- **m.** response to concerns, questions, and so forth

30. Sibling preparation for birth
- **a.** selecting an adult sibling attendant
- **b.** attending classes for siblings, sibling attendant, and parents
- **c.** involving siblings in antepartal visits (Figure 22-7), according to age level (e.g., listening to fetal heart, feeling fetal movement, feeling baby parts)
- **d.** involving siblings in baby preparations

31. Superstitions: "Old wives' tales" should be countered with facts, reason, and understanding.

32. Breathing and relaxation exercises: Techniques should be taught, or what is learned in classes for preparation for childbearing and parenthood should be reinforced.

33. La Leche League meetings: These provide a particularly good antepartal learning experience for a woman who plans to breastfeed, especially if this will be her first breastfeeding experience. Practical tips and a chance to observe other women breastfeeding will answer many questions and provide an opportunity to see individual variations of nursing and mother-baby interactions. La Leche League members also can be a source of help if needed after birth.

34. Signs and symptoms of labor and when to call the midwife and/or come to the hospital or birth center

35. Preparations for coming to the hospital or birth center if not giving birth at home (e.g., what to pack for self and baby, where to go, admissions procedures, what to expect, and so forth)

36. What to do in the event of emergency childbirth

37. Baby preparations
- **a.** supplies, furniture, equipment, clothing
- **b.** purchase and installation of infant car seat
- **c.** decision regarding method of infant feeding (i.e., by breast or bottle)
- **d.** preparation of couple for changes in life necessitated by a baby
- **e.** care of siblings during intrapartal and immediate postpartal period

FIGURE 22-7 Sibling listening to fetal heart tones.

APPENDIX A Immunization During Pregnancy

Immunobiologic Agent	Risk from Disease to Pregnant Woman	Risk from Disease to Fetus or Neonate	Type of Immunizing Agent	Risk from Immunizing Agent to Fetus	Indications for Immunization During Pregnancy	Dose Schedule	Comments
			Live Virus Vaccines				
Measles	Significant morbidity, low mortality; not altered by pregnancy	Significant increase in abortion rate; may cause malformations	Live attenuated virus vaccine	None confirmed	Contraindicated (see immune globulins)	Single dose SC, preferably as measles-mumps-rubella[a]	Vaccination of susceptible women should be part of postpartum care
Mumps	Low morbidity and mortality; not altered by pregnancy	Probable increased rate of abortion in first trimester	Live attenuated virus vaccine	None confirmed	Contraindicated	Single dose SC, preferably as measles-mumps-rubella	Vaccination of susceptible women should be part of postpartum care
Poliomyelitis	No increased incidence in pregnancy, but may be more severe if it does occur	Anoxic fetal damage reported; 50% mortality in neonatal disease	Live attenuated virus (oral polio vaccine [OPV]) and enhanced-potency inactivated virus (e-IPV) vaccine[b]	None confirmed	Not routinely recommended for women in United States except persons at increased risk of exposure	Primary: Two doses of e-IPV SC at 4- to 8-week intervals and a third dose 6–12 months after the second dose. Immediate protection: One dose OPV orally (in outbreak setting)	Vaccine indicated for susceptible pregnant women traveling in endemic areas or in other high-risk situations
Rubella	Low morbidity and mortality; not altered by pregnancy	High rate of abortion and congenital rubella syndrome	Live attenuated virus vaccine	None confirmed	Contraindicated	Single dose SC, preferably as measles-mumps-rubella	Teratogenicity of vaccine is theoretic, not confirmed to date; vaccination of susceptible women should be part of postpartum care
Yellow fever	Significant morbidity and mortality; not altered by pregnancy	Unknown	Live attenuated virus vaccine	Unknown	Contraindicated, except if exposure is unavoidable	Single dose SC	Postponement of travel preferable to vaccination, if possible; *breastfeeding mothers should also postpone travel as the neonate cannot be immunized because of vaccine-associated encephalitis

APPENDIX A Immunization During Pregnancy *(continued)*

Immunobiologic Agent	Risk from Disease to Pregnant Woman	Risk from Disease to Fetus or Neonate	Type of Immunizing Agent	Risk from Immunizing Agent to Fetus	Indications for Immunization During Pregnancy	Dose Schedule	Comments
			Inactivated Virus Vaccines				
Influenza	Possible increase in morbidity and mortality during epidemic of new antigenic strain	Possible increased abortion rate; no malformations confirmed	Inactivated virus vaccine	None confirmed	Women with serious underlying diseases; public health authorities to be consulted for current recommendation	One dose IM every year	
Rabies	Near 100% fatality; not altered by pregnancy	Determined by maternal disease	Killed virus vaccine	Unknown	Indications for prophylaxis not altered by pregnancy; each case considered individually	Public health authorities to be consulted for indications, dosage, and route of administration	
Hepatitis B	Possible increased severity during third trimester	Possible increase in abortion rate and prematurity; neonatal hepatitis can occur; high risk of newborn carrier state	Recombinant vaccine	None reported	Pre- and post-exposure for women at risk of infection	Three- or four-dose series IM	Used with hepatitis B immune globulin for some exposures; exposed newborn needs vaccination as soon as possible
			Inactivated Bacterial Vaccines				
Cholera	Significant morbidity and mortality; more severe during third trimester	Increased risk of fetal death during third-trimester maternal illness	Killed bacterial vaccine	None confirmed	Indications not altered by pregnancy; vaccination recommended only in unusual outbreak situations	Single dose SC or IM, depending on manufacturer's recommendations, when indicated	
Plague	Significant morbidity and mortality; not altered by pregnancy	Determined by maternal disease	Killed bacterial vaccine	None reported	Selective vaccination of exposed persons	Public health authorities to be consulted for indications, dosage, and route of administration	
Pneumococcus	No increased risk during pregnancy; no increase in severity of disease	Unknown	Polyvalent polysaccharide vaccine	No data available on use during pregnancy	Indications not altered by pregnancy; vaccine used only for high-risk individuals	In adults one SC or IM dose only; consider repeat dose in 6 years for high-risk individuals	

APPENDIX A Immunization During Pregnancy *(continued)*

Immunobiologic Agent	Risk from Disease to Pregnant Woman	Risk from Disease to Fetus or Neonate	Type of Immunizing Agent	Risk from Immunizing Agent to Fetus	Indications for Immunization During Pregnancy	Dose Schedule	Comments
			Inactivated Bacterial Vaccines (continued)				
Typhoid	Significant morbidity and mortality; not altered by pregnancy	Unknown	Killed or live attenuated oral bacterial vaccine	None confirmed	Not recommended routinely except for close, continued exposure or travel to endemic areas	Killed: (*vaccine of choice during pregnancy) *Primary:* Two injections SC at least 4 weeks apart. *Booster:* Single dose SC or ID (depending on type of product used) every 3 years. Oral: (*safety not known) *Primary:* Four doses on alternate days *Booster:* Schedule not yet determined	
			Toxoids				
Tetanus-diphtheria	Severe morbidity; tetanus mortality 30%, diphtheria mortality 10%; unaltered by pregnancy	Neonatal tetanus mortality 60%	Combined tetanus-diphtheria toxoids preferred: adult tetanus-diphtheria formulation	None confirmed	Lack of primary series, or no booster within past 10 years	Primary: Two doses IM at 1–2-month interval with a third dose 6–12 months after the second Booster: Single dose IM every 10 years, after completion of primary series	Updating of immune status should be part of antepartum care *Preferably administered during second or third trimester
			Specific Immune Globulins				
Hepatitis B	Possible increased severity during third trimester	Possible increase in abortion rate and prematurity; neonatal hepatitis can occur; high risk of carriage in newborn	Hepatitis B immune globulin	None reported	Postexposure prophylaxis	Depends on exposure; consult Immunization Practices Advisory Committee recommendations (IM)	Usually given with HBV vaccine; exposed newborn needs immediate postexposure prophylaxis

APPENDIX A Immunization During Pregnancy *(continued)*

Immunobiologic Agent	Risk from Disease to Pregnant Woman	Risk from Disease to Fetus or Neonate	Type of Immunizing Agent	Risk from Immunizing Agent to Fetus	Indications for Immunization During Pregnancy	Dose Schedule	Comments
			Specific Immune Globulins (continued)				
Rabies	Near 100% fatality; not altered by pregnancy	Determined by maternal disease	Rabies immune globulin	None reported	Postexposure prophylaxis	Half dose at injury site, half dose in deltoid	Used in conjunction with rabies killed virus vaccine
Tetanus	Severe morbidity; mortality 21%	Neonatal tetanus mortality 60%	Tetanus immune globulin	None reported	Postexposure prophylaxis	One dose IM	Used in conjunction with tetanus toxoid
Varicella	Possible increase in severe varicella pneumonia	Can cause congenital varicella with increased mortality in neonatal period; very rarely causes congenital defects	Varicella-zoster immune globulin (obtained from the American Red Cross)	None reported	Can be considered for healthy pregnant women exposed to varicella to protect against maternal, not congenital, infection	One dose IM within 96 hours of exposure	Indicated also for newborns of mothers who developed varicella within 4 days prior to delivery or 2 days following delivery; approx. 90–95% of adults are immune to varicella; not indicated for prevention of congenital varicella
			Standard Immune Globulins				
Hepatitis A	Possible increased severity during third trimester	Probable increase in abortion rate and prematurity; possible transmission to neonate at delivery if mother is incubating the virus or is acutely ill at that time	Standard immune globulin	None reported	Postexposure prophylaxis	0.02 mL/kg IM in one dose of immune globulin	Immune globulin should be given as soon as possible and within 2 weeks of exposure; infants born to mothers who are incubating the virus or are actually ill at delivery should receive one dose of 0.5 mL as soon as possible after birth
Measles	Significant morbidity, low mortality; not altered by pregnancy	Significant increase in abortion rate; may cause malformations	Standard immune globulin	None reported	Postexposure prophylaxis	0.25 mL/kg IM in one dose of immune globulin up to 15 mL	Unclear if it prevents abortion; must be given within 6 days of exposure

Abbreviations: SC = subcutaneously; PO = orally; IM = intramuscularly; ID = intradermally.

[a] Two doses necessary for adequate vaccination of students entering institutions of higher education, newly hired medical personnel, and international travelers.

[b] Inactivated polio vaccine recommended for nonimmunized adults at increased risk.

CHAPTER

23

Fetal Assessment

One of the hallmarks of midwifery care is the appropriate use of technology. Determining what is appropriate for an individual woman is one of the most complex areas of decision-making the midwife faces. Technology—in the form of laboratory tests, genetic assessments, ultrasound examinations, electronic fetal monitoring, and invasive testing—is growing at an exponential rate. The trend in medical management is often that "more is better." The midwife can easily be caught amidst medical standards, societal demands, women's issues, cost-benefit ratios, legal implications, the philosophy of pregnancy as a normal condition, and the wishes of an individual woman. This chapter is a guide to the array of testing that can provide information regarding fetal well-being from conception until the onset of labor. As in other areas of clinical care, there are few absolute rights and wrongs. Instead, a midwife's thorough knowledge of what methods of fetal assessment are available and the advantages and disadvantages of each is essential to counseling each woman in midwifery care to the safest and most satisfying pregnancy and birth possible for her individual situation.

Using technology with respect for the concerns of women and families also adds to the quality of midwifery practice. This chapter discusses many screening procedures and tests of fetal well-being. Knowing the indications, possible results, and implications of these tests and procedures is only a beginning. Experience with their use will assist the midwife in walking the fine line between offering useful information for management of pregnancy and sliding down the proverbial "slippery slope" toward overreliance on medical technology.

First Trimester Assessment of Pregnancy Well-Being

Confirmation of pregnancy is the initial reason women utilize medical technology during pregnancy. For most women, a single urine pregnancy test in the office and an initial prenatal visit comprise appropriate assessment of early pregnancy. Urine tests are now accurate once a woman has missed her menstrual cycle, as they are sensitive to human chorionic gonadotropin (hCG) levels below 50 mIUs. False positives (a positive urine test when no pregnancy actually exists) are rare; false negatives (a negative test when the woman is truly pregnant) can occur if the test is done too soon after conception. When the woman has a normal history and her clinical examination concurs with menstrual dates, additional assessment with technology such as ultrasound is not necessary to verify what the woman and her midwife have established. This early pregnancy period is a time to begin discussion about appropriate options among screening tests (e.g., maternal serum multiple marker screening) at various times during pregnancy. Directed teaching at this time regarding normal pregnancy growth and development as well as warning signs offers reassurance to women about normal pregnancy.

A woman who has an uncertain menstrual history, chronic disease, a history of repeated pregnancy loss, ectopic pregnancy, or congenital anomalies may require more complete assessment in early pregnancy. When a woman presents with pelvic pain, vaginal bleeding, loss of pregnancy symptoms, or unusual pelvic findings such as an adnexal mass, evaluation such as measurement of

serum beta human chorionic gonadotropin (B-hCG) levels and/or use of ultrasound may be necessary to establish that she is experiencing a viable, intrauterine pregnancy. When a woman has undergone assisted reproductive technology (ART)—such as intrauterine insemination (IUI), in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), or other procedures—use of serum B-hCG level and ultrasound may also be necessary for complete evaluation of the pregnancy.

The use of quantitative serum B-hCG levels is recommended for a pregnancy in which there is a question of normal development. An initial B-hCG level offers a baseline to which further assessment of the embryo can be added. Serum B-hCG can be detected within 8 to 11 days after conception [1]. After that it doubles every 2 days in the first weeks of pregnancy, peaking at about 10 weeks' gestation. As shown in Figure 23-1, there is then a rapid decrease in B-hCG between 12 and 16 weeks' gestation [2].

Because multiple gestation, spontaneous abortion, ectopic pregnancy, and hydatidiform mole may all affect B-hCG levels, any abnormality in these values merits further evaluation (see Chapter 24). Serum hCG levels that are doubling appropriately are usually associated with a normal pregnancy. Very rapidly increasing values may indicate a multiple pregnancy or a hydatidiform mole. Slowly rising or leveling hCG levels may represent an ectopic pregnancy [3]. In the case of rapid or very slow increase of serum hCG levels, ultrasound examination is required. Dropping hCG levels represent either early pregnancy loss or a viable pregnancy that is actually more than 12 weeks' gestation. Abnormal laboratory findings may precede physical signs and symptoms.

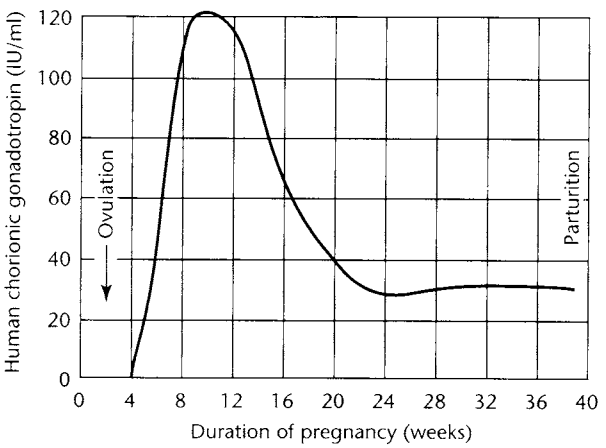

FIGURE 23-1 Hormonal excretion during pregnancy.

Source: Reproduced by permission from Guyton, A.C. *Human Physiology and Mechanisms of Disease*, 4th ed. Philadelphia: W.B. Saunders, 1987, p. 643.

When pain or bleeding occurs during the first 3 months of pregnancy, assessment for spontaneous abortion and ectopic pregnancy is made more accurate with the use of ultrasound. The transvaginal ultrasound transducer allows identification of a gestational sac by 5 postmenstrual weeks and of fetal heart motion by 7 weeks [4]. Women who have conceived with the assistance of reproductive technology are generally assessed using ultrasound to establish the implantation site, number, and viability of the embryos.

Careful history taking, thorough physical assessment, and ultrasound examination in combination with urine or serum B-hCG quantification can assist the midwife in making a correct assessment of the gestational age of the fetus and any abnormalities of the first trimester pregnancy. Whenever results of any pregnancy testing are abnormal, medical consultation or collaboration is indicated. The midwife must thus have resources immediately available for urgent referrals when the situation warrants, as well as the ability to offer urine, hematologic, and ultrasound screening. (See Chapter 24.)

Screening for Anomalies

One effect of the Human Genome Project and our increasing awareness of the role genetic changes play in many, if not most, health problems, has been to increase the importance of genetic history taking and patient counseling during pregnancy. All midwives should be able to identify common risk factors and historical events that increase a family's chance of having a child with a genetic birth defect, as well as other developmental or teratogenic complications.

The current standard of care is to offer all women screening for open neural tube defects and trisomies 21 and 18 and to counsel them in the implications of testing and of test results. All women are at some risk for genetic defects in their children. However, not all women are appropriate candidates for invasive genetic testing, such as chorionic villus sampling or amniocentesis, because of their very low risk status. Today, a woman who will be 35 on or before her expected delivery date, a woman with a personal or family history of defects for which diagnostic tests are available, or a woman who has abnormal screening test results is identified as a candidate for complete genetic evaluation [5]. However, 95 percent of all open neural tube defects, occur in previously unaffected families [6], and although the rate of genetic anomalies rises rapidly with maternal

age, 70 to 80 percent of all trisomies occur in women under 35 years of age [7]. Therefore, offering screening to all women permits the identification of an additional population of women who may benefit from genetic assessment. Maternal serum alpha-fetoprotein (MSAFP) or triple screening is performed on a maternal blood sample, usually between 15 and 18 weeks of pregnancy.

Assessment for Structural and Genetic Abnormality

History Taking The initial pregnancy history elicits information about the woman's age, ethnic background, history of pregnancy losses, congenital anomalies in her and her partner's families, and exposure to substances that may be mutagenic or teratogenic. Each of these may be an indication for testing.

Maternal age is probably the most widely known indication for genetic assessment. Table 23-1 lists the risk of chromosomal abnormalities in general and in Down syndrome, specifically, based on maternal age [6]. Indeed, as maternal age increases, the risk for congenital anomalies also increases. However, the maternal age of 35 is not a time of sudden increase in anomalies; rather, the equivalence of risk between a fetal chromosomal disorder and pregnancy loss due to amniocentesis makes age 35 the cutoff point for routinely offering a complete genetic evaluation.

TABLE 23-1 Risk of Down Syndrome by Maternal Age

Maternal Age	Risk for Down Syndrome	Risk for any Chromosomal Abnormality
21	1/1667	1/526
23	1/1429	1/500
25	1/1250	1/476
27	1/1111	1/455
29	1/1000	1/417
31	1/909	1/385
33	1/625	1/317
35	1/385	1/204
37	1/227	1/130
39	1/137	1/82
41	1/82	1/51
43	1/50	1/32
45	1/30	1/20
47	1/18	1/12
49	1/11	1/7

Table 23-2 lists many diseases and anomalies that currently can be diagnosed prenatally [8]. As research continues, this list will expand rapidly. The ethnic background of both partners should be taken into consideration. Table 23-2 also includes the primary ethnicity-linked disorders to be assessed in history taking. Awareness of a positive history in either the woman's or her partner's family of chromosomal disorders is critical to evaluation of risk.

Genetic Counseling

When genetic testing is offered during prenatal care, whether for screening or diagnosis, the midwife's role is to educate the pregnant woman and her family about the testing options and indications and the implications of the results. The midwife must be certain that the lab she recommends meets generally accepted criteria for safety and accurate results. A woman must be advised that not being tested is one of her options and that no single test or combination of tests can guarantee a healthy child.

Prior to offering genetic screening tests, the midwife should counsel the woman about the possible findings, the risk of both false positives and false negatives, and the range of options available to her for follow-up. This counseling should be nondirective and should allow the woman and her family to make the choices they are most comfortable with. The midwife documents counseling given, the woman's response, the woman's decision, and any referrals made.

When a woman meets age criteria, or after an abnormal finding on history or screening, women are counseled again about their specific risks. Appropriate diagnostic tests are explained and scheduled. Whenever possible, a genetic counselor should be involved at this point. Families deserve accurate information and the opportunity to understand the range of expression of possible anomalies. The performance of tests designed to identify fetuses at risk does not mandate any single course of action when a problem is found. Some families choose to terminate a pregnancy when a problem is discovered; others welcome information to allow them to prepare for their child's special needs.

Studies of women receiving abnormal results on screening tests have demonstrated their increased anxiety and negative attitudes toward the pregnancy. They experience increased distress compared to women offered testing because of advanced maternal age, who are already aware of their risks. The elevated level of anxiety generally

TABLE 23-2 Conditions Calling for Prenatal Diagnosis and Counseling, with Incidences and Carrier Frequencies

Conditions	Carrier Frequencies	Prenatal Diagnostic Methods
Couples at an increased risk		
Maternal age >35 years		US, AC, CVS
Balanced chromosome rearrangement		
Previous child with chromosome abnormality		
Low maternal serum alpha-fetoprotein		
Family history of birth defects and/or mental retardation

decreases with the receipt of normal results on follow-up diagnostic tests, but in some cases anxiety persists throughout pregnancy [9, 10]. These findings emphasize the importance of pretest teaching and of supportive counseling for women who receive abnormal results.

Because the process of testing for fetal anomalies as well as concern about risks to her child may raise a woman's anxiety [11], the midwife has an obligation to note signs of increased anxiety and negative attitudes about pregnancy. Assessment of a woman's knowledge and fears allows the midwife to provide realistic reassurance and support as well as further education as needed.

When genetic evaluation reveals an abnormal fetus, the family needs support and information to assist them in their decision-making regarding continuation or termination of the pregnancy. A small number of these identifiable conditions can be treated prenatally with medications or surgery. Others are amenable to carefully planned treatment after birth. In most cases, however, the woman and her family must face the diagnosis of an abnormal fetus. Most midwives find that a genetic counselor or pediatrician can help them explain the nature and possible severity of a fetus's condition. In addition, support from a psychiatric counselor or social worker may be invaluable.

It is the midwife's obligation to assist the woman in understanding what tests are available to her and the relative value of a given test. One example of these tests is couple screening for cystic fibrosis, which can identify 72 percent of CF cases prenatally [12]. Both partners must agree to provide mouth rinse samples, which are checked for known cystic fibrosis alleles. This allows genetic diagnostic testing to be offered to couples at risk when both may be carrying a recessive trait.

First Trimester Evaluation of Fetal Risks: Biochemical Markers

First trimester screening for Down syndrome through measurement of hCG and pregnancy associated plasma protein A (PAPP-A) is not yet widely available, but is being examined as a potentially effective replacement for second trimester screens. Fetuses with Down syndrome have been found to have an elevation of PAPP-A and a lower quantity of hCG. Taken together, they offer detection rates of approximately 60 percent, with false-positive rates of 5 percent. The benefits of early screening, if it matches the predictive value of current second trimester screens, are obvious. Among them are greater patient privacy in decision-making and safer procedures for families electing to terminate an affected pregnancy. However, the increased risk of miscarriage associated with chorionic villus sampling, the increased costs associated with offering multiple testing schemes, and the fact that some affected fetuses will abort spontaneously before second trimester screening would have been done, may affect the desirability of these tests [13, 14].

Nuchal Translucency Screening

Ultrasound is now being used to measure the neural tube at the level of the fetal neck. On ultrasound examination between 10 and 14 weeks of gestation, an increase in the sonolucent area at the back of the fetal neck to greater than 3 millimeters or the presence of cystic hygroma indicates an increased risk of fetal aneuploidy, including trisomies 21, 18, and 13, Turner syndrome (45, X), cardiac defects, and other anomalies [15–17]. An increase in the rate of fetal loss has also been reported, even in chromosomally normal fetuses [18]. When performed in skilled hands, sensitivity of this method approaches 80 percent. However, inaccuracies of measurement such as inclusion of the umbilical cord, poorly placed neck position during scanning, and fetal position near the unfused amniotic membrane, will yield false results [16]. The greatest benefit from nuchal translucency measurements will probably come from their inclusion in combined ultrasonographic and biochemical screens (see below).

Second Trimester Screening

Alpha-Fetoprotein Testing

Alpha-fetoprotein (AFP) is a protein synthesized first by the yolk sac and then primarily by the fetal liver. The fetal AFP level increases until about 20 weeks and then declines to term. The normal AFP levels in maternal serum continue to rise until around 32 weeks [19]. Alterations in AFP levels in either amniotic fluid or maternal serum have multiple possible etiologies. In general, an increase in maternal serum AFP is due to "leaking" of fetal AFP through an opening in the fetal skin—that is, an open neural tube defect or an open ventral wall defect. Table 23-3 identifies the major reasons for maternal serum alpha-fetoprotein (MSAFP) elevations.

Normative levels of MSAFP are dependent on many factors: gestational age, maternal age, race,

TABLE 23-3	Major Reasons for MSAFP Elevations
Underestimation of gestational age

weight, and diabetes. Therefore, careful assessment of gestational age and accurate reporting of maternal factors to the lab play a part in getting accurate screening results. About 1 to 2 percent of all women who undergo AFP testing have positive test results [6]. Such testing identifies 80 to 90 percent of fetuses with anencephaly, spina bifida, and omphalocele, using a cutoff value of 2.5 multiples of the mean (MOM) adjusted for maternal age, weight, and race. Women with diabetes have a higher incidence of structural fetal anomalies, and, therefore, a cutoff of 2.0 MOM is used. Some labs have slight variations in these normative values. The midwife must be aware of the limits used in the reference laboratory. Identification of multiple pregnancy is also critical for accurate screening results, as more than one fetus will elevate the MSAFP result.

Only about 1 in 15 women offered amniocentesis as a follow-up to MSAFP screening is found to be carrying a fetus with structural fetal defects. The number of false-positive screens is reduced as dating accuracy is improved. Therefore, women with uncertain dates or those with abnormal findings on examination need ultrasound confirmation of their gestational age [6]. As the quality of ultrasound anatomy assessment has improved, use of these scans has in large part replaced the use of amniocentesis as the evaluation following increased risk of open neural tube defects.

The placenta also plays a role in elevated MSAFP levels. If the placenta is large or malpositioned, more AFP may cross into the maternal circulation; a placental defect may also allow an abnormal amount of fetal AFP to pass from the fetal blood to the maternal serum. Many times when the MSAFP is elevated, the fetus is found to be structurally normal and the amniotic fluid AFP is also normal. An abnormal placenta or implantation site is a likely explanation for the increased risk of adverse pregnancy outcome with increased MSAFP when no obvious etiology is found [19]. Although MSAFP screening was initiated for identification of structural fetal anomalies, it has been found that there is a relationship between very low MSAFP levels and infants with Down syndrome. MSAFP alone identifies 25 percent of cases of Down syndrome among women younger than 35 [20].

Multiple Marker Screening

Multiple marker screening (also often referred to as a triple screen) was introduced in the late 1980s and improves the percentage of chromosomal anomaly cases detected to 60 percent among women who are at a risk level of greater than 1:270 [21]. Multiple marker screening most commonly consists of MSAFP, hCG, and unconjugated estriol, and it has replaced MSAFP alone as the most common screening test for ONTD and fetal aneuploidy. Both trisomy 21 (Down syndrome) and Edwards syndrome (trisomy 18) have increased detection rates with multiple marker screening. In trisomy 21, hCG levels are high, while estriol and AFP levels are relatively decreased. In trisomy 18, all three values are low. These tests are well demonstrated to increase the detection rates of chromosomal abnormalities, identifying about 60 percent of fetuses with trisomies 21 or 18 [22–24]. The same holds true for women over 35, who may in some cases be reluctant to undertake amniocentesis if their risk of anomaly is lower than their risk of procedure-related loss [25]. However, false-positive rates (positive test results in an unaffected fetus) remain a concern which should be addressed as women are counseled. It is essential that women understand that these tests are done to identify a large group of women whose pregnancies deserve closer evaluation, not to diagnose disease. Since Down syndrome is by far the most common chromosomal abnormality in live-born children, most focus is placed on this condition. Table 23-4 illustrates the detection and false-positive rates for Down syndrome associated with various maternal ages [26]. When a sonographic gestational age using the biparietal diameter is available, it is the preferred value for use in establishing gestational age in multiple marker screening programs, since anencephaly, spina bi-

fida, and Down syndrome all may affect this measurement [27]. Reducing the false-positive rates for Down syndrome reduces the burden of amniocentesis in normal pregnancies, without affecting diagnosis rates negatively.

It is important to recognize that elevated MSAFP screens and possibly abnormal hCG levels have been linked with an increase in poor perinatal outcomes even in the face of normal ultrasound and amniocentesis results. Specifically, an increased risk of stillbirth and preterm delivery has been identified [28, 29]. However, not all studies agree, and efforts to link second trimester biochemical markers to the prediction of preeclampsia have met with little success [30–32].

Modifications of screening programs are part of the continuing efforts to recognize pregnancy complications. Currently, the addition of inhibin A to second trimester screens, creating a quadruple test, is becoming available. When all four values are computed, the ability to identify cases of Down syndrome is raised to 80 to 85 percent with a false-positive rate of 5 percent [33, 34].

Multiple marker screening should be offered between 15 and 20 weeks' gestation. Earlier screening allows time for evaluation and management of abnormal results.

Integrated Screening

Several authors now advocate various combinations of first or second trimester biochemical screens with nuchal translucency testing. Such combinations, because the measurements are independently variable, maximize the benefit to the family. That is, they give the highest possible sensitivity, while reducing the need for invasive diagnostic testing. Probably the most commonly available is nuchal translucency measurement plus second trimester multiple marker screening [34, 35].

Management of Abnormal Screening

As a rule, abnormal AFPs should be tested again after confirmation of dates; thus, offering the test as close to 15 weeks as possible is important. An abnormal triple screen is generally not repeated but may be recalculated based on a new assessment of gestational age. When a triple screen is abnormal, the most common reason is miscalculation of gestational age. Therefore, an ultrasound examination is indicated to confirm dating as well as to rule out the presence of structural anomalies. Follow-up of abnormal findings should be performed in a timely manner to allow families to make decisions regarding genetic counseling and the possible need for more invasive testing. Triple screen dating criteria may be clarified at the same time as the 16- to 20-week ultrasound anomaly screen.

Genetic tests, biochemical evaluation, and ultrasound are used to make diagnoses following abnormal screens. Women with an increased risk for an open neural tube defect may be offered amniocentesis for amniotic fluid AFP, acetylcholinesterase testing, and karyotyping, in addition to a comprehensive ultrasound examination. In tertiary care centers, a comprehensive ultrasound examination is the preferred means of evaluation for neural tube or ventral wall defects. Because ultrasound performed by very skilled sonographers using high-resolution ultrasound equipment is a highly effective means of ruling out these specific anomalies, an amniocentesis may be considered unnecessary in these cases [36]. A combination of ultrasound and amniocentesis is necessary to diagnose chromosomal anomalies. Because extremely skilled sonographers and state-of-the-art high-resolution instrumentation are not widely available, the combination of amniocentesis and ultrasound remains the most common diagnostic approach in the United States for abnormal triple screen results.

Women at increased risk for Down syndrome and other chromosomal anomalies are offered re-

ferral for genetic amniocentesis. Ultrasound evaluation for associated structural defects is also usually recommended. Multiple sonographic markers have been associated with Down syndrome and are thought to improve the identification of affected fetuses. Because reliance on ultrasound alone has not been proved to be diagnostic of Down syndrome, amniocentesis remains the definitive diagnostic tool [37]. The performance of invasive diagnostic tests for genetic disorders, such as CVS or amniocentesis, itself carries a risk of pregnancy injury or loss. These tests also require specialized training and equipment and are expensive to perform. Women should be informed regarding procedure-related risks and their options, including no testing at all. In addition, every woman should be advised that no individual test or combination of tests can guarantee the eventual well-being of her child.

Invasive Fetal Assessment Throughout Gestation

Chorionic Villus Sampling

In the first trimester of pregnancy, chorionic villus sampling (CVS) is used to identify genetic diseases that affect the fetus. This test offers the advantages of early diagnosis, opportunity to terminate an affected pregnancy during the first trimester, and greater privacy for the woman and her family. It has been suggested that CVS might also facilitate prenatal bonding by providing early reassurance of the fetus's well-being [36]. CVS may be the test of choice for women who are more willing to terminate a pregnancy [38]. Rapid results for many of the common genetic abnormalities can now be obtained with polymerase chain reaction (PCR) technology in CVS specimens [39].

A disadvantage of CVS is that it carries a slightly increased risk of pregnancy loss compared to second trimester amniocentesis. After correction for the background rate of spontaneous abortion in the late first trimester, the increased risk of pregnancy loss amounts to approximately 0.8 percent [40]. Oligohydramnios, rupture of the amniotic membranes, and subchorionic hematoma have all been reported as sequelae of CVS. Another concern is the risk of limb reduction defects reported in some studies, particularly with CVS at 8 to 9 weeks' gestation. There appears to be no increase in the risk of these defects when CVS is performed at or after 10 weeks' gestation [19]. It is important to know the experience of the individuals actually performing the procedure in order to have a true estimate of risk.

Chorionic villus sampling is most often performed transcervically (Figure 23-2). In some cases, placental location, uterine position, cervical stenosis, or the woman's discomfort may lead the physician to enter the uterus transabdominally (see Figure 23-3). Ultrasound is used to guide the placement of a flexible catheter through which placental villi are removed. Villi from the developing placenta are then karyotyped. Adequate tissue will be obtained in 97 to 98 percent of all CVS samples, which will then culture successfully. The tissue samples undergo both direct analysis (which gives results in 48 hours) and more accurate culture techniques (with results in 10 to 14 days). Because chromosomal mosaicism can be evident in the placenta but not the fetus, in rare instances abnormal results may require amniocentesis in the second trimester [36, 41]. Mosaicism would be noted by the geneticist and included in the report.

Women who are Rh negative should receive Rh immune globulin (e.g., RhoGam) following invasive procedures. When a woman shows evidence of prior Rh sensitization, amniocentesis is preferred to CVS to delay any possible effects on the fetus [36, 40].

Women undergoing CVS should be advised that MSAFP testing for open neural tube defects is still

recommended. It is important to note, however, that because CVS may allow maternal-fetal blood exchange, there is the possibility that CVS may cause a falsely elevated MSAFP [19]. Ultrasound scans for anatomy and/or amniocentesis for AFP and acetylcholinesterase may be suggested when an abnormal MSAFP follows a normal CVS [41].

Amniocentesis

When both procedures are available in her community, a woman can choose amniocentesis or CVS based on personal preference, gestational age at registration, and concerns about risk. Standard genetic amniocentesis is performed at 15 to 16 weeks' gestation, when indicated. For women at risk for open neural tube defects, amniocentesis will provide specific measures of amniotic fluid alpha-fetoprotein and acetylcholinesterase, which CVS does not.

The technique of amniocentesis for removal of fluid from the uterine cavity is a century old. In the last 40 years, its usefulness has expanded to encompass genetic and biochemical diagnosis, assessment of fetal disease, and evaluation for fetal maturity. The procedure is performed under direct ultrasound guidance to reduce the risk of piercing the fetus and to avoid the placenta whenever possible. If the placenta lies anteriorly and cannot be avoided by needle puncture, the clinician must make a decision regarding the safest place in the placenta to pass the needle through; in the case of Rh isoimmunization, the decision may be to reevaluate the risk-benefit ratio of the amniocentesis. About 99 percent of amniocenteses for genetic testing are successful. Results are commonly available within 2 to 3 weeks, although FISH technology can make rapid results available for common aneuploidies.

Risks of amniocentesis include fetal loss in about 0.5 to 1.0 percent of all cases. There is a 0.1 percent risk of amnionitis; there have been rare reports of fetal injury. Maternal spotting or fluid leakage following the procedure is not usually associated with poor pregnancy outcomes. Rh negative mothers receive Rh immune globulin to prevent isoimmunization [36, 40].

Early Amniocentesis

Prior to 15 weeks of gestation, a modified amniocentesis can be used as an alternative to CVS, if technical considerations preclude CVS. As with second trimester amniocentesis, neural tube defect identification is enhanced, but at this early gestation, fewer cells are available for detecting metabolic errors. The relative risk of this procedure probably exceeds that of either CVS or later amniocentesis. Reasons for this increased risk include incomplete fusion of the amnion and chorion prior to 13 weeks gestation and less total amniotic fluid [42]. Several reports of trials of early amniocentesis indicated a significantly increased risk of fetal loss, leakage of amniotic fluid, and an increased incidence of talipes equivarnus. [43–45]. However, not all studies do so; also, some spontaneous losses will occur during the time frame separating early and standard amniocenteses, partially explaining the difference in rates of fetal loss or morbidity following the two procedures.

Amniocentesis After 20 Weeks

As the fetus reaches viability, the primary use of amniocentesis changes from genetic diagnosis to monitoring of fetal lung maturity. It is more common to use CVS for rapid karyotyping late in pregnancy. Testing of amniotic fluid obtained through amniocentesis prior to scheduled cesarean deliveries and elective labor inductions, particularly those scheduled before 39 weeks, can assist in the pre-

vention of iatrogenic prematurity and respiratory distress syndrome. Lecithin/sphingomyelin ratios (L/S) and phosphatidylglycerol (PG) tests can evaluate lung maturity. When PG is present in amniotic fluid, the risk of respiratory distress syndrome is minimal, even when the L/S ratio is less than 2 [40, 42]. The "shake" and "tap" tests and optical density assessments also utilize amniotic fluid samples. Pregnancies complicated by Rh isoimmunization can be monitored with optical density assessment based on the bilirubin content of the amniotic fluid [36].

Cordocentesis

Cordocentesis, also known as percutaneous umbilical blood sampling (PUBS), is the most current method of directly sampling fetal blood. This process utilizes ultrasound visualization of the fetus and the cord in order to allow needle puncture of the fetal cord to withdraw a sample of the fetal blood. This method can also be used to transfuse or to medicate the fetus.

The indications for cordocentesis are few and pertain to only a small number of very high-risk patients. The indications include the need for rapid karyotyping of the fetus by DNA, assessment and treatment of Rh isoimmunization, measurement of cord blood gases for severe intrauterine growth restriction (IUGR), diagnosis of fetal infection such as cytomegalovirus (CMV) or toxoplasmosis, and treatment of fetal disorders (e.g., use of digitalis for fetal cardiac arrhythmias). Risks of the procedure include spontaneous abortion, rupture of membranes, preterm labor, infection, bleeding, fetal trauma, and isoimmunization [46]. Figure 23-4 shows two methods for approaching the cord at its insertion to the placenta, the preferred site of sampling because of its relative stability [47]. With research and experience, more applications for this procedure will most likely evolve. Clearly, this invasive procedure is outside of the scope of midwifery practice. Women under the care of a midwife may require referral for complications of their pregnancies that necessitate this approach. It is currently being utilized only in large tertiary settings and is best performed by trained professionals.

Third Trimester Fetal Assessment

The purpose of fetal assessment in the third trimester is primarily the prevention of fetal death [48]. During the third trimester, assessment of fetal well-being is made by using nontechnological methods such as fetal movement counting (FMC) and the auscultated acceleration test (AAT) and/or technological methods of ultrasound and fetal monitoring, either independently or in combination. The midwife must be knowledgeable regarding the potential uses of each of these fetal assessment methods. Depending on the practice setting, midwives may be involved in performing and interpreting nonstress tests (NST), contraction stress tests (CST), the biophysical profile (BPP), amniotic fluid index (AFI), doppler velocimetry, or other limited ultrasound examinations.

Fetal Movement Counting

Fetal movement counting is by far the simplest of all fetal assessment techniques, and it is applicable to the largest group of women. Research has confirmed what mothers and midwives have known for centuries: fetal activity is reassuring and a dramatic decrease in fetal activity or cessation of movements is worrisome [48–51]. The total number of movements made by the fetus may be quite variable. The most important point is that a marked decrease in movement from a fetus's usual pattern is cause for concern and cessation of movements is highly correlated with impending fetal death [48, 51, 52]. Perinatal deaths from cord accidents, placental abruption, and other causes cannot be totally prevented [61, 62], but women should be aware of the potential concerns associated with a decrease in fetal movement and be enabled to report any concerns in a timely fashion.

Fetal movement has many influences, including the time of day, gestational age, glucose loading, sound stimulus, fetal behavioral states, maternal smoking, and maternal use of certain medications as well as hypoxia and acidemia [51–59]. Maternal perception of fetal movement can be diminished by the presence of polyhydramnios or oligohydramnios as well as by an anterior placenta [59]. Maternal obesity, however, has been shown not to interfere with maternal perception of fetal movement. Babies are also affected by diurnal variations, with fetuses being most active late at night and least active in the morning hours between 2:00 a.m. and 8:00 a.m. [53]. As pregnancy nears term, there may be a slight decrease in the actual number of movements. The amplitude of fetal movement tends to diminish as the volume of amniotic fluid decreases. This decrease in fluid volume leaves less space for fetal limb excursion, thereby producing a decrease in maternal perception of fetal movement.

Smoking only two cigarettes has been shown to decrease fetal activity for as long as 80 minutes [55]. Although it is ideal for pregnant women not to smoke, they should at least refrain from smoking for a 2-hour period before fetal movement counting or antepartum fetal testing in order to avoid false-positive test results.

Many methods of counting fetal movements have been proposed [50–52, 58, 60, 61], but none has been shown to be superior to another in predicting fetal outcome [48, 62]. The most important thing is that women be aware that consistent fetal movement patterns are important—they must report a decrease or cessation of fetal movement [54, 57, 61]. When selecting a fetal movement counting method, take the educational level of the woman into consideration. If your client is able to read and understand basic graphing procedures, the Count-to-Ten method described in Table 23-5 [53] and the chart in Figure 23-5 will be satisfactory. The Count-to-Ten method has the advantages of being simple to use, brief, and easy to interpret [53, 60]. If, however, graphing daily movement counts frustrates your client, then the documentation method must be changed. Use a time frame such as a 30-minute television program, during which the woman counts the baby's movements, and have her simply write down the date and time of the counts. Another method would be to have the woman put ten pennies out on the kitchen table each morning. For each fetal movement she feels, she places one penny in a cup. If the pennies are not all in the cup by lunchtime, she is to call the clinic to report diminished fetal movement [61]. Ways to document movement are many, but using a consistent method with daily documentation is important. The message to all women should be clear: Fetal movement and their own report of it are very important. It can be empowering to women to be responsible for their own fetal surveillance [61].

TABLE 23-5 Count-to-Ten Movement Counting Method

1. Schedule one count session daily.
2. Schedule session for the same time each day—e.g., at 8:00 a.m., or select a time when you have the time to count and when the fetus is usually active.
3. Chart how long it takes to reach 10 movements.
4. There must be at least 10 movements identified in 10 hr.
5. If there are fewer than 10 movements in 10 hr, if it takes an increasing time to reach 10 movements, or if no movements are felt within 10 hr, call your midwife.

Fetal movement counting should be started at 34 to 36 weeks for women at low risk for uteroplacental insufficiency. For those with identifiable risk factors, 28 weeks is a reasonable time to initiate formal fetal movement counting. When a woman reports decreased fetal movement, the midwife should follow the steps in Figure 23-6 [61].

History taking is a critical step. Women often report decreased fetal movement because they do not remember feeling activity for a period of time, but they may not have been paying close attention. Ask a woman to focus on fetal activity for a period of an hour, preferably when she is resting, well fed, and hydrated. If, during that hour, the woman feels at least three movements, reinforcement of fetal movement counting is all that is required. If, however, she reports only two or fewer movements, a nonstress test (NST) should be performed immediately. Often, the fetus has a reactive nonstress test, demonstrating adequate activity and fetal well-being. This can be a positive learning experience for mothers that reinforces them to be more aware of the sensation of fetal movement and to trust themselves to report even small moves that they previously may have thought insignificant. When the fetus has a reactive test, serial fetal assessment is not indicated. If fetal movement has been decreased in response to fetal compromise, there will be nonreassuring indicators, such as a nonreactive NST or a decreased biophysical profile score. It is then necessary to evaluate quickly for risk of fetal demise.

A very small group of women do not perceive fetal movement. The fetuses of these women are

Source: Reprinted from *Journal of Nurse-Midwifery* 36(3), Gegor, C. L., Paine, L.L., and Johnson, T. R. B., Antepartum fetal assessment: a nurse-midwifery perspective, 157, © 1991 American College of Nurse-Midwives, with permission from American College of Nurse-Midwives.

best evaluated by weekly nonstress testing, beginning at 34 to 36 weeks, to document fetal activity and heart rate accelerations [61]. Often these are women who have a history of previous stillborns or are very anxiety ridden for other reasons. The weekly NST can serve as an indicator of fetal well-being to both the provider and the mother.

Auscultated Acceleration Tests

For years, midwives and physicians used auscultation with a fetoscope to evaluate fetal status and in some cases to detect fetal heart rate (FHR) accelerations as reassurance of a healthy fetus [63–65]. Auscultation of the FHR with a fetoscope at or near 20 weeks' gestation continues to be of recognized clinical value [66, 67]. In the 1960s, however, handheld electronic devices for the detection of the FHR precipitated a general decline in the use of the fetoscope during labor and other periods of gestation [61].

During the 1980s, Paine researched the use of auscultation of the FHR as a means of predicting fetal well-being during the antepartum period. From this work, a method of auscultation was proposed as a simple alternative to the nonstress test and as a formal method of auscultation for antepartum use [61, 65–70]. The resulting 6-minute auscultated acceleration test (AAT) has shown promise as a predictor of both reactive and nonreactive NST results [65]. Table 23-6 is a description of the AAT procedure and interpretation [67]. The AAT graph shown in Figure 23-7 is used to document the FHR pattern [67]. Figure 23-8 illustrates a completed AAT and includes an inset of an NST completed simultaneously, for comparison.

The AAT has been proposed for women beyond 34 weeks' gestation with a single fetus. In general, use of the AAT may be of benefit for low-risk women who do not otherwise undergo antepartum testing by NST, particularly if combined with fetal movement counting. Anecdotal accounts indicate that use of both low-technology techniques has led

TABLE 23-6 AAT Procedure and Interpretation

Procedure
Use an Allen fetoscope. Auscultate the FHR for 6 min, counting during every other 5-sec interval. Document auscultated FHRs on AAT graph.
Interpretation
Identify the baseline FHR. An acceleration is present when the FHR is up by two grid points (2 beats per 5-sec period). A single FHR acceleration indicates reactivity.

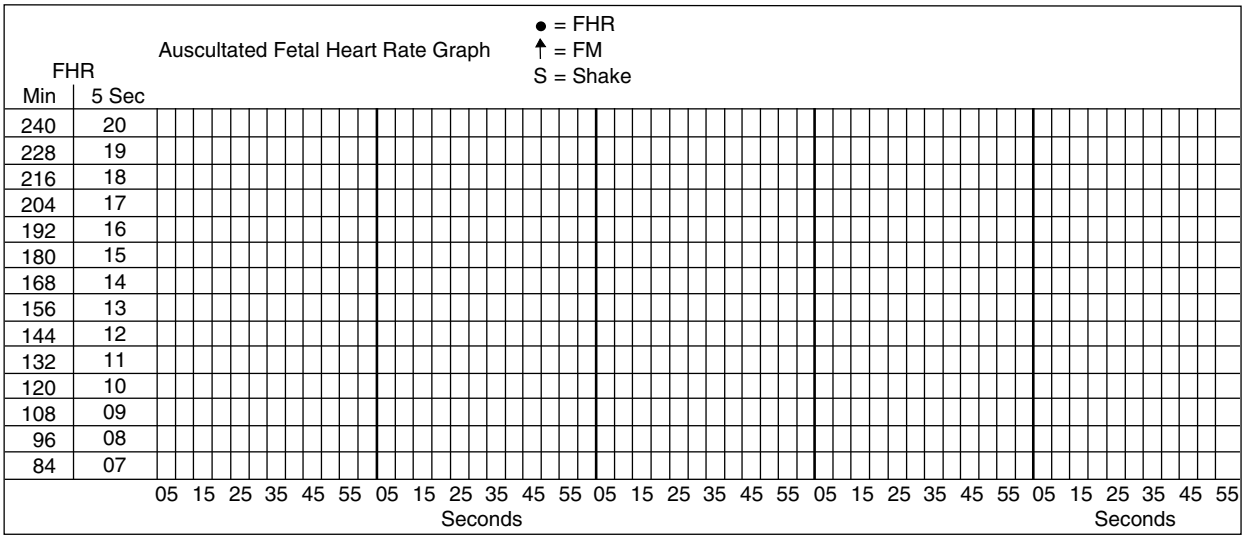

FIGURE 23-7 The AAT graph used to document the FHR pattern.

to appropriate management of compromised fetuses that would not otherwise have been identified as high risk by the usual criteria used in midwifery practice.

Nonstress Test

The most commonly used third trimester test of fetal well-being is the nonstress test (NST). The NST is performed using an external electronic fetal monitor. This test is indicated for women whose pregnancies are complicated by or have increased risk for uteroplacental insufficiency (UPI). Table 23-7 lists the most common obstetric indications for conducting an NST as a component of antepartum testing, while Table 23-8 identifies maternal indications for testing.

The method for performance of the NST is relatively standard and is outlined in Table 23-9. However, interpretation of the NST varies in the medical literature and in current clinical practice.

TABLE 23-7	Obstetric Indications for Antepartum Testing

Suspected intrauterine growth restriction (IUGR) in this pregnancy
History of IUGR in previous pregnancy
Pregestational diabetes
Gestational diabetes
Chronic hypertension
Pregnancy-induced hypertension
Preeclampsia
Multiple gestation
Oligohydramnios
Post dates
Rh isoimmunization
Preterm rupture of membranes (PROM)
Decreased fetal movement
Previous stillbirth

Hemoglobinopathies (hemoglobin SS, SC, or S-thalassemia)
Cyanotic heart disease
Systemic lupus erythematosus
Chronic renal disease
Type I diabetes mellitus
Hypertensive disorders

TABLE 23-9	Performance of the Nonstress Test (NST)

1. Place woman in a side-lying position (left or right side).
2. Initiate external electronic fetal monitoring (both FHR and contraction monitoring).
3. Identify the baseline FHR (minimum of 3 min).
4. Continue monitoring for a minimum of 20 min.

Note: A fetal event marker is not required for performance of the NST. FHR accelerations are associated with fetal movement, and maternal perception of this movement is not required.

Midwives must be familiar with the criteria used in the practice setting where they order or interpret the NST. For the sake of consistency in this chapter, the interpretation criteria in Table 23-10 will be used.

A reactive NST (Figure 23-9) is considered to be an excellent indicator of fetal well-being in the third trimester, because a fetus must receive adequate oxygen and other nutrients through the placenta and be neurologically not depressed in order to have accelerations of the fetal heart rate associated with fetal movement. FHR reactivity is a developmental milestone of the fetus that is usually achieved between 28 and 32 weeks' gestation [71, 72].

TABLE 23-10	Interpretation Criteria for the Nonstress Test (NST)
Interpretation	**Criteria**
Reactive	At least two accelerations of the FHR within a 20-min period that are off the baseline for at least 15 sec and that have a minimum amplitude of 15 bpm
Nonreactive	FHR tracing that fails to demonstrate adequate number or amplitude of FHR accelerations within any 20-min period
Inconclusive	A tracing of FHR that is uninterpretable because of difficulty obtaining the EFM tracing, or a tracing that does not demonstrate an FHR baseline (common with very vigorous fetuses)

A nonreactive NST in a term fetus is considered to be a nonreassuring finding, especially when reactivity has been previously demonstrated (Figure 23-10). In the preterm fetus, however, a nonreactive NST may be appropriate because of the immaturity of the fetus [71–74]. When an NST is nonreactive, the midwife must gain additional information regarding this fetus before the woman can be discharged from the clinical setting. Additional testing may be indicated, such as prolonging the NST [73], performing a biophysical profile (BPP) [75, 76], or a contraction stress test (CST) [71]. Table 23-11 lists reasons why the NST may be nonreactive.

Because a fetus experiences sleep states [77], continuing the NST for an additional 20 minutes may provide the fetus with adequate time to complete a prolonged sleep cycle and demonstrate reactivity. A preterm 28-week fetus may not be capable of demonstrating reactivity because of immaturity of its nervous system. Occasionally, a fetus will have an FHR pattern that has accelerations as well as multiple variable decelerations, which make interpretation of well-being difficult if not impossible [71, 74]. These multiple mild variable decelerations are generally believed to represent intermittent cord compression, and are often seen with fetal movement in the presence of oligohydramnios. If the

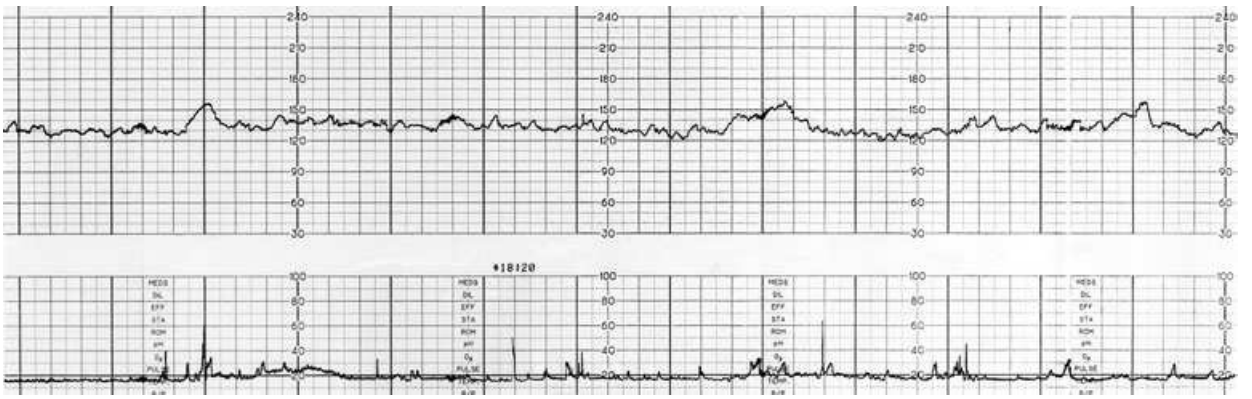

FIGURE 23-9 Reactive nonstress test.

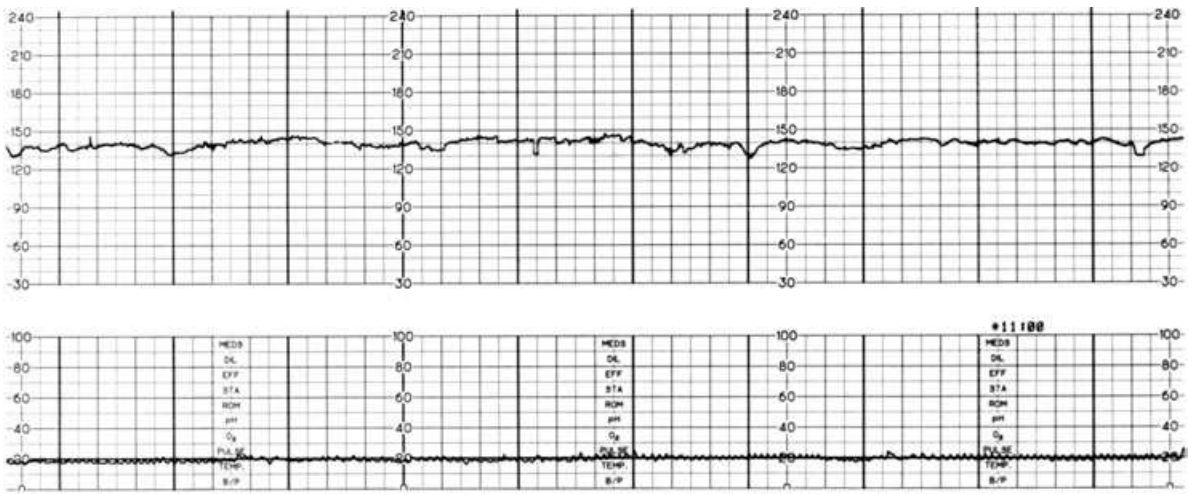

FIGURE 23-10 Nonreactive nonstress test.

variables are mild, brief (less than 30 seconds), and nonrepetitive, they are not associated with poor pregnancy outcomes [48, 78]. If, however, the decelerations are more frequent than 3 in 20 minutes, or are of a duration greater than one minute, there is an increased association with cesarean section and fetal demise [48, 78]. When an NST is nonreactive, regardless of the cause, some demonstration of fetal well-being must be obtained (e.g., BPP) before the woman is discharged from the care setting.

TABLE 23-11 Common Causes of Nonreactivity of the Nonstress Test (NST)

Fetal Causes	Maternal Causes
Gestational age (28–32 weeks)	Disease (e.g., diabetes, hypertension)
Deep sleep state	Medications (e.g., beta-blockers, CNS depressants, tocolytics, steroids)
Hypoxia	Illicit drug use
Oligohydramnios	Smoking
CNS or cardiac anomalies	Chorioamnionitis
Circadian rhythms	Dehydration

Inconclusive NSTs are usually the result of difficulty in obtaining a legible EFM tracing. This difficulty may be the result of a very active fetus, maternal obesity, or polyhydramnios. Mechanical difficulties may also be encountered. Sometimes a tracing is easily obtained, but the fetus is constantly moving, thus demonstrating a long series of accelerations with inadequate return to baseline (Figure 23-11). In this case, the NST cannot be evaluated because a baseline FHR is not obtainable. Usually, the fetus will eventually come to rest, and then the strip will be interpretable. The maximum duration of NST evaluation is disputed in the literature, ranging from 40 minutes to 2 hours [61, 74]. This

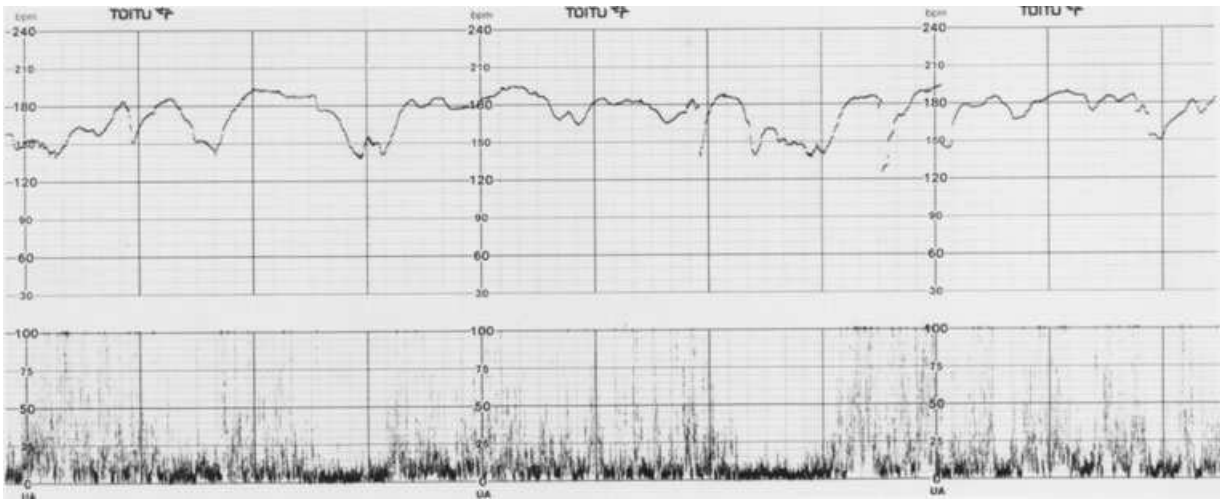

FIGURE 23-11 Inconclusive nonstress test (active, awake fetus).

time frame may depend not only on the fetus but also on the availability of ultrasound for performing a biophysical profile. If ultrasound is readily available, it may be more time efficient to stop the NST at 40 minutes and perform the BPP. However, if the ultrasound location is a great distance from the NST site, appointment times are not readily available, or cost is prohibitive for the woman, then prolonged NST may be the best option. A CST may also be considered when the NST is nonreactive and ultrasound is not readily available to perform a BPP.

Once serial testing is initiated, the frequency of testing will depend on the indication for testing, the severity of uteroplacental insufficiency (UPI), and the policies in each setting. As a test of fetal well-being, the NST should be done at least once a week. For women who have a particularly high risk of poor pregnancy outcome related to UPI, twice-weekly testing is often recommended. For women at home on bedrest, there are a growing number of services that will send nurses to perform the NST in the home; in some cases the woman herself can perform the test and send the data by phone [79]. The nurse or midwife may also elect to perform an AAT.

It is well accepted that most fetuses with a nonreactive NST are actually healthy [80–84]. Many different methods have been tried to induce a nonreactive fetus to become reactive, including shaking the baby in utero—a practice that has overall proved to be futile [80–83]. Probably the most common method of attempting to "make" a baby reactive is maternal ingestion of juice as a source of glucose. However, the research to date shows rather convincingly that a glucose load does not significantly change fetal movement or fetal heart rate reactivity [81, 83]. Other than vibroacoustic stimulation, the only intervention that increases the rate of reactivity is waiting for a longer time.

Vibroacoustic Stimulation

In an effort to decrease the number of nonreactive NSTs, vibroacoustic stimulation (VAS) was introduced [85–89]. VAS uses an artificial larynx to deliver both auditory and vibratory stimuli to the fetus. The fetus responds with a startle, activity, and FHR accelerations. Ease of use, rapidity of fetal response, low cost of equipment, and the perceived noninvasiveness of the procedure are additional reasons VAS gained popularity.

VAS is performed by placing the vibroacoustic stimulator against the maternal abdomen directly above the fetal head and causing it to emit one or several brief stimuli. The most probable effect of VAS is to startle the fetus from a sleeping to an awake state [90]. The fetal response is commonly an acceleration of the FHR followed by reactivity. A fetal response of tachycardia (over 160 beats per minute), an abnormal heart rate pattern, is also common; this response requires that a woman continue fetal monitoring for a prolonged period until a normal baseline heart rate has been reestablished, often negating any time-saving benefits of VAS [91]. Several methods of interactive stimuli are currently being investigated, including maternal voice stimulation [82] and lesser degrees of vibration and sound than current VAS.

Interpretation of VAS FHR strips varies among authors. Most do not include the initial acceleration as an interpretive criterion but rely on subsequent accelerations of the FHR to meet basic NST criteria. The midwife must be aware of accepted interpretive criteria in the practice setting when using this method of fetal assessment.

During the intrapartum period, VAS may be used to help elicit a response in order to differentiate between a fetus in a deep sleep state and a hypoxic fetus. In this case, a prolonged FHR tracing with minimal or no variability may make interpretation of fetal well-being difficult. VAS may be used in place of fetal scalp sampling in some cases (refer to Chapter 27 for more detail).

Contraction Stress Test

The contraction stress test was the first test to be widely used as a screening test for fetal well-being [71]. This test has now been mostly replaced by the NST and amniotic fluid index (AFI) or the BPP. However, the CST has two major advantages over the NST. First, the CST remains the most accurate predictor of uteroplacental insufficiency (UPI) [71, 74]. Second, the CST is a reliable test from 26 weeks until term. Disadvantages of the CST are that it has a high false-positive rate (about 30 percent of the positive results are for fetuses who are actually well), it is more expensive than the NST, takes more time, and is more invasive; in addition, women prefer the NST and/or the BPP.

Women with an indication for the CST are those with UPI or who are at high risk to experience UPI during their pregnancies. Therefore, the indications for the CST are the same as those for the NST if it is being used as the primary screening test. Currently, the CST is used mostly for women who are known to have a fetus with intrauterine growth restriction (IUGR). When the NST is nonreactive and ultrasound is not readily available to perform a BPP, the CST is the most useful test to determine fetal well-being.

Contraindications for the CST fall into two categories: absolute and relative. Absolute contraindications include clinical situations when labor would be dangerous—for example, women who have had a previous classical cesarean section or myomectomy entering the uterine cavity, those with placenta previa, or those who are at current risk for preterm labor. Relative contraindications include gestational age less than 37 weeks and multiple gestation. In the case of relative contraindications, a risk-benefit consideration is necessary, to weigh the possible consequences of an unintended labor from contraction stimulation against the need for information regarding fetal status.

The CST can be performed in two ways: the oxytocin challenge test (OCT) or nipple stimulation. Table 23-12 delineates these two procedures for inducing contractions; the criteria for choosing the procedure may be different from one practice site to another. Due to the potential for stimulation of labor and of late decelerations, it is advisable that the CST be performed in a hospital. This site may be the labor and delivery suite, a fetal assessment center, or the in-hospital obstetric clinic.

Interpretation of the CST is highly standardized in the medical literature as well as in practice. Table 23-13 lists the interpretation criteria. It is important

TABLE 23-12 Procedures for Inducing Contractions for the Contraction Stress Test (CST)

Breast Stimulation
Stimulation of one nipple, through the clothing
2 min stimulation
5 min resting
Do not stimulate through a contraction
If not successful within 45 min, perform OCT
Oxytocin Challenge Test (OCT)
Intravenous infusion, D5/0.2NS keep-vein-open rate
Oxytocin solution: 10 units pitocin in 500 cc D%/0.2NS per infusion pump
Titrate oxytocin from 1 mlU/min
Increase 1 mlU/min every 15 min
Continue until adequate contraction pattern or abnormal FHR patterns

TABLE 23-13 Contraction Stress Test (CST) Interpretation Criteria

Procedure
Establish FHR baseline prior to initiation of CST.
Prior to interpretation of FHR patterns, the EFM strip must demonstrate 3 contractions within 10 min.
Minimum contraction duration is 40 sec off the baseline (unnecessary for the woman to perceive the contractions).
Interpretation
Negative (reassuring): FHR baseline stable, without evidence of late decelerations
Positive (nonreassuring): Repetitive late decelerations
Equivocal:
Unable to obtain satisfactory tracing
Hyperstimulation
Nonrepetitive decelerations

to note that whether contractions are elicited by nipple stimulation, oxytocin challenge, or occur spontaneously, interpretation is the same and has the same predictive value. A positive CST (Figure 23-12) is a very strong predictor of uteroplacental insufficiency. As previously mentioned, the CST has about a 30 percent false-positive rate [74]. Therefore, nearly a third of women with a positive CST have a fetus that is actually normal. This is in contrast to a false-negative rate of less than 1 percent, meaning that it is rare for an affected fetus to have a negative CST. It is important to take results of the CST very seriously but also to interpret them in the context of the woman's overall clinical situation. For example, if a woman has well-controlled chronic hypertension and her pregnancy has progressed normally, with adequate fetal growth, and she then has a positive CST at 39 weeks, a false-positive test must be considered. This CST would best be followed by a BPP or by a repeat CST within 24 hours. On the other hand, if a woman with a 32-week pregnancy complicated by diabetes and hypertension and a fetus with IUGR is found to have a positive CST, the result is more likely to be accurate, and immediate assessment of the pregnancy is imperative.

A negative CST (Figure 23-13) is considered to be predictive for 7 days [71], thereby requiring no more than weekly retesting for the purpose of screening for UPI. If the negative CST also demon-

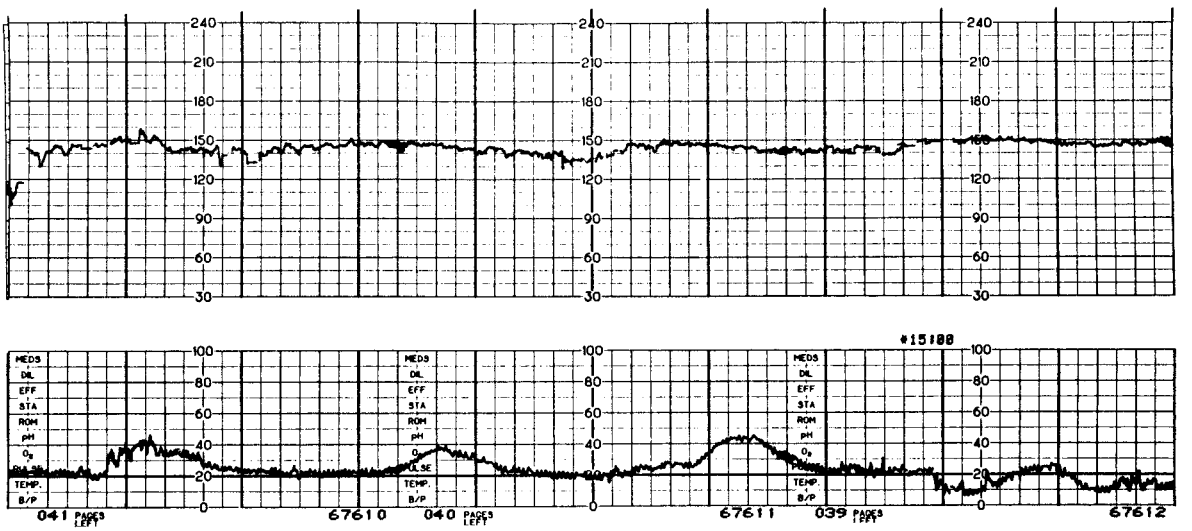

FIGURE 23-12 Positive contraction stress test. Note the presence of a late deceleration following each contraction.

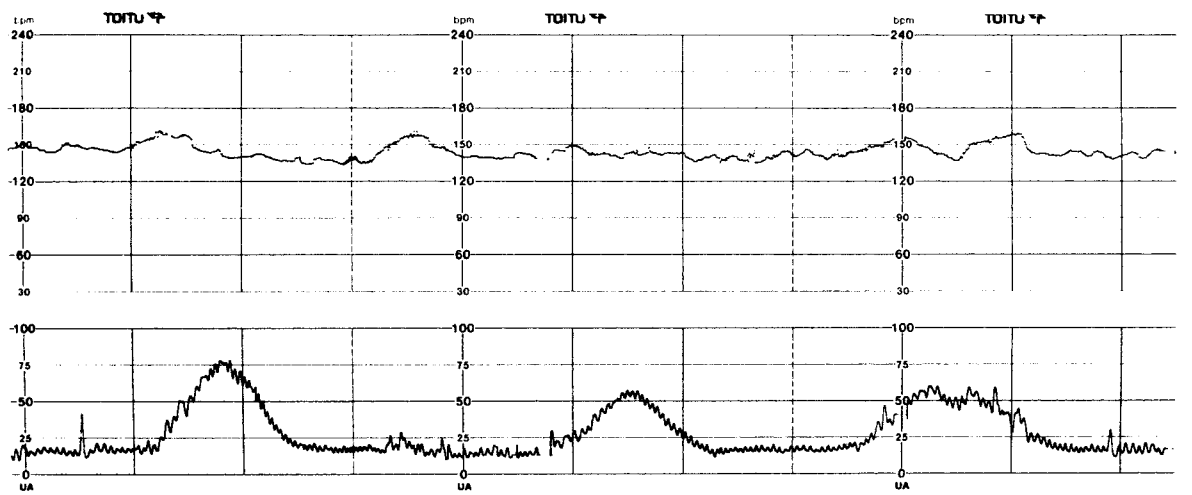

FIGURE 23-13 Negative contraction stress test.

strates FHR accelerations that meet the NST criteria, then the woman has an added measure of reassurance [74].

Equivocal CST results occur when the tracing is inadequate because of fetal or maternal activity, maternal obesity, or polyhydramnios. A test may also be considered to be equivocal if the woman shows evidence of uterine hyperstimulation, which is defined as more than 5 contractions in a 10-minute period or any single contraction lasting longer than 90 seconds. When hyperstimulation occurs, the FHR pattern cannot be evaluated to indicate uteroplacental insufficiency. The last reason for considering CST results as equivocal is when it shows nonrepetitive decelerations, suggestive of late decelerations. Because of the potential for uteroplacental insufficiency in the presence of an equivocal test, the woman must be continuously assessed in the hospital setting until more complete information is available. An equivocal CST may be repeated within 24 hours or a BPP may be performed [92, 93]. If the BPP results are reassuring, the CST need not be repeated.

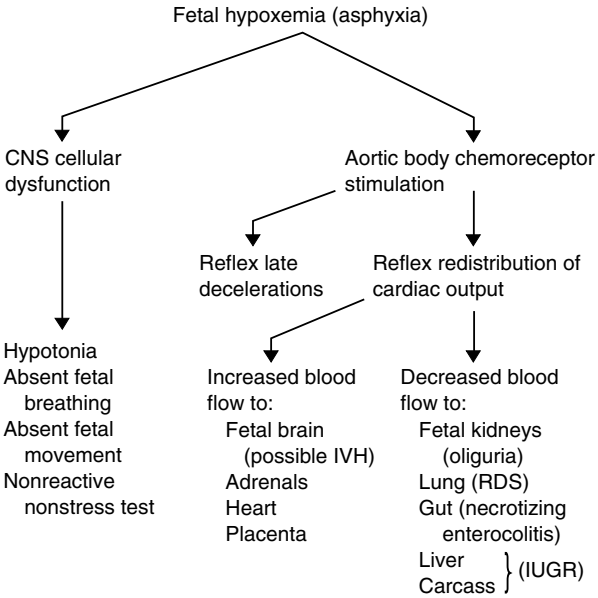

FIGURE 23-14 Biophysical effects of hypoxia on the fetus.

CNS: central nervous system; IUGR: intrauterine growth retardation; IVH: intraventricular hemorrhage; RDS: respiratory distress syndrome

Biophysical Profile

The biophysical profile utilizes both electronic fetal monitoring and ultrasound instrumentation. The BPP evaluates the fetus by combining observation of fetal behavior with the nonstress test and measurements of the volume of amniotic fluid. The BPP is based on the premise that when a fetus is fully oxygenated and neurologically intact, it has a variety of characteristics, including muscle tone, gross movement, and respiratory activity. In addition, the mature fetus will have a reactive NST. Because the amniotic fluid is primarily fetal urine in the third trimester, it is quantified as a measure of fetal renal function. When the fetus becomes hypoxic, the criteria observed by the BPP are diminished in reverse order of their developmental appearance. Figure 23-14 shows the effects of hypoxia on the fetus in utero [94].

Indications for the BPP include known or suspected IUGR, oligohydramnios, insulin-dependent diabetes, preeclampsia, postdates, nonreactive NST or positive CST, and multiple pregnancy. Weekly testing is the usual recommendation. For insulin-dependent diabetics and for pregnancies beyond 42 weeks' gestation, a twice-weekly testing scheme is recommended [92]. In addition, any time there is a change in maternal status—e.g., rapid onset or labile hypertension—there may be need for repeated BPP. Testing is generally begun at the earliest gestational age that the clinician would consider delivery if the results indicated an acidemic fetus [92]. Specific testing strategies are discussed in the section on antepartum complications in Chapter 24, when each specific clinical indication is reviewed. Fetuses with anomalies, especially of the genitourinary, respiratory, or central nervous systems may have decreased BPP scores due specifically to their anomalies.

Evaluation of the BPP and the scoring of the examination are listed in Table 23-14 [92]. Management of the woman based on the BPP should always take the full clinical situation into consideration. If the BPP results seem not to reflect the clinical situation, then the woman must be carefully evaluated and tested again if appropriate. Table 23-15 describes the possible outcomes within 1 week of testing and identifies possible management for BPP scores with the Manning criteria [76].

A BPP score of 10/10 (read as 10 out of a possible 10), the possibility of fetal hypoxia is minimal and the fetus should do well for the following week. As noted in Table 23-15, the perinatal mortality (PMR) rate within 1 week with a score of 10/10 is < 1/1000. It is important to know that these are "adjusted" PMRs that reflect the deaths occurring due to uteroplacental insufficiency, after eliminating

TABLE 23-14 Manning Criteria for Biophysical Profile (BPP) Scoring

Biophysical Variable	Normal (Score = 2)	Abnormal (Score = 0)
Fetal tone	At least one episode of active extension with return to flexion of fetal limb(s) or trunk; opening and closing of hand considered normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absent fetal movement, or partially open fetal hand
Gross body movement	Two or more discrete body/limb movements in 30 min (episodes of active continuous movement considered a single movement)	Less than two episodes of body/limb movements in 30 min
Fetal breathing movements	At least one episode of ≥ 20 sec duration in 30 min observation	No episode of ≥ 20 sec duration in 30 min
Reactive fetal heart rate	At least two episodes of acceleration of ≥ 15 bpm and >15 sec duration in 20 min	One or no accelerations or acceleration < 15 bpm in 20 min
Amniotic fluid volume	At least one pocket of amniotic fluid measuring ≥ 2 cm in vertical axis	Either no amniotic fluid pockets or a pocket < 2 cm in vertical axis

TABLE 23-15 Obstetrical Management Based on Biophysical Profile (BPP) Results

BPP Score	Interpretation	Percent Risk of Asphyxia (umbilical venous blood pH 7.25)	Risk of Fetal Death (per 1000/week)	Recommended Management
10/10	Nonasphyxiated	0	0.565	Conservative management
8/10 (normal AFV)	Nonasphyxiated	0	0.565	Conservative management
8/8 (NST not done)	Nonasphyxiated	0	0.565	Conservative management
8/10 (decreased AFV)	Chronic compensated asphyxia	5–10	20–30	If mature (> 37 wks), deliver; serial testing (twice weekly) in the immature fetus
6/10 (normal AFV)	Possible acute asphyxia	0	50	If mature (> 37 wks), deliver; repeat test in 24 hr in immature fetus; if < 6/10, deliver
6/10 (decreased AFV)	Chronic asphyxia w/possible acute asphyxia	>10	>50	Factor in gestational age; if > 32 wks, deliver; if < 32 wks, test daily
4/10 (normal AFV)	Acute asphyxia likely	36	115	Factor in gestational age; if > 32 wks, deliver; if < 32 wks, test daily
4/10 (decreased AFV)	Chronic asphyxia w/ acute asphyxia likely	>36	>115	If > 26 wks, deliver
2/10 (normal AFV)	Acute asphyxia nearly certain	73	220	If > 26 wks, deliver
0/10	Gross severe asphyxia	100	550	If > 26 wks, deliver

the perinatal deaths that would be considered unpredictable—for example, from cord accidents or congenital anomalies.

A BPP score of 8/10 when the amniotic fluid volume (AFV) is normal is also predictive of a PMR < 1/1000 within 1 week. Therefore, if the NST is nonreactive, but the fetal tone, movement, breathing and amniotic fluid volume are all normal, the risk of stillbirth within 1 week is very low—the same risk as for the score of 10/10. It follows then that if the ultrasound component of the BPP is all normal—i.e., a score of 8/8 for tone, movement, breathing, and AFV—then there is no requirement to obtain a fetal heart rate tracing, as the predictive value of an 8/10 BPP with normal AFV is equivalent to a 10/10 [92]. If, however, any of the components of the ultrasound are abnormal, the nonstress test is a critical part of the fetal evaluation [92].

The role that oligohydramnios plays in the predictive value of the BPP is dramatic. As noted in Table 23-15, an 8/10 due to oligohydramnios has a perinatal mortality rate of 89/1000 within 1 week. This is based on Manning's data using a single pocket of fluid measuring less than 2.0 cm.

As the BPP score decreases to 6/10, the incidence of perinatal complications increases. If the AFV is normal, the score is equivocal, and requires careful evaluation of the individual mother and fetus. A preterm fetus may be normal with a nonreactive NST and absent fetal breathing. A term fetus, however, would be expected to earn full points for both reactivity and breathing and a score of 6/10 may be predicative of hypoxia. When the score is equivocal or does not seem to reflect the clinical picture, a repeat BPP in 12 to 24 hours may be indicated. In any event, the woman should not be discharged from the clinical setting until there is evidence of fetal well-being.

A score of 4/10 or less from the BPP is highly predictive of perinatal asphyxia and may indicate the need for delivery for fetal indications [95]. The midwife must always consult with a physician whenever the scores are nonreassuring.

Amniotic Fluid Volume

Alterations in the volume of amniotic fluid are known to be associated with untoward outcomes of pregnancy. Both maternal and fetal characteristics are related to alterations in the amniotic fluid volume [96].

Oligohydramnios, an abnormally low quantity of amniotic fluid, is highly associated with uteroplacental insufficiency and fetal hypoxia [97, 98]. A decrease in or absence of amniotic fluid may also be indicative of fetal genitourinary or lung anomalies [96]. In recent years, a significant decrease in AFV has been correlated with fetal distress in labor, poor Apgar scores, meconium-stained amniotic fluid, and meconium aspiration, as well as with postmaturity syndrome [97–100].

Polyhydramnios, an overaccumulation of amniotic fluid, is more frequently present with chromosomal disorders, structural anomalies such as tracheoesophageal fistulas, neural tube defects, and CNS malformations as well as maternal substance abuse and maternal diabetes [96]. A high percentage of polyhydramnios is of unknown etiology [101].

Measuring the AFV has been an ongoing challenge for ultrasonographers [102–109]. Until recently, the "eyeball-guesstimate" method has been the most reliable means of quantifying AFV. In more recent years, there have been several semiquantitative measurements of amniotic fluid volume introduced [75, 96, 105, 108, 109]. Most notable are the single pocket measurement, which has been suggested to be oligohydramnios if less than 1.0 centimeters or 2.0 centimeters [105–109]. Further studies have recommended use of the four-quadrant amniotic fluid index (AFI) [100–103]. The evaluation of AFV has been enhanced with the use of the amniotic fluid index (AFI), an assessment of the depth of the fluid pockets in each quadrant of the uterus [101–104]. The procedure for performing an AFI is shown in Table 23-16; Figure 23-15 shows the four quadrants within which the amniotic fluid is measured [110]. Figure 23-16 shows a sonogram of the vertical axis measurements that are made in each of the four quadrants. The AFI has the advantage of offering a measurement of amniotic fluid that permits the midwife to determine whether the volume is within a normal range as well as how the volume is changing over time [111, 112].

According to Phelan, the AFI at term will normally range between 5.0 centimeters and 23.0 cen-

TABLE 23-16 Procedure for Performing an Amniotic Fluid Index (AFI)

1. Place woman in supine position with slight left tilt.
2. Identify four quadrants of maternal abdomen.
3. Scan with the transducer placed perpendicular to the floor, aligned longitudinally with the maternal spine.
4. Measure vertical depth of largest clear pocket of amniotic fluid in each quadrant.

Note: The AFI is equal to the sum of the four quadrants.

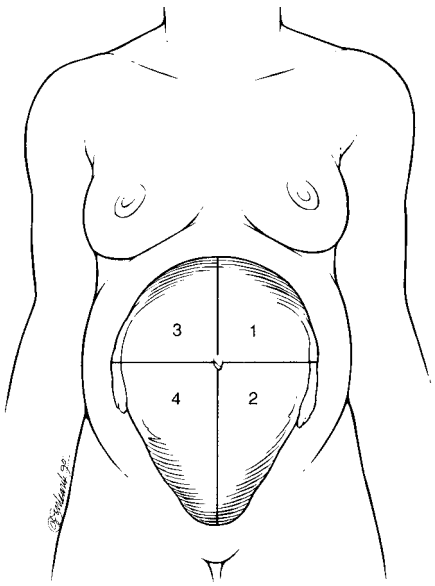

FIGURE 23-15 Schematic of the four quadrants of the maternal abdomen.

timeters [100, 101, 111]. Other authors have identified an AFI of 5.0 to 8.0 centimeters as borderline oligohydramnios [106]. There is disagreement in the literature regarding the appropriate management of a woman at term with oligohydramnios [107, 108]. It is important that each midwife be familiar with the accepted measurements of amniotic fluid volume and management practices in the specific clinical setting.

Modified Biophysical Profile: NST/AFI

The modified biophysical profile represents a recent trend in antepartum testing, combining the nonstress test with the amniotic fluid volume in assessing fetal well-being. It has been shown to have a predictive value similar to that of a full biophysical profile when the NST is reactive and the AFI is greater than 5.0 centimeters [113–116]. This technique is being utilized to save time for both the woman and the provider and is a more cost-effective procedure than a full BPP. If the NST is nonreactive or if the AFI is less than 5.0 centimeters, a complete BPP should be performed. It should also

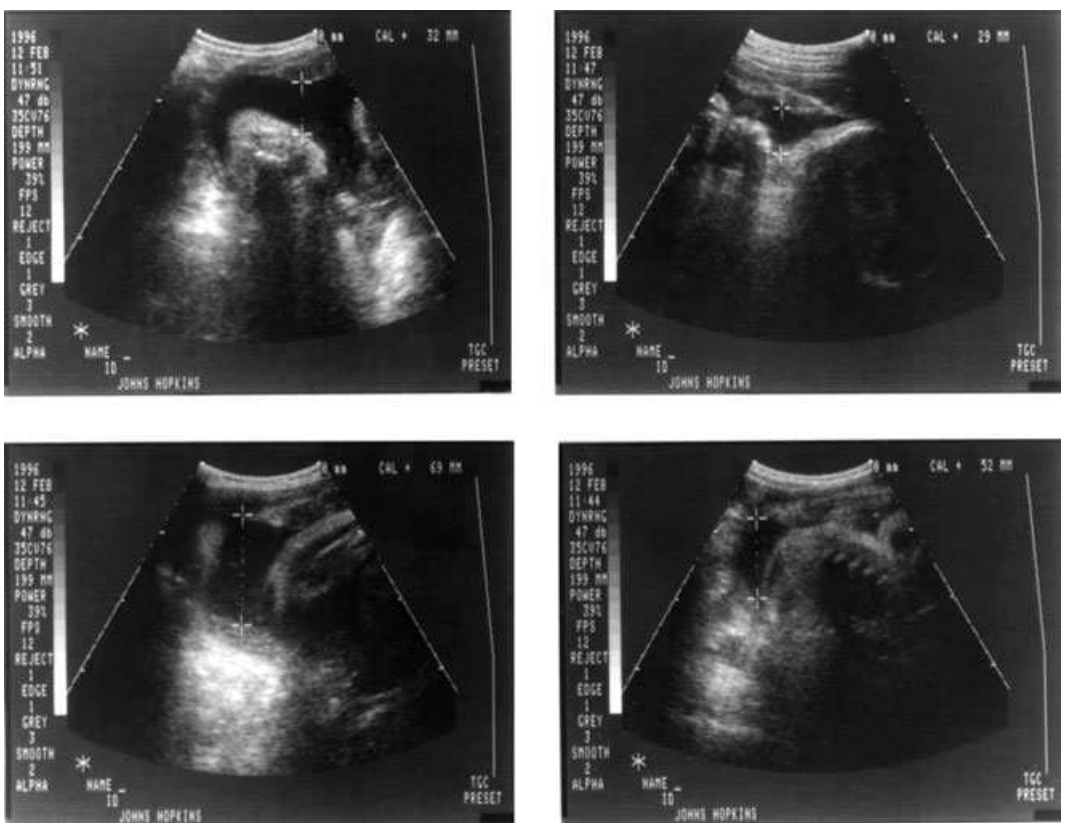

FIGURE 23-16 Sonogram of an amniotic fluid index (AFI). Note the verticle measurements in each quadrant, which are added together to total the AFI.

be noted that if the ultrasound components of the BPP are all reassuring, the NST is not necessary for confirmation of fetal well-being [48].

Doppler Velocimetry

Through the use of Doppler ultrasound, we can gain insight to the developments taking place in the maternal, fetal, and uteroplacental circulations [117]. The blood vessels most usually evaluated are the fetal umbilical arteries. However, the fetal aorta, middle cerebral, and renal arteries can also be investigated. Maternal uterine arteries and some placental vasculature are possible sites for Doppler studies.

Doppler ultrasound is used to determine the velocity of blood flow through the fetal umbilical artery to the placenta. Normally, the velocity of blood flow from the fetal heart "downstream" to the placenta is rapid, and even when the fetal heart is at rest, in diastole, the velocity of flow through an umbilical artery remains modest because the large vessels of the normal placenta have quite low resistance. In the placenta of a fetus with intrauterine growth restriction, however, these placental vessels are narrowed, and the ratio between systolic flow and diastolic flow increases [117–119]. In the case of severe IUGR, some blood still flows through the cord to the placenta during fetal systole. But in diastole, because of the severely narrowed sclerotic placental vessels, there is no longer any flow. The most severe (but rarely occurring) finding is when blood flow actually reverses direction in the cord during fetal diastole.

Doppler studies are indicated when IUGR is present or highly suspected [117–125]. Once IUGR is identified by ultrasound measurements of the fetus and clinical assessment, Doppler velocimetry studies have been demonstrated to reduce the incidence of perinatal morbidity [48, 120, 125, 126]. An in-depth discussion of identification and management of IUGR is found in Chapter 25.

The use of color flow Doppler demonstrates the direction of flow of blood in fetal blood vessels superimposed on the traditional sonogram image. "Color" Doppler is indicated specifically in the diagnosis of congenital cardiac anomalies. Currently, Doppler procedures are usually offered primarily in tertiary care centers.

Ultrasound

Diagnostic ultrasound has been used in obstetrics for nearly 50 years. During that time, the indications and usefulness of ultrasound have grown dramatically. Obstetrical ultrasound provides a "window" to the uterus and developing fetus and has offered an opportunity to learn a great deal about human growth and development as well as to understand far more regarding the pathophysiology of abnormal pregnancy. Management of pregnancy and its complications has been strongly affected. There are potential indications for the use of ultrasound in any trimester of pregnancy.

For the midwife, ultrasound presents both advantages and disadvantages. The advantages include improvement in gestational age assessment and identification of fetal anomalies. Ultrasound is also an excellent means of assessing fetal growth if this is a concern, and it accurately identifies fetal demise, placental location, fetal position, and fetal number when deviations from normal are suspected. But the disadvantages of ultrasound are that it can give a false sense of fetal well-being and false-positive diagnoses, and it can lead to overreliance on technology, not to mention an increase in health care costs. It is therefore critical that the midwife have an in-depth knowledge of the indications for ultrasound and the true value and limitations of this imaging methodology. In addition, the policies of the specific practice site must be understood.

The National Institutes of Health (NIH) delineated indications for ultrasound during all trimesters of pregnancy during a consensus conference in 1984 (see Table 23-17) [127]. These indications remain the standard for care in the United States. Use of ultrasound for specific obstetric complications is discussed in Chapters 24 and 25. Whether ultrasound is indicated for use in normal pregnancy is discussed later in this chapter. Both the American College of Obstetrics and Gynecology (ACOG) [128] and the American Institute of Ultrasound in Medicine (AIUM) [129] offer guidelines for obstetrical ultrasound examinations. The most common criteria for components of the basic ultrasound examination are listed in Table 23-18.

When ultrasound was first used clinically, there was only one "level" of obstetrical ultrasound examination. Over time, however, the improvement of imaging quality and the development of biochemical markers for identification of fetal anomalies led to structuring the obstetrical ultrasound examination based on risk status of the pregnancy. The language identifying scans as level 1 to indicate a screening examination and level 2 to indicate an in-depth examination has changed. ACOG now recommends that a "basic" ultrasound consisting primarily of fetal measurements and a brief survey

TABLE 23-17 Indications for Obstetrical Ultrasound

Estimated gestational age for patients with uncertain clinical dates
Evaluation of fetal growth
Vaginal bleeding of undetermined etiology in pregnancy
Determination of fetal presentation
Suspected multiple gestation
Adjunct to amniocentesis
Significant uterine size/clinical dates discrepancy
Pelvic mass
Suspected hydatidiform mole
Suspected ectopic pregnancy
Adjunct to special procedures, e.g., fetoscopy, cordocentesis, chorionic villus sampling, in vitro fertilization, cervical cerclage placement
Suspected fetal death
Suspected uterine abnormality
Localization of intrauterine contraceptive device
Surveillance of ovarian follicle development
Biophysical evaluation for fetal well-being
Observation of intrapartum events, e.g., version/extraction of second twin
Manual removal of placenta
Suspected polyhydramnios or oligohydramnios
Suspected abruptio placentae
Adjunct to external cephalic version
Estimation of fetal weight
Abnormal serum alpha-fetoprotein value
Follow-up observation of identified fetal anomaly
Follow-up evaluation of placental location for identified placenta previa
History of previous congenital anomaly
Serial evaluation of fetal growth in multiple gestation
Evaluation of fetal condition in late registrants for prenatal care

Source: National Institutes of Health. *Diagnostic Ultrasound Imaging in Pregnancy: Report of a Consensus Development Conference Sponsored by the National Institute of Child Health and Human Development* (DHHS publication NIH 86-667). Washington, DC: NIH, 1984, pp. 3–13.

TABLE 23-18 Components of a Basic Obstetric Ultrasound Examination

First Trimester Sonography

Scanning may be performed abdominally or vaginally, dependent on gestational age and information required. The following assessments should be made:

Gestational sac location (intra- or extra-uterine)
Identification of embryo
Crown-rump length
Presence or absence of fetal cardiac activity (identify rate when possible)
Fetal number
Evaluation of the uterus and adnexal structures for size, shape, and location

Second and Third Trimester Sonography

Unless technically impossible, the following aspects should be assessed during a basic ultrasound examination:

Fetal number
Fetal presentation
Documentation of fetal cardiac activity
Placental localization
Amniotic fluid volume assessment (single pocket measurement or amniotic fluid index)
Gestational age dating, using at least two fetal parameters (biparietal diameter, abdominal circumference, femur length)
Detection and evaluation of maternal pelvic masses
Survey of fetal anatomy for gross malformations (cerebral midline, 4-chamber heart, stomach, kidneys, bladder, and identification of all fetal limbs)

TABLE 23-19 Indications for Limited Scans

A limited ultrasound examination may be appropriate and desirable in certain circumstances—for example, when specific information is required or the clinical situation is urgent. A limited examination may be useful for the following tasks:

Assessment of amniotic fluid volume
Conducting fetal biophysical profile
Conducting ultrasound-guided amniocentesis
Guidance of external cephalic version
Confirmation of fetal life or death
Localization of placenta
Confirmation of fetal presentation

Source: American College of Nurse-Midwives. *Limited Obstetrical Ultrasound in the Third Trimester*. Clinical Bulletin. Washington, DC: ACNM, 1996. Reprinted by permission.

of fetal anatomy and maternal pelvic organs "suffices for most obstetric patients" [128]. A "comprehensive ultrasound" examination may be indicated for a woman who is suspected of carrying a physiologically or anatomically defective fetus, based on history, clinical evaluation, or prior ultrasound examination [128].

In addition to the complete basic or comprehensive studies, "in certain circumstances, a limited ultrasound examination may be appropriate and desirable" [128, p. 2]. Table 23-19 identifies the potential uses of a limited ultrasound exam. The activities on the list are often necessary during labor and delivery triage or for third trimester assessment of fetal well-being. As ultrasound equipment has become more portable and as more obstetrical providers have gained skill in scanning, the technology has become increasingly useful in bedside management decisions in clinical obstetrics. Ultrasound instrumentation is now available in many obstetri-

cal office practices. Few labor and delivery suites are without ultrasound equipment and some personnel trained in its use. Although midwives generally do not perform basic or comprehensive ultrasound examinations themselves, they must be knowledgeable regarding the scope and limitations of each study.

Limited ultrasound scans are most appropriate for women who have previously had at least a basic scan in the second trimester or later. When the limited study occurs in an urgent care setting, a follow-up basic ultrasound examination should be completed in a reasonable time frame, if indicated by the clinical situation. Therefore, if a woman is coming for sequential BPP studies, she should have had a previous basic scan. This puts the responsibility for identification of anomalies and for gestational age assessment on the sonographer and sonologist performing and interpreting a complete study. If a basic scan has not been completed prior to an emergent event, it should be performed after the emergent situation is resolved, if it is clinically indicated.

Prior to ACOG's 1991 publication of a list of "circumstances . . . when it may be unnecessary to perform a full fetal survey" [130], ultrasound professionals strongly asserted that if a scan were to be performed, a complete study would be required. They argued that a complete study is important to decrease the chances of missing critical information in the pursuit of specific data. For example, it is unacceptable to determine fetal position by finding the head but to fail to identify twins, a central placenta previa, or a fetal demise. However, it is often very useful in management of pregnancy to have specific information, such as during an emergent situation or when information such as fetal biometry is not useful or even reliable—for example, when a woman presents in labor with an uncertain lie, a large amount of vaginal bleeding, or nonreassuring fetal heart rate.

In order to bridge the gap between a complete basic ultrasound exam and the need for specific data, minimal components of a limited ultrasound examination must be determined. The demand for limited scanning has come primarily in the area of assessment of fetal well-being. A growing number of nurses and midwives are performing the limited studies of the BPP and the AFV [131, 132]. The ACOG's list of exceptions to a full fetal scan [130] has become the basis of *Nursing Practice Competencies and Educational Guidelines for Limited Ultrasound Examinations in Obstetric and Gynecologic/Infertility Settings* [133], written by the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN, formerly NAACOG). This document establishes which limited ultrasound examinations it is appropriate for perinatal nurses to perform when they have had adequate lecture and clinical scanning education. It therefore follows that midwives may also rely on these guidelines as a basis for performing limited ultrasound studies. The guidelines clearly state the minimum components of the limited ultrasound exam. ACNM supports both AWHONN's minimum components for limited studies and the performance and interpretation by midwives of limited ultrasound examinations for assessment of fetal well-being and for labor and delivery triage [134]. This means that just finding the fetal heartbeat or just finding the fetal head is not an appropriate use of ultrasound. Instead, if midwives choose to incorporate ultrasound skills into their practice, they must follow the guidelines of the ACNM Clinical Bulletin, Limited Obstetrical Ultrasound in the Third Trimester [134], for education and clinical competence, as well as perform the minimum components for each limited ultrasound examination. The ACNM Guidelines for Incorporating New Procedures into Nurse-Midwifery Practice [135] must also be followed. Table 23-20 lists the minimum components of limited scans in the second and third trimesters.

Limited scanning in the first trimester carries the risk of missing an ectopic pregnancy, a potentially life-threatening entity. Therefore, before using ultrasound in the first trimester, it is necessary that the midwife have the skills to survey the entire pelvis, identify the maternal bladder, uterus, ovaries, and any other masses or fluid to identify clearly whether the pregnancy is in fact intrauterine and viable. Practitioners without the expertise to

TABLE 23-20 Minimum Components of Limited Obstetrical Ultrasound, Second and Third Trimester

rule out an ectopic gestation should avoid limited scanning for identification of early pregnancy and fetal heart rates [132]. It is critical that midwives who are performing limited obstetrical ultrasound exams at any time in pregnancy have a practitioner qualified to perform complete studies available for consultation and follow-up. Ongoing competency assessment is also advisable.

Bioeffects of Ultrasound

The first commandment regarding clinical ultrasound is that the benefits to the patient must outweigh the risks of the exam [136]. The biologic effect of ultrasound on human tissue is a continuing concern for all obstetrical care providers. Studies conducted during at least 40 years of investigation have demonstrated no adverse bioeffects on the human embryo or fetus. This research includes, but is not limited to, studies evaluating fetal, neonatal, and childhood neurologic development; chromosomal anomalies; infections; abnormal hearing; visual acuity; malignancy; immunologic maturation; behavior; fetal growth; and cognitive function [136].

The 1984 National Institutes of Health (NIH) consensus conference stated that theoretically, diagnostic levels of ultrasound could cause two bioeffects: thermal effects and cavitation [127]. The actual thermal change in the fetal environment caused by ultrasound is difficult to quantify. One reason for the difficulty is that the amount of heat generated by ultrasound is so small that it is within the normal (1°C) range of fluctuation of body temperature. The American Institute of Ultrasound in Medicine (AIUM) came to this conclusion regarding a thermal bioeffects mechanism: "Based solely on a thermal criterion, a diagnostic exposure that produces a maximum temperature rise of 1°C above normal physiological levels may be used in clinical examinations without reservation" [137].

Cavitation is the process whereby tiny gas bubbles in cells can be caused to expand and contract or to burst. Cavitation in human tissue caused by diagnostic levels of ultrasound is only a theoretical danger. After careful study of all available documented evidence, the NIH concluded that there is no evidence that ultrasound causes physical or genetic damage to human embryos or fetuses [127]. The official statement of AIUM on the clinical safety of diagnostic ultrasound is as follows:

> Diagnostic ultrasound has been in use since the late 1950s. Although the possibility exists that such biological effects may be identified in the future, there are no confirmed biologic effects on patients or sonographers caused by exposure at intensities typical of present diagnostic ultrasound instruments. Given the known benefits and recognized efficacy for medical diagnosis, current ultrasound data indicate that the benefits to the patient of the prudent use of diagnostic ultrasound outweigh the risks that may be present. [137, 138]

None of this is to suggest that no effects will ever be substantiated; indeed, research on biologic effects is ongoing, which is particularly important as new technologic applications for ultrasound are developed that use higher power outputs. AIUM has indicated that each ultrasound operator has the responsibility to utilize ultrasound in a prudent manner and to "complete the examination using scan modes and power outputs which result in energy exposures which are 'as low as reasonably achievable' (ALARA)" [137].

Despite the lack of evidence of danger, many pregnant women and their partners are concerned about the bioeffects of obstetrical ultrasound. Some confuse ultrasound with ionizing radiation and unnecessarily avoid ultrasound examinations that may be advantageous. It is the responsibility of the midwife to assure a woman and her family that, when indications for ultrasound are present, any theoretical risk is overshadowed by the benefit of information that may assist in management of the pregnancy. One well-timed ultrasound exam can help lessen the need for other interventions later in pregnancy.

Routine Ultrasound Screening

Few topics in the care of pregnant women arouse such emotion and differences of opinion as the question of routine ultrasound scanning. Ultrasound has added a great deal to the potential for identifying maternal and fetal anatomy and for broadening the knowledge base regarding pregnancy and fetal development.

There is general agreement that ultrasound has value for women with indications for sonography during pregnancy, and the list of indications from NIH is the standard (see again Table 23-17). The question is whether women who are normal—at very low risk for poor pregnancy outcomes—and who do not have any specific indication for scanning have improved maternal or fetal outcomes with the routine performance of ultrasound. For midwives, long champions of nonintervention in normal pregnancy, this is an issue of special concern.

Over the past 20 years, numerous randomized controlled trials have been conducted throughout the world in an attempt to answer this question [139–143]. The majority of the trials were conducted in Europe and did not specifically differentiate between normal women and those with pregnancy-related complications [139–140, 143–145]. Each trial had slightly different outcomes; however, there are some common findings [144–145]. The primary common finding is that ultrasound is a very accurate means of assessing gestational age. During the first half of pregnancy, ultrasound predicts gestational age within 10 days. This accuracy is improved earlier in pregnancy and diminishes as pregnancy progresses. Therefore, when a woman has uncertain dates, her dates are not consistent with the clinical examination, or when she registers for care after the first trimester, ultrasound examination can improve the quality of pregnancy dating and affect the ongoing management of prenatal care [139–145]. In-depth discussion of assessment of gestational age is included in Chapter 25.

Ultrasound has also been shown to improve identification of multiple pregnancy and to identify major congenital anomalies. Conflict does exist in the literature in this regard; there is wide discrepancy in the rate of identification of anomalies [139, 141, 143, 144, 147]. In the European trials, identification rates of major anomalies ranged between 21 and 84 percent [145]. In the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial conducted in the United States, only 17 percent of major anomalies were identified prior to 24 weeks in the routine screening group compared to 11 percent in the control group [141–143]. Some authors have used identification of anomalies as the justification for routine ultrasound screening [145, 146], a practice that the RADIUS trial makes questionable. An important point about anomaly identification that is not widely discussed is that, despite a higher identification of anomalies in the routine screening group than in the control group, there was no difference in perinatal mortality rates between the groups after controlling for elective terminations in the screening group and spontaneous losses from anomalies not consistent with life in the control group [139, 144, 147]. In fact, there has been no demonstrated improvement in the live birth rate, a rate that takes into consideration all pregnancy losses, including miscarriage, elective termination, and perinatal deaths [144].

Anomaly screening has two primary benefits for women: (1) It identifies many fetuses with major structural anomalies early enough in pregnancy to allow for termination of the pregnancy if the woman elects to do so; (2) it gives the woman the opportunity to plan for the care of an abnormal fetus. In a few situations, the fetus may benefit from intrauterine treatment, and the future may well be promising in this regard. For most abnormal fetuses, a plan of delivery in a tertiary setting may improve the chances of survival and of well-being. In addition, an immeasurable potential benefit of anomaly screening is the opportunity for the parents and other family members to begin to accept the disability and to gain greater understanding of the possible range of care needed by the infant. Bucher and Schmidt, in their meta-analysis, state that women must be informed that ultrasound screening is being used as a means of prenatal diagnosis of congenital anomalies and that "if a woman does not consent to screening for malformations, . . . routine ultrasound scanning is not indicated" [144].

When referring women for obstetrical ultrasound examinations, it is important to know the experience of the ultrasound providers and the quality of their work. The quality of the information provided in the report is strongly based on the skill of the sonographer, the interpretive expertise of the interpreting physician, and the instrumentation used [143]. There is often a great difference between a community radiology group which offers a full range of scans with moderate range machines and a maternal-fetal medicine ultrasound expert using state of the art technology with extensive experience evaluating congenital anomalies and assessing fetal status. This difference in the scanning expertise of the sonographer is felt to be the reason for wide discrepancies in identification of anomalies between different studies [143]. If a woman has a history placing her at risk for anomalies or IUGR, or if a basic ultrasound has identified a problem, a scan done in a high-risk center may be indicated.

The report on the 1984 NIH Consensus Conference on Diagnostic Ultrasound in Pregnancy asserts that there remains "no evidence that the routine use of ultrasound in all pregnancies improved the perinatal outcome or decreased perinatal mortality or morbidity" [127]. The conference called for the performance of large-scale randomized controlled trials in the United States to determine whether routine scanning of normal women was appropriate; the RADIUS trial was conducted in response to this call [141, 142]. This has been the largest trial of ultrasound outcomes in the world—

53,367 women were screened for the study. After meeting rigorous exclusionary criteria that identified theirs as normal pregnancies, 15,530 women were randomized into screening and control groups [141, 142]. Those in the screening group were placed on a routine scanning schedule of one scan for dating at 18 to 20 weeks (allowable range, 15 to 22 weeks) followed by a scan at 31 to 33 weeks (range, 31 to 35 weeks) for assessment of growth. The control group had ultrasound only as indicated, based on the clinical judgment of their obstetric providers. To summarize briefly the results of this study: There were no significant differences between the groups in the areas of fetal death, neonatal death, or moderate or severe neonatal morbidity [141]. In addition, there were no differences between the groups in the areas of maternal outcome measures, including rates of induced abortion, amniocentesis, tests of fetal well-being, external version, induction, cesarean section, and/or total hospital days [142].

The data from the RADIUS trials have been criticized because of the very low-risk population that was evaluated, but that was in fact the primary intent of the study [148–150]. It is important to keep this distinction in mind and not generalize the RADIUS results to a wider population of women.

As if the controversy strictly within the medical community were not complex enough, other factors play a part in decisions regarding ultrasound screening. These include societal demands, potential psychological aspects, cost effectiveness, insurance coverage, and legal implications.

Ultrasound has become ingrained in our society's expectations of prenatal care. Today, most mothers-to-be want to "see" the baby and to ascertain its gender. Fewer women come to delivery not knowing the gender of the fetus. Levi states that parents have fears that their unborn child may have an abnormality, and therefore, "thirst for reassurance about the absence of fetal congenital anomalies" [151]. When ultrasound is not routinely offered or available, many women feel as if their care is second rate, that they are being denied an integral part of prenatal care. Little is actually known about the psychosocial effects of this technology on society and on how parents "bond" with their unborn children.

Like other screening tools for congenital anomalies, ultrasound for diagnostic purposes has been implicated as a stressor in pregnancy. Women experience significant anxiety when presented with an unexpected risk to their pregnancies. Clear explanations prior to the procedure and frequent feedback during the sonogram can help allay anxiety, as, of course, do normal results. Ultrasound has been demonstrated to be reassuring and potentially to improve bonding [152–154]. Some studies have found that use of ultrasound can reduce short-term use of tobacco and alcohol [154, 155]. These indirect, nonmedical benefits of ultrasound are additional considerations for midwives.

In the RADIUS study, women in the screened population had an average of 2.2 scans per pregnancy, as opposed to those in the control group, who had only 0.6 scans per pregnancy [142]. This increase in scans for routine screening creates increased health care expense. But according to LeFevre, "this increase in the cost of care is associated with no apparent benefit" [142, p. 488].

The use of routine ultrasound is often difficult for midwives. As clinicians whose philosophy dictates the appropriate use of technology, they are responsible for educating women about the limitations, cost-benefit ratio, and risks of ultrasound. Women also need to understand how the clinicians' choices about ultrasound are made. This holds particularly true for women whose pregnancies are low risk and well dated. At the same time, the ultrasound procedure is perceived as routine and, therefore, is expected by many women. The midwife must balance unregulated use of ultrasound with families' needs and desires for obstetric technology. Skupski and Chervenak suggest the following model of informed consent to utilize in this debate:

> Shortly after the pregnancy is diagnosed, every pregnant woman should be provided with information about the actual and theoretical benefits and harms of obstetric ultrasound. Second, the woman should evaluate this information in terms of her own values, something every autonomous patient is qualified to do. Patients routinely make complex decisions in their personal lives. . . . The third stage in prenatal informed consent for sonogram (PICS) is for the woman to articulate her preference regarding the use of ultrasound in the management of her pregnancy. The fourth stage is for the physician to [make a] recommendation, if he or she has one. The fifth stage is a thoughtful and sensitive discussion of any disagreement that may emerge. Lastly, the woman makes her final decision. This decision should then determine the use of obstetric ultrasound for that woman. [148, p. 437]

A thorough review of issues with each woman and documentation of the woman's choices will decrease the midwife's liability if a poor outcome ensues. Practice settings may define patterns of referral for ultrasound and thereby limit the opportunity for complete informed consent and autonomy by the woman. However, the midwife must be well informed regarding the indications for ultrasound and its limitations, risks, and benefits and make every attempt to individualize care for the greatest benefit to each mother and baby.

CHAPTER

24

Screening for and Collaborative Management of Antepartal Complications

This chapter discusses antepartal complications from the viewpoint of screening and collaborative management. The signs and symptoms, midwifery management, and collaborative management of common complications are presented. Complications rarely seen in practice—e.g., genital tract developmental abnormalities, choriocarcinoma, hypofibrinogenemia and fibrinogenopenia, disseminated intravascular coagulation, urinary calculi, and gastrointestinal diseases such as gastric ulcers, gallbladder disease, liver diseases, pancreatitis, intestinal obstruction—are not included. Common medical diseases that have specific implications during pregnancy are discussed or identified for physician referral. Midwives interested in the study of these and other complications are encouraged to consult standard medical and obstetrical textbooks and journals.

The midwife is an expert on normal childbearing and detection of complications. In order to detect abnormality, a thorough knowledge of the range of normal is essential. Knowledge of the signs and symptoms of the more common complications enables the midwife to identify possible complications and initiate the process of differential diagnosis and physician consultation at the earliest indication of a problem.

There are some commonly occurring, minor complications that midwives manage independently within their scope of practice. These include isolated urinary tract infections, iron deficiency anemia, gestational diabetes, and mild hypertensive disorders. Other conditions/complications that are diagnosed and treated by the midwife include vaginal infections, sexually transmitted diseases, and the common discomforts of pregnancy (see Chapters 8, 15, and 22).

The conditions and complications in this chapter are those the midwife will either manage, consult the physician about, contribute to the management of care in collaboration with the physician, or refer to the physician for medical management. The midwife assumes any one of these roles either initially, after diagnostic laboratory work, or in the event of increasing severity of the problem. The scope of midwifery care will depend on the practice setting, the experience and education of the midwife, the collaborative relationship with medical consultants and the clinical practice agreement in place.

The ACNM has issued this statement about clinical practice:

> Practice occurs within a health care system that provides for consultation, collaborative management or referral as indicated by the health status of the client. . . . Collaboration is the process whereby health care professionals jointly manage care. The goal of collaboration is to share authority while providing quality care within each individual's professional scope of practice. Successful collaboration is a way of thinking and relating that requires knowledge, open communication, mutual respect,

> a commitment to providing quality care, trust and the ability to share responsibility. [1]

For midwives with a strong interest in high-risk obstetrics, in general, or a specific complication, it is very appropriate to extend their knowledge and care for a broader range of women. This chapter describes a scope of knowledge and care with which all midwives should be comfortable. The involvement of midwives with women with complicated pregnancies is limited only by the knowledge base, patient population, and setting in which the care is provided. As long as there is a system developed with availability to consultation and referral, and the midwife works within agreed upon guidelines established collaboratively with the medical consultants, midwifery care may be offered. Often midwives are part of a multidisciplinary team providing a range of services. Women of all risk and complication levels can benefit from the individualized care, education, and support of midwifery. Throughout our profession, there are midwives who care for women in specialty cites such as clinics for pregnant women with HIV, twins (or more), substance abuse, diabetes, hypertension, lupus, infertility, and more. So, this chapter is not a limitation but a starting gate from which each midwife may determine their scope of practice and circle of safety.

First Trimester Bleeding

While normal pregnancy is associated with amenorrhea and a complete lack of vaginal bleeding, many women experience episodes of vaginal bleeding in the first trimester. The bleeding may be fresh (bright red) or old (dark brown). It may be slight and persist for several days or have a sudden heavy onset. Only one-third of women who have painless vaginal bleeding during the first half of pregnancy are having symptoms of impending abortion. Other possible causes of bleeding include ectopic pregnancy, severe cervicitis, cervical lesions, cervical polyp, postcoital bleeding, spotting during implantation, or bleeding that comes from a subchorionic bleed. Demise of a twin may also cause vaginal bleeding without any expulsion of products of conception. Rarely, the bleeding may be a symptom of hydatidiform mole.

Regardless of the cause, bleeding during pregnancy must be investigated to rule out causes that threaten the integrity of the pregnancy or the health of the mother. The following is a review of the symptomatology, diagnostic steps, and management approaches for causes of first trimester vaginal bleeding.

Database for First Trimester Vaginal Bleeding

If the woman calls the midwife during the first trimester with complaint of vaginal bleeding, a thorough history is required. If the woman has never been seen by the midwife or in the same practice, due to the risk of an ectopic pregnancy, it may be necessary to have her seen for an emergency office visit, or refer her to an emergency room for thorough evaluation. If the woman is known to the practice, then some of the following data may already have been collected and disposition may be possible without an emergent visit. This will be at the midwife's discretion after she has asked some questions and gotten information about the pregnancy and the current symptoms.

The history includes the following:

1. LMP, regularity of menses, use of contraception prior to pregnancy, confirmation of dates by exam and or sonogram, is there an established EDC?
2. Pregnancy test results: by urine or blood sample and when positive?
3. Previous pregnancy history: any previous spontaneous abortions (SAB) or ectopic pregnancy?
4. Contraceptive history, specifically for current use of an IUD.
5. History of bleeding? When did it start? How much bleeding is present? Is it dark or bright red? Do you need to change a pad? How frequently?
6. Is there pain or cramping? When did it start? Where is the pain (lower front, midline, right or left side, back, rectal, shoulder, painful with breathing)? What is its nature (mild, intense, sharp, dull)?
7. Has there been fever or urinary tract symptoms?
8. Has there been a urinary tract infection or sexually transmitted disease recently or during this pregnancy?
9. Has there been any change in pregnancy symptoms (worsening nausea, suddenly improved nausea, improved breast tenderness)?
10. Has there been recent intercourse? When? Was there any impact on the pain or bleeding either during or after sexual contact?

If the woman is known to the practice, reports that bleeding is slight and she has no low abdomi-

nal or back pain, the midwife may ask the woman to make an appointment to be seen in the office the next day. In the meantime, she should advise the woman to follow the instructions given to her for minor first trimester bleeding (see Table 24-1).

If a woman reports moderate or heavy bleeding, lower abdominal, back, or generalized pelvic pain or if the woman is febrile or reports symptoms of hypotension, the midwife should recommend immediate physician evaluation. This arrangement should be made in the method best used in the clinical setting, such as emergent appointment for evaluation by the midwife with physician consultation, immediate appointment with a physician, or referral to the local emergency room.

During office evaluation of first trimester bleeding, the midwife should take the following steps:

1. Review or update the history from the previous phone conversation (above).
2. Evaluate the woman's blood pressure, temperature, pulse, and respirations.
3. Confirm a pregnancy test if indicated (this could be delayed menses).
4. Perform an abdominal exam including
   a. palpation for tenderness/pain
   b. palpation for fundal height or other masses
   c. assessment for rebound tenderness
   d. auscultation for bowel sounds (diminished in appendicitis)
   e. palpation for CVA tenderness (pyelonephritis can present with referred pelvic pain)
5. Perform a gentle speculum examination of the vagina and cervix.
   a. Screen for vaginitis and cervicitis with cultures and a wet prep if indicated.
   b. Observe the cervical os for dilation, presence of fluid, blood, clots, pus, or fetal parts or membranes.
6. Perform a gentle bimanual examination for
   a. size of uterus
   b. cervical effacement, dilatation, and status of membranes
   c. adnexal masses or pain
   d. cervical motion pain
7. Attempt to auscultated for the FHT if the pregnancy is deemed to be greater than 10 weeks gestation.
8. Obtain a hemoglobin and hematocrit if indicated.
9. Order a sonogram if indicated (see discussion below).
10. Serial serum quantitative beta human chorionic gonadotropin (B-hCG) or progesterone measurement may be indicated (see discussion below).

TABLE 24-1 Instructions for Minor First Trimester Bleeding

1. *Rest:* Do not change your activity level but be very aware of symptoms as they occur. If bleeding, and/or cramping escalate, try to be in an environment where you can rest, be watchful of any bleeding, and have supportive person/s with you. Bedrest has been shown to have no effect on outcome of the pregnancy, and it can be disruptive to family functioning.
2. *Pelvic rest:* Do not have sexual intercourse; do not douche or insert tampons or anything else into your vagina (except for progesterone suppositories if you have been using them prior to the bleeding).
3. Do not engage in non-vaginal sexual activity that leads to orgasm; orgasm causes contraction of the uterus.
4. Notify the midwife immediately of the following:
   An increase in vaginal bleeding
   Lower abdominal cramps or back pain
   Pelvic pain other than cramping
   A gush of fluid from the vagina (indicative of rupture of the membranes)
   A fever of more than 100.4° F

If the woman has not been seen for a new prenatal appointment during this pregnancy, routine laboratory tests may be performed at this visit. If the lab results are available from an earlier visit, they may be useful at that time to determine presence of vaginal infection, urinary tract infection, anemia and blood type and Rh.

Based on the data collected at this visit, a differential diagnosis may be formulated. A review of causes of first trimester bleeding, their specific symptoms, and the data necessary to formulate a diagnosis follow. Management by the midwife and need for consultation and referral are also identified.

B-hCG quantification can be useful in determining normal hormonal progression, identifying ectopic pregnancy and identifying appropriate timing for ultrasound. B-hCG is produced by the trophoblastic tissue and increases rapidly in the first trimester (see Chapters 21 and 23). Single values are of minimal value unless they are in the single digit range. Therefore, serial samples must be gathered at 2-day intervals. Intrauterine pregnancies will demonstrate an increase of at least twofold in a 48-hour period. Decreasing values are consistent with a nonviable pregnancy. Values that increase at a slower than anticipated rate may indicate an ectopic

pregnancy. By the time the B-hCG is 1500 mIUs/ml, a gestational sac should be visible by transvaginal ultrasound examination. Transabdominal ultrasound may not be able to visualize a gestational sac until after the B-hCG reaches 6000 mIUs/ml [2–4].

Progesterone is produced by the corpus luteum in the first trimester of pregnancy. If the serum progesterone value is ≥ 25ng/ml, ectopic pregnancy can be ruled out in more than 97 percent of pregnancies. Similarly, a value of ≥ 25 ng/ml is virtually 100 percent indicative of a viable intrauterine pregnancy. For women with no major risk factors for ectopic pregnancy, this value alleviates the need for further investigation for an ectopic pregnancy. If the serum progesterone level is < 5 ng/ml, then the pregnancy is nonviable; however, this does not rule out an ectopic pregnancy. Further documentation with ultrasound may be necessary. When the value of serum progesterone is between 5 and 25 ng/ml, then further evaluation of the pregnancy is indicated [3, 4]. A potential problem with the use of progesterone is that some labs take several days to return results, decreasing the use of this as a diagnostic tool.

First trimester ultrasound exams can be very useful in evaluating a woman with bleeding early in pregnancy. The scan can be performed by transvaginal and/or transabdominal routes. Findings of sonography in the first trimester include identifying intrauterine versus extrauterine pregnancy, gestational age (accurate within 5 days), number of fetuses, viability with cardiac activity, adnexal masses (ectopic pregnancy, ovarian cyst, dermoid cyst), uterine fibroids, and presence of fluid in the cul-de-sac. Subchorionic bleeding within the uterus can be detected as a potential reason for bleeding without termination of the pregnancy. Incomplete abortion with retention of products of conception can also be evaluated. Ultrasound examination is diagnostic of a molar pregnancy. Evaluation of fetal anatomy is limited in the first trimester. Measurement of nuchal translucency for genetic evaluation is discussed in Chapter 23.

Cardiac activity can usually be identified by 6 weeks' menstrual age. Once cardiac activity has been identified at a normal FHR, the incidence of spontaneous pregnancy loss drops to 3 percent [2]. This can be a very reassuring exam.

Cervical/Vaginal Causes of Bleeding

During early pregnancy, the cervix is very vascular. Any situation that would cause inflammation of the cervix and vaginal tissue may cause bleeding. On speculum examination, observe for any blood (dark or bright) in the vagina. If possible, try to determine the source as coming through the cervix and therefore from within the uterus, or from a cervical or vaginal source outside of the uterus.

If blood is flowing from within the uterus, then an ultrasound examination and serum B-hCG and progesterone are indicated. Completion of the bimanual exam may also provide data regarding the etiology of the bleeding.

However, if the bleeding is caused by superficial cervical bleeding (wipe the cervix with a large cotton swab and observe for bleeding) then an infectious process may be to blame. Gonorrhea, chlamydia, trichomonads, or cervical dysplasia are all associated with cervical friability and bleeding. A herpes lesion may be present on the cervix or other site in the vagina. Vaginal yeast infections and bacterial vaginosis are very common in early pregnancy and may also be responsible for cervical inflammation and bleeding. (See Chapter 15 for evaluation and treatment recommendations.) Another possible cause is a cervical polyp. In the absence of a specific infectious process, simple increased vascularity of the cervix may be implicated. Agitation of the cervix and vagina by sexual intercourse may stimulate or worsen the bleeding.

Bleeding from the cervix or vagina is of concern to the woman and requires evaluation and treatment, but it is rarely associated with pregnancy loss. In most cases, the woman may be reassured that the pregnancy is not in jeopardy. However, if risk factors for ectopic pregnancy, a history of pregnancy losses, or any findings on the bimanual exam are of concern, then an ultrasound examination may be indicated for complete evaluation.

Spontaneous Abortion

Abortion is the termination of pregnancy by expulsion of the products of conception prior to the ability of the fetus to survive if born. This is generally accepted to be up to 20 weeks' gestation or 500 grams in weight. Spontaneous abortion (SAB)—also commonly known as "miscarriage"—occurs naturally, without having been induced. Approximately 10 to 15 percent of all clinically diagnosed pregnancies are lost [2]. The primary reason for early pregnancy loss is genetic abnormality, accounting for 75 to 90 percent of all losses [2]. Other reasons for an SAB include abnormal progesterone levels, thyroid abnormalities, uncontrolled diabetes, uterine anomalies, infection, and autoimmune dis-

eases. Within the diagnosis of spontaneous abortion are its varied expressions, which include threatened abortion, inevitable abortion, missed abortion, and incomplete abortion. The signs, symptoms and potential management of each follow. Elective termination of pregnancy is discussed in Chapter 22.

Threatened Abortion

The pregnancy is considered threatened at any time when there is vaginal bleeding during the first half of pregnancy. A threatened abortion may or may not be accompanied by lower abdominal cramping pain or low backache. The prognosis for continuation of a pregnancy is poor when a woman experiences a combination of bleeding and pain. Evaluation of the pregnancy with physical examination, serum B-hCG and progesterone, and ultrasound are indicated in order to determine a source of bleeding and initiate treatment if necessary.

Inevitable Abortion

When a spontaneous abortion is almost certain to occur and cannot be stopped, it is classified as inevitable. This happens when there is cervical dilatation and/or rupture of the membranes in addition to vaginal bleeding and lower abdominal or back pain.

If the woman is in the first trimester, does not have excessive bleeding or pain, has normal vital signs, is not severely emotionally distressed, and has a previous hematocrit of at least 30 percent, you may offer her two choices. One choice is for the consulting physician to assist the abortion by terminating the pregnancy with a suction D&C. The other choice is for the woman to return home to await the inevitable spontaneous evacuation of the products of conception. Apprise your consulting physician of the situation and the woman's decision either way.

If the woman chooses to remain at home during the abortion, instruct her to take her temperature every 4 hours (unless she is asleep) or more often if she has chills and to call you if she soaks through a regular sanitary napkin in an hour or less, passes clots larger than 3 centimeters (the size of a 50-cent piece), or has a fever of 100.4°F (38°C) or above. She should also call when she aborts. If she has had two or more consecutive spontaneous abortions, ask her to save, if possible, the products of conception in a container for genetic studies. The products of conception may also be sent to the lab for verification of placental villi to confirm a complete abortion and verify that the pregnancy had been intrauterine.

If any of the assessment data are outside the limits given in the aforesaid situation, then arrange for your consulting physician to evaluate the woman. Completion of the SAB may then be done by D&C.

Incomplete Abortion

Incomplete abortion occurs when the placenta is not expelled with the fetus at the time of the abortion. The retained placenta (all or part) will eventually be the cause of bleeding, which may be profuse, or infection, especially if the abortion occurred during the second trimester. The midwife involves the consulting physician regarding the management of care in the event of an infection and to complete evacuation of the uterus.

Missed Abortion

In missed abortion the fetus dies but the products of conception are retained for a prolonged period of time (2 or more weeks). Signs and symptoms of a missed abortion include the following:

1. Normal early pregnancy without accompanying presumptive and probable signs of pregnancy
2. Vaginal spotting or bleeding or lower abdominal or back pain at the time of death of the fetus (may or may not occur)
3. Fundal height not only ceases to increase but after a while the uterus becomes smaller (due to maceration of the fetus and absorption of the amniotic fluid)
4. Regression of mammary changes of pregnancy
5. The woman often loses a few pounds in weight
6. Persistent amenorrhea
7. No fetal heart tones when anticipated by dates

When a woman presents with these signs and symptoms, order an ultrasound examination for confirmation of fetal death. If fetal death has occurred, there is an increased risk of abnormal clotting mechanisms and potential development of disseminated intravascular coagulopathy (DIC). The woman should be referred for medical management. The following baseline coagulation studies may be requested:

1. Prothrombin
2. Partial prothrombin
3. Fibrinogen
4. Platelets

Habitual Abortion

Habitual abortion is the term applied when spontaneous abortion has terminated the course of three or more consecutive pregnancies. Genetic counseling and an endocrinologic workup should be considered if the woman has experienced repeated abortions. Developmental abnormalities of the genital tract (e.g., bicornuate uterus, vaginal septum) should be ruled out in any woman having multiple spontaneous abortions or second trimester losses.

Follow-up care of the woman by the physician/midwife team includes support through the grieving process, counseling regarding contraception and resumption of sexual intercourse within 2 to 4 weeks, and future pregnancy counseling.

Regardless of the category of spontaneous abortion, all postabortal Rh-negative mothers with negative antibody titers should receive Rh immune globulin (e.g., RhoGAM) within 72 hours of the abortion.

Ectopic Pregnancy

Ectopic pregnancy occurs whenever the blastocyst implants anywhere except in the endometrium lining the uterine cavity. Possible sites for ectopic pregnancy include the cervix, fallopian tubes, ovaries, and abdomen. Predisposing factors to ectopic pregnancy include pelvic infections, intrauterine contraceptive devices, previous ectopic pregnancy, and prior tubal surgery. Early symptoms of an ectopic pregnancy are usually vaginal bleeding and spotting, and occasionally pelvic pain. Because the levels of B-hCG are lower and more slowly rising, a woman may have fewer presumptive signs of pregnancy. She may or may not be certain of a diagnosis of pregnancy.

Uterine changes are not diagnostic because the uterus grows to the same size and consistency as a pregnant uterus for the first trimester due to the influence of the placental hormones. However, the uterus may be displaced to one side by the tubal pregnancy.

Early diagnosis of ectopic pregnancy in recent years has greatly improved the outcome of tubal patency and diminished the numbers of catastrophic tubal rupture. Consideration of ectopic pregnancy in the differential of all early pregnancy vaginal bleeding and pelvic pain as well as the use of serial B-hCG, serum progesterone, and ultrasound have increased the likelihood of early diagnosis. There is an old adage, "You only have one chance to miss an ectopic." It is imperative that midwives always proceed in this manner.

Medical management of ectopic pregnancy with methotrexate has diminished the need for surgical intervention and has also improved the potential of preserving tubal function and therefore a woman's fertility. However, medical management is reliant on early diagnosis prior to significant distortion of the fallopian tube and rupture of the pregnancy into the abdomen.

Tubal Pregnancy

Tubal pregnancy accounts for 95 percent or more of ectopic pregnancies [2]. Signs and symptoms are those of tubal rupture or abortion and may vary widely from woman to woman. The classic case of tubal rupture involves a woman who may or may not realize she is pregnant because slight vaginal bleeding or spotting has substituted for menstrual periods. Without warning, she suddenly experiences a sharp, stabbing, tearing, severe lower abdominal pain. Hypotension and other signs of shock may or may not develop quickly. Her abdomen is tender, and vaginal examination is quite painful. Movement of the cervix elicits exquisite pain. A tender, boggy mass may be felt to one side of the uterus. The cul-de-sac may be full of blood, thereby causing the posterior vaginal fornix to bulge. Pain in the neck or shoulder, especially on inspiration, may be present as a result of diaphragmatic irritation from blood in the peritoneal cavity.

Data collection should be the same for history and physical examination as noted above for evaluation of first trimester bleeding. Specific signs and symptoms that may presage the full-blown classic case described above include the following:

1. Pelvic examination may be quite painful, especially with movement of the cervix—or may not be painful at all.
2. A soft, pliable pelvic mass may be palpated posterior or lateral to the uterus. The mass may be firm if distended with blood.
3. The entire decidual lining of the uterus (decidual cast) may be expelled.
4. Neck or shoulder pain may occur as a result of diaphragmatic irritation from intraperitoneal blood.
5. The woman experiences acute abdominal pain in the upper or lower abdomen; pain may be unilateral, bilateral, or generalized.
6. Diarrhea and rectal pressure may occur as a result of irritation from blood in the abdomen.

7. The woman may have had negative urine pregnancy tests due to very low chorionic gonadotropin levels.
8. The white blood cell count may be normal or may range up to 30,000 due to presence of an inflammatory process.

The ambiguity of the symptoms obviously makes diagnosis difficult. This problem is compounded if the presenting symptom is pelvic or abdominal pain because the midwife also must consider a differential diagnosis of salpingitis, threatened or incomplete abortion, appendicitis, a twisted ovarian cyst, or a ruptured corpus luteum or follicular cyst.

For any woman who the midwife suspects of having an ectopic pregnancy or when an intrauterine pregnancy cannot be confirmed and the woman is symptomatic for an ectopic pregnancy, medical management is indicated. Screening with history, physical assessment, and laboratory evaluation, including ultrasound scanning, is within the scope of midwifery care. If ectopic pregnancy cannot be ruled out, the midwife should consult with the physician.

Ovarian Pregnancy

Ovarian pregnancy is rare. Vaginal bleeding or spotting may be the presenting complaint. Symptoms relate to rupture into the peritoneal cavity and are similar to those of tubal rupture. On examination, the midwife may palpate an enlarged ovary or ovarian mass which may or may not be painful. The uterus may be slightly enlarged from the endometrial response to progesterone and hCG. Diagnosis will be made with slowly rising B-hCG levels and ultrasound exam. Referral for medical management is always indicated.

Abdominal Pregnancy

Abdominal pregnancy is almost always the result of an early tubal pregnancy rupture or abortion into the peritoneal cavity. In a few exceedingly rare cases, the fertilized ovum makes the abdomen the site of its primary implantation. Pregnancy may in fact proceed even to term. In addition to the signs and symptoms of a ruptured tubal pregnancy, the following may exist:

1. Gastrointestinal disturbances (diarrhea, constipation, flatulence, abdominal pain, nausea, and vomiting)
2. A transverse lie (very common)
3. Marked pain from fetal movements late in pregnancy
4. Ease in palpating small parts
5. Readily audible fetal heart tones
6. Inability to stimulate contraction of the musculature surrounding the fetus
7. Ability to palpate the uterus on vaginal examination and small parts outside of it
8. Cervical displacement
9. Dilatation (up to 2 centimeters) but no effacement of the cervix as a result of spurious labor

Ultrasound examination may or may not make the diagnosis, especially later in pregnancy. Delivery must be by abdominal route, clearly requiring medical management.

Cervical Pregnancy

Cervical pregnancy is rare. Signs and symptoms include painless bleeding soon after the time of implantation and palpation of a cervical mass with distention and thinning of the cervical wall, partial dilatation of the external cervical os, and a slightly enlarged uterine fundus. Diagnosis will be made with slowly rising B-hCG levels and ultrasound exam. Referral for medical management is always indicated.

Hydatidiform Mole

Hydatidiform mole is a genetically abnormal pregnancy that manifests itself as a developmental anomaly of the placenta. In complete hydatidiform mole (CHM), the pregnancy is genetically entirely from the father, usually diploid 46, XX, with no fetal tissue apparent. A partial hydatidiform (PHM) mole is usually triploid (e.g., 69, XXY), with both villus changes and fetal tissues [5]. The placental villi become a mass of clear, cystlike vesicles hanging in clusters from thin pedicles, resembling a bunch of grapes. A CHM is all vesicles, whereas a PHM mole also has a nonviable fetus or amniotic sac. On rare occasion, there may be a twin pregnancy, with one normal fetus and placenta and one mole.

A hydatidiform mole is usually a benign neoplasm, but it has the potential for becoming malignant and often precedes the extremely malignant but fortunately rare trophoblastic neoplasm known as choriocarcinoma. With current chemotherapeutic drugs, the cure rate of choriocarcinoma is nearly 100 percent [5].

The overall incidence of hydatidiform mole is approximately 1.5 in 1000 pregnancies. Risk is increased in women of Asian ethnicity. The incidence is ten times higher in women over 45, indicating that hydatidiform mole is much more common in pregnancies at the end of the child-bearing cycle. Women with a previous molar pregnancy also have an increased recurrence rate [5].

Rapid growth of the abnormal placental tissue is responsible for many symptoms as the B-hCG values are very high. Signs and symptoms include the following:

1. Persistent, often severe, nausea and vomiting.
2. Uterine bleeding evident by the twelfth week of pregnancy; spotting or profuse bleeding is possible but usually the woman evidences just a bloody discharge, more brown than red, occurring intermittently or continuously over time.
3. A large-for-dates uterus clearly out of proportion to presumed gestational age (occurs in about one-third of cases).
4. Shortness of breath.
5. Often enlarged, tender ovaries (theca lutein cysts).
6. No fetal heart tones.
7. No fetal activity.
8. Fetal parts not evident with palpation.
9. Pregnancy-induced hypertension, preeclampsia, or eclampsia before 24 weeks' gestation.

These findings indicate that the midwife should obtain a specimen for a serum chorionic gonadotropin titer and a sonogram. Hydatidiform mole has a characteristic pattern on ultrasonography. A persistently high, or even rising, level of chorionic gonadotropin after 100 days from the first day of the last menstrual period is indicative of abnormal trophoblastic growth or a multiple gestation. The woman is referred to the consulting physician.

Hyperemesis Gravidarum

Hyperemesis gravidarum is excessive nausea and vomiting during pregnancy. This pernicious vomiting is differentiated from the more common and more normal morning sickness by the fact that it is of greater intensity and extends beyond the first trimester. Associated with ketonemia, weight loss, and dehydration, hyperemesis gravidarum may occur in any trimester, usually beginning in the first and persisting at varying degrees throughout gestation. The etiology is unknown but is probably a combination of hormonal changes and psychological factors [6]. It is important to rule out diseases such as cholecystitis, pancreatitis, hepatitis, and thyroid disease. Ptyalism, an apparent excessive production of saliva, is associated with severe nausea and vomiting of pregnancy. Women are unable to swallow the saliva and go through pregnancy spitting 1 to 2 liters a day. The etiology is unknown.

The following are signs, symptoms, and effects:

1. Pernicious vomiting
2. Poor appetite
3. Poor nutritional intake
4. Weight loss
5. Dehydration
6. Electrolyte imbalance
7. Extreme response to underlying psychosocial problems
8. Vomiting not controlled by treatment measures for morning sickness (see Chapter 22)
9. Acidosis due to starvation
10. Alkalosis resulting from loss of hydrochloric acid in the vomitus
11. Hypokalemia

When a woman presents with a complaint of nausea and vomiting, the following history should be obtained to assist in distinguishing between the benign form of nausea and vomiting associated with pregnancy and this pathologic situation.

History

1. Frequency of vomiting episodes
2. Relationship of vomiting to food intake (amount and type)
3. Dietary history (what foods and fluids, amounts, timing, reaction)
4. Medication history (medication reactions)
5. Elimination (frequency, amount, constipation, diarrhea)
6. Blood in vomitus (peptic ulcer or esophagitis from repeated vomiting)
7. Fever or chills
8. Exposure to viral infection
9. Exposure to contaminated food
10. Abdominal pain
11. History of eating disorders
12. History of diabetes
13. Previous abdominal surgery
14. Amount of rest she is getting
15. Family support
16. Anxieties regarding the pregnancy

Physical Examination

1. Weight (and relationship to previous weights)
2. Temperature, pulse, respirations
3. Skin turgor
4. Moistness of mucous membranes
5. Condition of tongue (swollen, dry, cracked)
6. Abdominal palpation for: organomegaly, tenderness, distention
7. Bowel sounds
8. Sweet odor to breath
9. Assessment of fetal growth

Laboratory

1. Urine dipstick for ketones
2. Urinalysis
3. BUN and electrolytes
4. Liver function tests (rule out hepatitis, pancreatitis, and cholestasis)
5. TSH and T4 (rule out thyroid disease)

Assessment

Poor tissue turgor, dry tongue and mucus membranes, increased pulse and respirations, decreased urinary output, and increased urine specific gravity are all symptoms indicating that the woman is dehydrated. If the urine dip is positive for ketones, the breath has a sweet odor, or she has lost weight, the woman has had too few calories and is acidotic due to burning fat for energy. If there are no symptoms of dehydration or acidosis, the woman may not truly have hyperemesis. The immediate, initial treatment is as follows:

1. Administration of IV fluids using a solution with 5% dextrose. (If the woman is diabetic, physician consultation is required before any treatment is initiated.) A rapid flow of 200 ml/hour for the first liter can be used to assist in replacement of fluids.
2. NPO or minimal sips of clear fluid and ice chips for several hours to let her stomach rest.
3. The following antiemetics are frequently used:
   a. promethazine (Phenergan) 25 mg into the IV or by rectal suppository.
   b. chlorpromazine (Thorazine) rectal suppository 25–50 mg q 6–8 hours or 25–50mg IM q 3–4 hours.
   c. prochlorperazine (Compazine) 10 mg IM or $2\,^1/_2$–10 mg IV q 3–4 hours or 25 mg rectal suppository bid.
   d. metoclopramide (Reglan) 10 mg po qid (do not combine with the above phenothiazines due to possible extrapyramidal effects [6]).
   e. methylprednisolone 16 mg tid for 3 days, then tapered over 2 weeks (for recalcitrant hyperemesis).
4. After a few hours, offer oral fluids very gradually. If nausea or vomiting resume, revert to NPO. If the fluids are tolerated, increase gradually.
5. Dip all urine samples for the presence of ketones.
6. Once the ketones have "cleared," assess maternal status for maintenance.

Some women will be able to stop the IV fluids, continue with oral fluids and the food, and progress without a problem. More commonly, the nausea and vomiting will persist. If the woman is not able to tolerate oral fluids or food after an initial course of IV fluids, antiemetics, and then progressive introduction of oral fluids, the physician should be consulted for further evaluation and management. Medical treatment will consist of aggressive use of sedatives and antiemetics. The woman will then be maintained on antiemetics as long as necessary to allow her to consume adequate nutrition. In severe cases, it may be necessary to progress to IV total parenteral nutrition (TPN).

Nonphysiologic influences must be considered. If the woman has a history of depression, if this is a very stressful pregnancy, if she has a history of eating disorder, or if she is not responsive to initial medical management, psychologic or sociologic counseling may be appropriate. It is important to recognize that hyperemesis can be chronic through the pregnancy, and may cause significant distress to the family. This can interfere with parenting and other home responsibilities, and it may be a financial burden if the woman is unable to work. Supportive care for the woman and the family is needed.

Incompetent Internal Cervical Os

Incompetent internal cervical os, more commonly referred to as an incompetent cervix, is diagnosed when the cervix effaces and dilates without pain in the second or early third trimester. The typical scenario is of a woman presenting to the office or L&D with a complaint of vaginal bleeding, pelvic pressure, or ruptured membranes and is found on examination to have a cervix with advanced dilation. For women with an incompetent cervix, this sequence of events is repeated in subsequent consecutive pregnancies, regardless of the pregnancy interval.

Traditionally, the diagnosis has been retrospective, following at least two midtrimester losses with painless onset of labor and birth. More recently, a history of a previous loss or any other risk factor for preterm loss may heighten investigation into cervical changes during pregnancy. See Chapter 29 for a full discussion of preterm labor and ultrasound evaluation of the cervix.

The risk factors for internal cervical os incompetence include the following:

1. History of fetal loss at 14 weeks' gestation or more
2. History of cervical laceration following vaginal or cesarean birth
3. Overdistension of the cervix with prolonged second stage in a previous pregnancy [7]
4. Multiple first or second trimester elective abortions [8]
5. DES exposure
6. Previous cervical conization with a large amount of tissue removed [9]

Women who present with a history of previous second or early third trimester pregnancy loss may benefit from a thorough history which should include the following:

1. Description of signs and symptoms surrounding previous loss (e.g., bleeding, abdominal cramping/contractions, suprapubic pain, low back pain, vaginal or lower abdominal pressure, vaginal discharge without signs or symptoms of vaginal infection, ruptured membranes) and when they occurred in relation to delivery
2. Gestational age at time of each consecutive loss
3. Congenital abnormalities of previously aborted fetuses
4. Family history of early fetal loss
5. Previous first trimester suction abortions (three or more) or one or more second trimester abortions
6. History of cervical trauma with previous delivery
7. History of any other cervical trauma or surgery on the cervix

Pelvic examination for any woman with a suspicious history or current symptoms for incompetent cervix should include the following:

1. Speculum exam—visualization for
   a. cervical discharge
   b. cervical length
   c. evidence of previous cervical laceration
2. Bimanual exam—digital examination for
   a. consistency and length of the cervix
   b. dilatation of the internal and external cervical os
   c. palpable membranes
   d. position and station of the presenting part

If a woman has a history of previous second or early third trimester pregnancy loss, consultation with the physician is required. Depending on the current and historical circumstances, she may be a candidate for weekly or biweekly vaginal ultrasound to measure cervical length and perform cervical cerclage if indicated.

If a woman presents with cervical effacement, dilatation, pelvic pressure, or vaginal bleeding of unknown source, she requires immediate medical management. If the membranes are still intact and the cervix is amenable, the common treatment is use of a cervical cerclage. Several types of cerclage are used, which are selected by the clinical situation, cervical length and dilatation, and physician experience. Further discussion of cervical cerclage is included in Chapter 29, p. 858.

Emotional support is especially important for women with repeated losses. These women walk a fine line between hope, fear of another loss, and the potential for disappointment. Cultural attitudes toward the ability to bear children may strongly affect the psyches of such women.

Infections

Infections are caused by microorganisms, primarily those in the following categories: viruses, bacteria, fungi, rickettsias, protozoans, and animal parasites. The danger of these microorganisms in pregnancy is twofold. One is the direct effect that microorganisms can have on the mother (e.g., maternal dehydration, poor nutritional intake, and electrolyte imbalance) and the subsequent indirect effect of these on the fetus. Colds and influenza with the possible sequela of pneumonia are examples of diseases with this type of effect. The other danger is the direct effect microorganisms can have on the fetus, as certain microorganisms are known to cause congenital malformations.

Tuberculosis

Since 1993, tuberculosis (TB) case rates have been declining, suggesting that the nation is recovering

from the resurgence of TB that occurred in the mid-1980s and is back on track toward TB elimination [10]. However, TB cases, including drug-resistant cases, continue to be reported in every state.

Tuberculosis is an infection caused by *Mycobacterium tuberculosis*. Inoculation with the tubercle bacillus occurs through droplet inhalation. Once inoculation has occurred, an initial lesion develops in the lung with formation of a localized inflammatory exudate combined with necrosis of the surrounding lung tissue. The infection spreads to the lymphatic nodes and can then be disseminated throughout the body. Because of this dissemination, tuberculosis can be extrapulmonary (e.g., genital, skeletal). In the majority of individuals infected, the primary (pulmonary) lesion is arrested by encapsulation, fibrosis, and calcification. These individuals may never suffer from active tuberculosis. A chest x-ray examination of such individuals will reveal evidence of calcification of the primary lesion. Usually this calcification represents host resistance at the time of the initial infection and indicates that the local and systemic progression of the disease has been arrested.

Persons who are infected but who do not have TB disease are asymptomatic and not infectious; such persons usually have a positive reaction to the tuberculin skin test. About 10 percent of infected persons will develop TB disease at some time in life, but the risk is considerably higher for persons who are immunosuppressed, especially those with HIV infection [10].

The incidence of tuberculosis appears to be affected by geographical location and the socioeconomic status of a given population. Tuberculosis remains one of the more common infectious diseases among women of childbearing age. It is endemic in certain countries, such as those in Southeast Asia. Factors contributing to the spread of TB include substance abuse, AIDS, poverty, homelessness, and an influx of immigrants from countries where tuberculosis is endemic. Communal living environments can be a source of infection when one or members of the group have active TB. This pertains to institutional living such as long-term care facilities or homeless shelters. TB has become more difficult to treat and eventually eliminate as strains of tuberculosis have become drug resistant when courses of therapy have not been completed. The diagnosis of active tuberculosis is made through history, physical examination, sputum culture, and chest x-ray, as follows:

History

1. Previous history of tuberculosis evidenced either by symptoms or by a positive chest x-ray.
2. Exposure to other individuals with tuberculosis.
3. Fever—one of the earliest symptoms; initially minimal to moderate temperature elevation occurs daily in the late afternoon or evening, usually accompanied by a feeling of euphoria and well-being; temperature elevations reach 103°F (39.5°C) or higher as disease progresses.
4. Night sweats—the daily rise in body temperature is reversed at nighttime with accompanying diaphoresis.
5. Weight loss—minor weight loss with anorexia early in the disease; increased weight loss, fatigue, and irritability as the disease progresses.
6. Persistent colds and a chronic cough, which is worse in the morning.
7. Chronic, productive cough with large amounts of purulent, greenish-yellow sputum; may be accompanied by hemoptysis.
8. Pleurisy with effusion—in young childbearing women, the findings indicative of pleurisy should lead you to suspect active tuberculosis, as pleurisy in this age group is uncommon.
9. Spontaneous atelectasis, especially in a young person, may be a sign of active tuberculosis.

Physical examination is considered to be positive if crepitant rales are present on auscultation, heard best after the woman coughs.

Diagnostic Tests

1. Sputum culture (looking for acid-fast organisms)
2. Chest x-ray

If you suspect that a woman has active tuberculosis, obtain a chest x-ray and sputum for culture (for acid-fast organisms) and discuss with your consulting physician whether the woman should be referred for care of the tuberculosis. Do not give PPD to someone with signs or symptoms of active tuberculosis; a chest x-ray and sputum culture are diagnostic for such an individual.

Screening Test

The purpose of screening for tuberculosis is to detect those individuals who have active or inactive disease who would benefit from treatment. Screening for TB infection should be done in well-defined high-risk groups that can be divided into two categories: (1) persons at higher risk for TB exposure or infection and (2) persons at higher risk for TB disease once infected (see Table 24-2). Groups that are not at high risk for TB should not be tested routinely in order to

TABLE 24-2 High-Risk Groups That Should Be Tested for Tuberculosis Infection

Persons at Higher Risk for TB Exposure or Infection

- Close contacts of persons known or suspected to have TB (i.e., those sharing the same household or other enclosed environments)
- Foreign-born persons, including children, from areas that have a high TB incidence or prevalence (e.g., Asia, Africa, Latin America, Eastern Europe, Russia)
- Residents and employees of high-risk congregate settings (e.g., correctional institutions, nursing homes, mental institutions, other long-term residential facilities, and shelters for the homeless)
- Health care workers who serve high-risk clients
- Some medically underserved, low-income populations as defined locally
- High-risk racial or ethnic minority populations, defined locally as having an increased prevalence of TB (e.g., Asians and Pacific Islanders, Hispanics, African Americans, Native Americans, migrant farm workers, or homeless persons)
- Infants, children, and adolescents exposed to adults in high-risk categories
- Persons who inject illicit drugs; any other locally identified high-risk substance users (e.g., crack cocaine users)

Persons at Higher Risk for TB Disease Once Infected

- Persons with HIV infection
- Persons who were recently infected with *M. tuberculosis* (within the past 2 years), particularly infants and very young children
- Persons who have medical conditions known to increase the risk for disease if infection occurs—e.g., diabetes, end-stage renal disease
- Persons who inject illicit drugs; other groups of high-risk substance users (e.g., crack cocaine users)
- Persons with a history of inadequately treated TB

avoid a high occurrence of false positives and to conserve resources [10].

Screening tests will detect hypersensitivity to the tuberculin protein. The Mantoux test, commonly known as a PPD (purified protein derivative) is the only test recommended by the CDC for screening [10]. The multiple puncture tests (MPTs), which were widely used in the past, have been found to be unreliable. The Mantoux test is safe throughout pregnancy.

The Mantoux test consists of 0.1 milliliters of purified protein derivative (PPD) tuberculin containing 5 tuberculin units, administered intradermally in the forearm. The reaction to the PPD should be read 48 to 72 hours after injection. If a patient's reaction is not read until after 72 hours and it is negative, the test should be repeated. A positive reaction may be measurable up to 1 week after testing. Reaction is the diameter of a palpable swelling (induration), measured in millimeters. Erythema is not included in the measurement.

Many individuals from countries outside the United States (e.g., England, Caribbean Islands, some African countries) receive bacille Calmette-Guerin (BCG) vaccine in childhood to prevent tuberculosis infection. Previous BCG vaccination is not a contraindication to skin testing, but it is a major cause of false-positive test results. Care should be taken as PPD can cause serious cellulitis and localized damage to the forearm. If the woman reports a previous positive PPD, avoid another injection and have a chest x-ray performed. Individuals who have received BCG, have had a positive PPD, and remain asymptomatic may be screened with a chest x-ray every two years.

A tuberculin reaction of ≥ 15 millimeters of induration is classified as positive in persons with no known risk factors for TB. However, targeted skin-testing programs should be conducted only among high-risk groups. In general, these guidelines for interpreting skin test reactions should also be applied to persons who may have occupational exposure to TB (e.g., health care workers or the staff in nursing homes, drug treatment centers, or correctional facilities). Thus the appropriate cutoff for defining a positive reaction depends on the employee's individual risk factors for TB, including recent TB exposure, and the prevalence of TB in the facility. In facilities where the risk of exposure is very low, ≥ 15 millimeters may be an appropriate cutoff for employees with no other risk factors. In facilities where TB patients receive care, ≥ 10 millimeters may be an appropriate cutoff for employees with no other risk factors (see Tables 24-3 and 24-4).

TABLE 24-3 Classification of the Tuberculin Reaction, Based on Risk Factors

A tuberculin reaction of ≥ 5 mm of induration is classified as positive in the following groups:

- HIV-positive persons
- Recent contacts of TB case
- Persons with fibrotic changes on chest radiograph consistent with old healed TB
- Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥ 15 mg/day of prednisone for ≥ 1 month)

A tuberculin reaction of ≥ 10 mm of induration is classified as positive in persons who do not meet the preceding criteria but who have other risk factors for TB. These include the following:

- Recent arrivals (< 5 years) from high-prevalence countries
- Injection drug users
- Residents and employees of high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other health care facilities, residential facilities for AIDS patients, and homeless shelters
- Mycobacteriology laboratory personnel
- Persons with clinical conditions that place them at high risk
- Children < 4 years of age, or children and adolescents exposed to adults in high-risk categories.

A tuberculin reaction of ≥ 15 mm of induration is classified as positive in persons with no known risk factors for TB. However, targeted skin testing programs should only be conducted among high-risk groups. In general, these guidelines for interpreting skin test reactions should also be applied to persons who may have occupational exposure to TB (e.g., health care workers or the staff in nursing homes, drug treatment centers, or correctional facilities). Thus the appropriate cutoff for defining a positive reaction depends on the employee's individual risk factors for TB, including recent TB exposure, and the prevalence of TB in the facility. In facilities where the risk of exposure is very low, ≥ 15 mm may be an appropriate cutoff for employees with no other risk factors. In facilities where TB patients receive care, ≥ 10 mm may be an appropriate cutoff for employees with no other risk factors.

TABLE 24-4 Classification System for Tuberculosis [10]

Class	Type	Description
0	No TB exposure Not infected	No history of exposure Negative reaction to tuberculin skin test
1	TB exposure No evidence of infection	History of exposure Negative reaction to tuberculin skin test
2	TB infection No disease	Positive reaction to tuberculin skin test Negative bacteriologic studies (if done) No clinical, bacteriological, or radiographic evidence of active TB
3	TB, clinically active	*M. tuberculosis* cultured (if done) Clinical, bacteriological, or radiographic evidence of current disease
4	TB Not clinically active	History of episode(s) of TB *or* Abnormal but stable radiographic findings Positive reaction to the tuberculin skin test Negative bacteriologic studies (if done) *and* No clinical or radiographic evidence of current disease
5	TB suspected	Diagnosis pending

Health care providers should comply with state and local laws and regulations requiring the reporting of TB. All persons with class 3 or class 5 TB should be reported promptly to the state and local health department.

Source: National Center for HIV, STD, and TB Prevention. *Core Curriculum on Tuberculosis: What the clinician should know*, 4th ed. November 2001. http://www. cdc.gov/nchstp/ tb/pubs/corecurr.

Anergy is a condition in which the tuberculin reaction (a delayed-type hypersensitivity response) may decrease or disappear in immunosuppressed persons. Anergy is caused by HIV infection, overwhelming miliary or pulmonary tuberculosis, severe or febrile illness, measles or other viral infections, Hodgkin's disease, sarcoidosis, live-virus vaccination, and the administration of corticosteroids or immunosuppressive drugs [10]. Persons with anergy may be infected with tuberculosis, but their immune systems cannot produce a positive reaction to the PPD [10]. For persons with any of the conditions listed above that may cause anergy, the diagnosis of tuberculosis should not be ruled out solely on the basis of a negative Mantoux test. Anergy is ascertained by injecting two other delayed-type hypersensitivity antigens—such as *Candida*, mumps, or tetanus toxoid—intradermally on the other forearm to serve as controls. These are antigens to which at least 90 percent of the population has been exposed. Any induration equal to or greater than 3 millimeters is proof that the immune system is capable of responding to skin tests, and a negative PPD is thus truly negative. If all the controls are negative, however, this means the immune system is incapable of reaction and tuberculin skin testing is rendered invalid [10, 11].

Pregnancy

Pregnant women should be screened for tuberculosis according to risk factors as noted in Table 24-3. All pregnant women with a positive skin reaction should have a chest x-ray. The woman's abdomen should be shielded during the x-ray procedure. A positive radiologic finding should be followed by a series of three sputum cultures for AFB. Positive AFB cultures and/or positive x-ray findings must be referred to physician care for treatment.

Pregnant women must be given adequate therapy as soon as TB is suspected. The preferred initial treatment regimen is isoniazid, rifampin, and ethambutol (ethambutol may be excluded if primary isoniazid resistance is unlikely). Streptomycin should not be used because it has been shown to have harmful effects on the fetus. In addition, pyrazinamide should not be used routinely because its effect on the fetus is unknown. Because the 6-month treatment regimen cannot be used, a minimum of 9 months of therapy should be given. To prevent peripheral neuropathy, it is advisable to give pyridoxine (vitamin B_6) to pregnant women who are taking isoniazid [10].

Breastfeeding during the course of TB therapy is not contraindicated. Women are encouraged to breastfeed their infants. The trace amounts of medication transferred to the infant via breast milk cannot be construed as treatment of the newborn.

You should inform your consulting physician about all women with a positive PPD and women in whom you suspect active disease. The families of women with a positive PPD and of women in whom you suspect active tuberculosis should be evaluated for active disease and, if tuberculosis is not evident, they should be screened with PPD.

Tuberculosis is a reportable disease. Midwives need to know their state reporting regulations, which may include penalties for late reporting or nonreporting, and be in compliance with them.

Hepatitis

Hepatitis can present as an active infection or be identified as a chronic infection through lab studies during routine prenatal care. However this is manifested, there are specific things the midwife must know related to hepatitis in pregnancy. Refer to Chapter 8 for a full discussion of identification, treatment, and prevention of hepatitis.

Rubella

The virus that causes rubella, or German measles, is particularly virulent during pregnancy. The most important consequences of rubella are the miscarriages, stillbirths, fetal anomalies, and therapeutic abortions that result when rubella infection occurs during early pregnancy, especially during the first trimester [12]. If a woman contracts rubella during the first trimester, there is approximately a 52 percent chance that her baby will be born with congenital rubella syndrome (CRS). This figure is as high as 85 percent if the woman contracts the virus during the first eight weeks of pregnancy [22]. The most common malformations associated with CRS are cataracts, cardiac defects, and deafness. There may also be glaucoma, microcephaly, and other defects involving the eyes, ears, heart, brain, and central nervous system. Infants with CRS frequently exhibit both intrauterine and postnatal growth retardation [12]. Infection after the twentieth week of gestation rarely causes defects.

The occurrence of rubella infection, once common, is now rare in the United States. Implementation of mandatory childhood immunization and enhanced surveillance for immunity in at-risk populations had led to record low numbers of cases of CRS. At this time, it is critical that surveillance remain high, as this is a disease that has its greatest impact on the developing fetus. Although immunization is nearly universal in the United States, it is uncommon in most areas of the world, making eradication unlikely. Attention to high-risk populations, and continued offering of vaccine for children, adolescents, and those known to be nonimmune will keep protection high.

Most rubella cases in the United States occur among young Hispanic adults born outside the United States [13], and most infants with CRS are born to foreign-born mothers. Ensuring immunity in women of childbearing age, especially those at highest risk for exposure, will help to prevent CRS.

Ascertainment of rubella-immune status of women of childbearing age and the availability of rubella vaccination should be components of the health care program in places where the risks for disease exposure and transmission are substantial (e.g., day care facilities, schools, colleges, jails, and communal living situations).

The ACIP has recommended that MMR vaccine be offered to all women of childbearing age (i.e., adolescent girls and premenopausal women) who do not have acceptable evidence of rubella immunity. Efforts should be made to ensure that all susceptible women of childbearing age, especially those who grew up outside the 50 states in areas where routine rubella vaccination may not occur, are vaccinated with MMR vaccine or have other acceptable evidence of immunity [14].

Screening in Pregnancy

A rubella antibody titer for immunity (hemagglutination inhibition) should be done routinely as part of the initial antepartal examination. An antibody titer of 1:10 or above is generally accepted as indicative of immunity. Below 1:10 indicates lack of immunity, and the midwife should include a note in the woman's record to offer rubella immunization postpartally. High antibody titers of 1:64 or above may indicate present disease, since there is a prompt antibody response with infection. Such a situation requires searching for signs and symptoms of the disease, ordering a series of antibody titers, and consulting with the physician.

Rubella vaccination during pregnancy of women who are not immune is not recommended because the vaccine is an attenuated live virus that could theoretically cause malformations. Women who do not know they are pregnant and who receive a rubella vaccine can be reassured, as no evidence of teratogenicity from the vaccine has been demonstrated [14].

To avoid risk, it is prudent to offer rubella vaccine to the nonimmune woman immediately postpartum. If not postpartum, women should be asked if they are pregnant, informed of potential risk, and advised to avoid pregnancy for 1 month after receiving the vaccine [14]. Breastfeeding is not a contraindication to vaccination.

Diagnosis

Clinical signs and symptoms of rubella, when they are present, include the following:

1. Low-grade fever
2. Drowsiness
3. Sore throat
4. Rash—pale or bright red on the first or second day, spreading rapidly from the face over the entire body, and fading rapidly
5. Swollen neck glands
6. Duration of 3 to 5 days

Diagnosing rubella may be difficult because the disease may be subclinical, thereby infecting the fetus but not exhibiting itself clinically in the mother. If the mother knows she has been exposed to rubella and has an antibody titer below 1:10 (not immune), a blood specimen should be obtained for serologic testing (IgG and IgM) and the physician consulted. Authorities differ on the administration of hyperimmune gamma globulin in such a situation.

Prevention

The primary objective of the rubella immunization program is the prevention of CRS. The major components of the rubella and CRS elimination strategy are achieving and maintaining high immunization levels for children and adults, especially women of childbearing age; conducting accurate surveillance for rubella and CRS; and undertaking control measures promptly when a rubella outbreak occurs. Since the late 1970s, this strategy has effectively prevented major epidemics of rubella and CRS in the United States [15].

Vaccination of susceptible women of childbearing age should be part of routine general medical

and gynecologic outpatient care, take place in all family-planning settings, and be provided routinely before discharge from any hospital, birthing center, or other medical facility [15].

An additional concern is for women or their families when traveling outside of the continental United States. As rubella vaccine is not routine in many countries, travelers should be advised to be certain of immunity prior to travel. For women who have been documented as nonimmune during pregnancy, travel to high-risk countries should be avoided until after the pregnancy [16].

Cytomegalovirus

Cytomegalovirus (CMV) is a member of the herpesvirus group, which includes herpes simplex virus types 1 and 2, varicella-zoster virus (which causes chickenpox), and Epstein-Barr virus (which causes infectious mononucleosis) [17]. CMV infects between 50 and 85 percent of adults in the United States by 40 years of age, most with few symptoms and no long-term sequelae. Occasionally, mononucleosis-like symptomatology or mild hepatitis will occur. As with other viruses, once it infects an individual, the virus remains for the duration of that person's life, and may be reactivated at any time. Usually, these subsequent infections are mild or the person is completely asymptomatic. Severe stress or circumstances with immunosuppression may create the potential for a clinical infection. However, CMV is the virus most frequently transmitted to a developing child before birth [18].

Generally, CMV is not highly contagious. Infection requires close, intimate contact with a person excreting the virus in their urine, saliva, blood, tears, semen, and breast milk. The most significant spread among essentially healthy individuals occurs within households and among young children in day care centers and the classroom.

This is important for women cared for by midwives as they are often in situations to care for small children as mothers, teachers, nurses, or other child care workers. When women are planning a pregnancy or are currently pregnant, they should be advised to maintain excellent hand-washing technique in order to diminish the likelihood of infection (see Table 24-5).

Most transmission is through infected bodily fluids that come in contact with hands and then are absorbed through the nose or mouth of a susceptible person. Therefore, care should be taken when handling children, soiled tissues, drinking cups, and items like diapers. Simple hand washing with soap and water is effective in removing the virus from the hands.

The incidence of primary CMV infection in pregnant women in the United States varies from 1 to 3 percent [17]. The greatest risk of congenital CMV infection is in women who have never had a previous infection and who become infected for the first time during pregnancy. As with other adults, most women have minimal if any symptoms and are unaware of the infection. The fetus, however, is at risk if this is a primary infection. Infection is usually not recognized until birth. Of those infants, only 30 percent will become infected in utero, and less than 15 percent of these infants will have symp-

TABLE 24-5 CDC Recommendations for CMV During Pregnancy

1. Throughout her pregnancy, a pregnant woman should practice good personal hygiene, especially hand washing with soap and water, after contact with diapers or oral secretions (particularly with a child who is in day care).
2. Pregnant women working with infants and children should be informed of the risk of acquiring CMV infection and the possible effects on the unborn child.
3. Women who develop a mononucleosis-like illness during pregnancy should be evaluated for CMV infection and counseled about the possible risks to the unborn child.
4. Routine laboratory screening is not recommended; however, laboratory testing for antibody to CMV can be performed to determine if a women has already had CMV infection.
5. Recovery of CMV from the cervix or urine of women at or before the time of delivery does not warrant a cesarean section.
6. The demonstrated benefits of breastfeeding outweigh the minimal risk of acquiring CMV from the breastfeeding mother.
7. There is no need to either screen for CMV or exclude CMV-excreting children from schools or institutions because the virus is frequently found in many healthy children and adults.

Source: Centers for Disease Control and Prevention. National Center for Infectious Diseases. Cytomegalovirus (CMV) Infection, 2002. http://www.cdc.gov/ncidod/diseases/cmv.htm.

toms at the time of birth [18]. The complications that can occur include the following:

1. Generalized infection with symptoms ranging from moderate enlargement of the liver and spleen (with jaundice) to fatal illness.
2. Most infants with CMV disease survive, but 80 to 90 percent will have complications that may include hearing loss, vision impairment, and varying degrees of mental retardation.
3. Approximately 5 to 10 percent of infants who are infected but without symptoms at birth will subsequently have varying degrees of hearing and mental or coordination problems.

The virus can also be transmitted to the infant at delivery from contact with genital secretions or later in infancy through breast milk. However, these infections usually result in little or no clinical illness in the infant.

Diagnosis

Although CMV is a common viral infection, it is not frequently diagnosed because of the minimal presence of symptoms. The following clinical situations should lead to suspicion of CMV infection:

1. Symptoms of infectious mononucleosis with negative test results for mononucleosis and Epstein-Barr virus
2. Signs of hepatitis with negative test results for hepatitis A, B, and C.

Laboratory Testing

The enzyme-linked immunosorbent assay (or ELISA) can be used to determine if acute infection, prior infection, or passively acquired maternal antibody in an infant is present. If serologic tests detect a positive or high titer of IgG, this result should not automatically be interpreted to mean that active CMV infection is present. However, if antibody tests of paired serum samples, taken at 2 week intervals, show a fourfold rise in IgG antibody and a significant level of IgM antibody (equal to at least 30 percent of the IgG value), or virus is cultured from a urine or throat specimen, the findings indicate that an active CMV infection is present [17].

Treatment

There is no treatment for CMV infection in healthy persons. Immunocompromised patients and those with severe mononucleosis or hepatitis symptoms may be treated symptomatically or with appropriate antiviral therapies.

Toxoplasmosis

Toxoplasmosis is a protozoal infection caused by the intracellular parasite *Toxoplasma gondii*. It is the third most common cause of food-related death in the United States [19]. Approximately 1 in 1000 pregnant women are infected each year. If contracted, toxoplasmosis can cause severe congenital malformations when the mother acquires the infection while pregnant, because it crosses the placenta to the fetus. The potential for infection of the fetus is only 5 percent if contracted prior to 8 weeks, and increases to 80 percent as gestation continues. However, the most severe cases tend to be those when transmission occurs late in the first trimester [20]. Many infants do not demonstrate symptoms at the time of birth, instead developing seizures, motor and cognitive deficits, and mental retardation throughout childhood. The most severely affected will have neurologic anomalies such as anencephaly, hydrocephalus, microcephaly, and intracranial calcifications [20].

Toxoplasma gondii has three life phases, with the first two causing infection within their host—the animals or humans who consume them. The third phase, which allows for sexual replication of the protozoan, occurs only in cats. Cats become infected by eating infected mammals such as mice or rats and then pass the oocytes, which become infectious three days after excretion when they can be contracted by direct or aerosolized exposure. Oocytes from cat feces in the soil can remain infectious for up to a year. Therefore, humans are exposed to toxoplasmosis through exposure to cat feces, infected soil, or ingestion of infected raw or under-cooked meat. It has been shown that about 50 percent of human exposure to toxoplasmosis is through infected meat, pork being the most frequent.

For the midwife, the most important aspects of dealing with toxoplasmosis will be through careful history taking and prevention through education of women planning for a pregnancy and who are already pregnant. Table 24-6 presents recommendations from the CDC for prevention of toxoplasmosis.

Most persons infected with toxoplasmosis are asymptomatic. The signs and symptoms of toxoplasmosis in the pregnant woman are vague, similar to mononucleosis, but when present include the following:

1. Fatigue and malaise
2. Muscle pain
3. Fever

TABLE 24-6 CDC Recommendations for Prevention of Toxoplasmosis

1. To prevent toxoplasmosis and other foodborne illnesses, food should be cooked to safe temperatures. A food thermometer should be used to measure the internal temperature of cooked meat to ensure that meat is cooked all the way through. Beef, lamb, veal roasts, and steaks should be cooked to at least 145°F, and pork, ground meat, and wild game should be cooked to 160°F before eating. Whole poultry should be cooked to 180°F in the thigh to ensure doneness.
2. Fruits and vegetables should be peeled or thoroughly washed before eating.
3. Cutting boards, dishes, counters, utensils, and hands should always be washed with hot soapy water after they have contacted raw meat, poultry, seafood, or unwashed fruits or vegetables.
4. Pregnant women should wear gloves when gardening and during any contact with soil or sand because cat waste might be in soil or sand. After gardening or contact with soil or sand, they should wash their hands thoroughly.
5. Pregnant women should avoid changing cat litter if possible. If no one else is available to change the cat litter, use gloves, then wash hands thoroughly. Change the litter box daily because *Toxoplasma* oocysts require several days to become infectious. Pregnant women should be encouraged to keep their cats inside and not adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats.
6. Health education for women of childbearing age should include information about meat-related and soilborne toxoplasmosis prevention. Health care providers should educate pregnant women at their first prenatal visit about food hygiene and prevention of exposure to cat feces.

Source: Centers for Disease Control and Prevention. Preventing congenital toxoplasmosis. *MMWR* 49(RR02); 57–75. March 31, 2000.

4. Sore throat
5. Enlarged posterior cervical lymph nodes

If the woman is seronegative for mononucleosis, then toxoplasmosis screening should be done.

Serum testing is done for IgM and IgG with repeated testing in three weeks. Recent infection will be characterized with a high or increasing IgM with seroconversion from negative to positive IgG. It is important that this testing be performed in a well-recognized reference laboratory. Health care providers who are in contact with pregnant women should be educated about two potential problems associated with *Toxoplasma* serology tests. First, no assay exists that can determine precisely when initial *Toxoplasma* infection occurred. Second, in populations with a low incidence of *Toxoplasma* infection, such as in the United States, a substantial proportion of the positive IgM test results will probably be false positive [19].

For any woman with a high suspicion of toxoplasmosis during pregnancy, immediate referral for ultrasound examination and medical management are indicated. Ultrasound can be useful in identifying any fetal anomaly, hepatomegaly, ascites, or intracranial abnormalities. Amniotic fluid and fetal blood can be sampled to confirm fetal infection [21].

Treatment of most adults is not required, but for pregnant women, treatment can reduce the potential harmful effects to the fetus. This includes use of sulfonamides, pyrimethadine, and spiramycin by the physician.

Varicella

Varicella (chickenpox) is a highly contagious viral infection caused by a form of herpesvirus. Varicella may remain dormant in the dorsal ganglia of the nerves and become reactivated years later as herpes zoster (shingles). Herpes zoster is rare in pregnancy and has no known adverse effect on mother or fetus.

Varicella during pregnancy has serious effects on both the mother and the fetus or infant. Between 25 and 40 percent of fetuses exposed to varicella in utero will be affected and demonstrate congenital varicella syndrome [22]. The earlier in pregnancy the mother has varicella, the greater the risk of congenital varicella syndrome. The greatest risk occurs in the first 20 weeks of pregnancy. Congenital varicella syndrome is associated with cataracts, chorioretinitis, limb hypoplasia, hydronephrosis, microcephaly, mental retardation, dermatome lesions, and cutaneous scars (see Table 24-7).

Maternal varicella infection that occurs from 6 days before through 2 days after delivery can be passed to the newborn; in such a situation there will not be sufficient time for the mother to develop immunity and pass it on to the baby. Without the passive immunity from the mother, the infant can become seriously ill; approximately 5 percent of infants who contract varicella this way will die.

Varicella infection in adults can be grave, with approximately 10 to 30 percent of cases developing varicella pneumonia. Varicella pneumonia leads to

TABLE 24-7 Management of Care of Woman with Varicella Based on Patient Exposure or Route of Infection

Exposure/Infection Route	Management of Care
Household member exposed to varicella (e.g., child in day care)	**1.** Determine history of varicella in exposed household member. **2.** Conduct serologic test for immunity in woman. **3.** Have woman avoid contact with exposed household member until incubation period ends without evidence of infection.
Direct exposure to varicella (child with varicella infection)	**1.** Conduct serologic test for immunity. **2.** Administer VZIG within 96 hr of exposure if woman's immunity is negative or unknown.
Varicella infection in mother in first 20 weeks of pregnancy	**1.** Provide symptomatic relief with mild analgesics and antipyretics. **2.** If woman is experiencing fulminant disease with high fever, extensive rash, and/or pulmonary symptoms, refer to physician for intravenous acyclovir. **3.** Consult MD for ultrasound and possible fetal blood sampling (identify fetal infection).
Varicella infection in mother after 20 weeks but no later than 10 days before delivery	**1.** Provide symptomatic relief with mild analgesics and antipyretics. **2.** If woman is experiencing fulminant disease with high fever, extensive rash, and/or pulmonary symptoms, refer to physician for intravenous acyclovir. **3.** Infant will receive passive immunity from mother.
Varicella in mother beginning in the period 6 days before delivery	**1.** Give VZIG to mother. **2.** Prepare for the possibility of tocolysis. **3.** Give VZIG to infant at birth. **4.** May need to isolate infant from mother, even if no maternal rash. **5.** Possibly pump breast milk for infant, to minimize infant's contact with any maternal lesions.
Varicella in mother beginning within first 72 hr postpartum	**1.** Treat infant with VZIG. **2.** Treat mother with VZIG if rash has not appeared (may reduce risk of serious infection). **3.** Isolate mother and baby together. **4.** Pump breast milk for infant, to minimize infant's contact with any maternal lesions.
Exposure of mother/baby to varicella after 72 hr postpartum	**1.** Determine serologic status of mother (immune mother passes antibodies to fetus/newborn). **2.** Treat infant of nonimmune mother with VZIG or notify infant health care provider. **3.** Avoid mother/baby contact with infected individual.

Source: Centers for Disease Control and Prevention. National Immunization Program. Varicella. In *Epidemiology and Prevention of Vaccine—Preventable Diseases*, 7th ed. CDC. Atlanta, GA: April 2002.

maternal death in almost 40 percent of cases in pregnant women unless treated with acyclovir [21]. Up to 95 percent of adults have a history of childhood varicella, which confers lifetime immunity. Of those adults who do not report a history of varicella, immunity can be demonstrated in 75 to 80 percent by serologic testing.

Varicella is transmitted by direct contact and respiratory transmission of the virus. The incubation period from exposure until the first symptoms is from 10 to 21 days. The disease is communicable beginning 2 days before lesions appear and ending when all lesions are crusted over, about 7 to 10 days later. Crusted lesions do not release communicable virus.

Clinical signs and symptoms of varicella infection include fever, chills, myalgia, and arthralgia, followed in a few days by the eruption of characteristic vesicles. Vesicles are extremely pruritic and follow a typical pattern: they begin on the head and neck and spread to the trunk and extremities, break open, and crust over. In women who develop varicella pneumonia, symptoms appear between 1 and 6 days after the appearance of vesicles. Symptoms of varicella pneumonia include a nonproductive cough with pleuritic chest pain, persistent fever, and dyspnea.

Evaluation of a woman with suspected varicella includes the following:

1. History
   a. childhood history of varicella exposure or infection (considered adequate evidence of immunity)

- **b.** evidence of significant exposure
  - **(1)** date of exposure
  - **(2)** nature of exposure (risk for acquiring disease increases with likelihood of droplet transmission)
  - **(3)** duration of exposure (close proximity contact of at least 1 hour increases risk of disease transmission)
  - **(4)** stage of disease when exposure occurred (exposure when all lesions are crusted carries less risk than when lesions are fresh)

2. Physical
- **a.** temperature
- **b.** respiratory rate
- **c.** auscultation of lungs for evidence of pneumonia
- **d.** skin examination for lesions (note pattern of lesions on the body and whether lesions are fresh or crusted to assist in establishing the date of exposure)

3. Laboratory
- **a.** serologic test for varicella antibodies
- **b.** chest x-ray if evidence of pneumonia

Management of varicella in pregnancy is based on the extent of the exposure, when in gestation the infection occurs, and the severity of the illness in the woman. Table 24-7 summarizes the management of varicella in pregnancy. Once exposure occurs, varicella-zoster immune globulin (VZIG) given to the mother within 96 hours of exposure, may offer some protection from more serious infection, including varicella pneumonia. The cost (approximately $400 to $500) may prohibit use on a routine basis for all pregnant women who think they may have been exposed to varicella but are not sure if they ever had it. Of these women, 80 percent will demonstrate evidence of prior infection upon serologic testing and not need VZIG, but results of the test most likely will not be known within 96 hours. Thus, some clinicians limit the use of VZIG to those women who are directly exposed to varicella within the first 20 weeks of gestation and who do not know if they have ever had the disease [22].

VZIG provides no known benefit to the fetus. However, the infant of a woman who develops varicella infection 6 days before through 2 days after delivery should receive VZIG because of the high associated neonatal mortality.

Because of the high communicability of varicella, women who have been exposed or infected should be seen before or after regular office hours to avoid exposure of other patients; staff with known immunity to varicella should evaluate and care for them. Women exposed to or infected with varicella should be counseled to avoid exposure of others.

With the availability of a reliable vaccine, it is possible to prevent the majority of cases of varicella. Encouragement of childhood immunization decreases the incidence of varicella and the potential exposure of adults, including pregnant women. During preconception counseling, serologic testing for varicella antibodies can be offered to women without a history of infection. Vaccination can be offered prior to pregnancy. It is reasonable to add serologic screening for varicella to the initial laboratory evaluation of pregnant women who do not have a history of infection. If serologic testing confirms a lack of immunity, varicella vaccine can be offered postpartum and/or interconceptionally. Varicella vaccine is an attenuated live vaccine and therefore is contraindicated in pregnancy. Women receiving the vaccine need to be counseled to avoid pregnancy for 1 month afterward. In the event that a woman is vaccinated and then finds that she is pregnant, she should be advised that the risk to the fetus is theoretical, as no known anomalies or cases of CVS have been documented after vaccination. The case should also be reported to the Varicella Vaccination in Pregnancy Registry (maintained by the vaccine manufacturer and the CDC) at (800) 986-8999 [22].

Parvovirus B19 (Fifth Disease, Erythema Infectiosum)

The most common presentation of parvovirus B19, is a flushed red face, with a characteristic "slapped cheek" pattern. Prior to onset of the rash, symptoms often include mild fever, malaise, myalgias, and headache. A symmetric, maculopapular, lacelike, pruritic rash may then appear on the trunk and move peripherally to the arms, buttocks, and thighs. In rare cases, adult women may experience arthralgia and arthritis. The virus may rarely cause transient red-cell hypoplasia or aplastic crisis [23].

The virus is transmitted primarily through contact with respiratory secretions, but it can also be transmitted by percutaneous exposure to blood or blood products, and by vertical transmission from mother to fetus. The virus is common in elementary and middle school children, with a high incidence of spread among family members.

The period of greatest contagion is prior to the onset of symptoms, and transmission is rare after onset of the rash. Therefore, once symptoms are present, there is no need for isolation of children or of pregnant women. The incubation period from exposure to onset of symptoms is 4 to 21 days. Rash and joint symptoms may not appear for 2 to 3 weeks after exposure.

Diagnosis is done by parvovirus B19-specific immunoglobulin antibody (IgM). When positive, IgM indicates infection within the past 2 to 4 months. The presence of serum IgG antibody is indicative of previous infection and immunity.

When parvovirus infection occurs during pregnancy, there is a 20 to 30 percent placental transfer rate. For those fetuses that are affected, some will experience aplastic anemia, nonimmune hydrops, and rarely death. Fetal hydrops is present in 18 percent and fetal death occurs in 3 to 9 percent, with the most severely affected when the infection occurs in the first half of pregnancy [24]. Congenital anomalies are not associated with parvovirus.

For women who have been exposed to parvovirus B19, serum IgM and IgG should be obtained. If immunity is present (with positive IgG), no further testing is required. Nonimmunity (negative IgG) testing should be repeated in 3 to 4 weeks. If seroconversion occurs, the fetus should be monitored weekly by ultrasound examination for fetal hydrops, placentomegaly, and fetal growth restriction. Physician consultation should be sought.

Urinary Tract Infections

Urinary tract infections, especially asymptomatic bacteriuria and cystitis, are a common complication of pregnancy. Pyelonephritis, while less common, carries significant maternal morbidity and potential poor pregnancy outcomes. Due to the hydronephrosis that normally occurs during pregnancy, urinary stasis can result, a condition that makes an excellent medium for bacterial growth. Identification and treatment of urinary tract infections during pregnancy are critical, as they are associated with preterm labor, low birth weight, hypertension, preeclampsia, and maternal anemia [25]. In addition, minor bladder infections, left untreated have a high incidence of developing into pyelonephritis.

Women with a history of urinary tract infections, sickle cell trait, sickle cell anemia, and diabetes are at increased risk. However, due to the potential hazards, frequent lack of symptoms, ease of screening, and effectiveness of treatment, the screening of all women with a urine culture at the first prenatal visit is recommended [25, 26].

Both asymptomatic bacteriuria and cystitis are infections of the lower urinary tract. The causative organisms are the same. Bacteria frequently ascend from the closely placed vagina and rectum, but as many as 35 percent of urinary tract infections arise from the kidneys [25].

The presence of bacteria in the urine (bacteriuria) is considered significant when the urine is a clean catch specimen and contains 100,000 bacteria of the same species per milliliter. This most often indicates an infection that should be treated.

Escherichia coli is the most common pathogen found in urinary tract infections [27]. This bacteria is normative and nonpathogenic in the intestinal tract, but highly pathogenic outside it. Similarly, *Proteus*, which is normally found in the intestinal tract is pathogenic in the urinary tract. *Klebsiella*, a common respiratory infectious agent, may also cause urinary tract infections, as can *Pseudomonas aeruginosa*, which is pathogenic in humans, including causing urinary tract infections. Another common urinary tract bacteria is *Beta-hemolytic streptococcus*. The term *Enterococcus* refers to any species of streptococcus normally inhabiting the intestinal tract and pathogenic in the urinary tract.

Not all bacteria are pathogens to the urinary tract, but they are identified in urine culture samples. These bacteria are, instead, contaminants. *Alpha-hemolytic streptococcus* is a common flora of the skin and mucous membranes. *Staphylococcus epidermidis* is also common on the mucous membranes and skin, including the genital area, and it is a major source of urine specimen contamination. *Lactobacillus* is normal in the mouth, intestinal tract, and vagina, and it is considered to be a urinary contaminant. When more than one type of bacteria is identified, the specimen should also be considered to be contaminated. When a culture report identifies a contaminated specimen, the recommendation is to repeat the specimen at the next prenatal visit.

Asymptomatic Bacteriuria

As the name states, there are no symptoms associated with this infection, which occurs in up to 11 percent of pregnancies. There is not an increase in asymptomatic bacteriuria during pregnancy. However, the dramatically increased rate of pyelonephritis and as-

sociated complications makes this a true concern during pregnancy. It has been reported that as many as 40 percent of untreated lower urinary tract infections will progress to pyelonephritis [25].

Cystitis

Cystitis, by definition, is inflammation of the bladder. Usually the inflammation is due to a bacterial infection. Signs and symptoms of cystitis include the following:

1. Urinary urgency
2. Urinary frequency
3. Dysuria
4. Nocturia
5. Lower abdominal (suprapubic) pain
6. Hematuria (possible)

When women report symptomatology, it is prudent to obtain a dipstick urine assessment and a urinalysis. If the dipstick is positive for WBCs, nitrates, or protein above trace, or if the urinalysis is positive for WBCs, RBCs, and/or bacteria, a culture is indicated. Sometimes symptoms are difficult to assess as they are the same or similar to normal pregnancy symptomatology (e.g., frequency, nocturia, lower abdominal pressure). Whenever a question arises of normal symptoms versus urinary tract symptoms, it is prudent for the midwife to obtain a dipstick and or urinalysis. Laboratory findings from microscopic urinalysis include the following:

1. Bacteriuria
2. Abnormally increased number of white blood cells
3. Red blood cells
4. Nitrites

Treatment is ideally based on targeting culture specific organisms. However, when the woman is symptomatic and the urine dipstick or U/A is positive, then empiric antibiotic therapy should be initiated and then changed if necessary when the culture results are available. Antibiotic therapy has been shown to decrease the risks of pyelonephritis as well as the accompanying preterm labor and low birth weight infants [27]. (See Table 24-8.)

The treatment of asymptomatic bacteriuria is best based on a report of the antimicrobial agents to which the microorganisms present are sensitive. Most, however, are sensitive to sulfa drugs (e.g., Bactrim), nitrofurantoin (e.g., Macrodantin), the cephalosporins, and ampicillin or amoxicillin. The sulfa drugs are contraindicated after 36 weeks and may be a factor in kernicterus of the newborn; the nitrofurantoin drugs are contraindicated in women with glucose-6-phosphate dehydrogenase (G6PD) deficiency, since drug-induced hemolysis may occur and cause hemolytic anemia. When Group B Streptococcus is identified as a urinary pathogen, the woman should be treated antepartally and on labor [29].

TABLE 24-8 Antibiotic Treatment of Lower Urinary Tract Infections

Medication	Dosage	Frequency
Amoxicillin	500 mg po	tid
Ampicillin	250 mg po	qid
Cephalosporin (Keflex)	250 mg po	qid
Nitrofurantoin (Macrodantin)	100 mg qid	qid
Sustained release nitrofurantoin (Macrobid)	100 mg po	bid

Notes:

Trimethoprim/sulfamethoxazole (TMP/SMX) (Bactrim DS) 160 mg/800 mg po bid are contraindicated after 36 weeks, and with G6PD. During pregnancy, treatment should be given for 3 to 7 days.

Repeat urine culture should be done 1 to 2 weeks after completion of antibiotic therapy as a test of cure.

When Group B Streptococcus is identified, the woman should be treated antepartally and in labor.

Source: Adapted from Samuels, P., and Colombo, D. F. Renal disease. In Gabbe, S. G., Niebyl, J. R., and Simpson, J. L. *Obstetrics: Normal and Problem Pregnancies*. New York: Churchill Livingstone, 2002, ch. 31.

A follow-up urine culture should be performed within 2 weeks of treatment as a test of the effectiveness of the prescribed therapy. If the test of cure shows continuing infection, obtain a careful history of compliance with the treatment regimen, prescribe another course of treatment with a different drug (based on sensitivity testing), and schedule another test of cure urine culture 1 to 2 weeks after completion of this course of antibiotics.

Suppressive therapy is used when two courses of treatment have been completed without cure of asymptomatic bacteriuria or cystitis. A continuing dose of an antimicrobial agent will suppress the offending organism as long as the drug is taken but, as has already been demonstrated, will not effect a cure. Nitrofurantoin (Macrodantin) 100 mg once daily at bedtime, or cephalexin (Keflex) 250 mg once daily at bedtime, is usually used for suppressive therapy throughout the rest of pregnancy [28]. Effectiveness is monitored by monthly urine cultures. By suppressing the occurrence of asymptomatic bacteriuria, the midwife reduces the incidence of pyelonephritis, preterm delivery, and low birth weight babies.

Acute Pyelonephritis

Pyelonephritis, by definition, is inflammation of one or both kidneys. The infectious agent is bacterial. Incidence of pyelonephritis in pregnancy, including the puerperium, is approximately 2 percent [25]. The complications of pyelonephritis—preterm labor and delivery, adult respiratory distress syndrome, hemolysis resulting in anemia, and septic shock—can be life threatening for mother and fetus. It is the primary nonobstetric indication for hospitalization of pregnant women [28]. Pyelonephritis results in part from a number of naturally occurring physiological and anatomical events associated with pregnancy, including the following:

1. Compression of the ureters at the pelvic brim by the uterus
2. Dilatation and decreased tone of the ureters due to hormonal effects (probably progesterone)
3. Urinary stasis favorable to microorganisms, caused by 1 and 2 above
4. Dilatation of the renal pelves and calyces allows greater virulence by microorganisms
5. Decreased bladder tone and urine stasis in the immediate puerperium

Pyelonephritis is a symptomatic disease. Signs and symptoms of acute pyelonephritis are as follows:

1. Fever—temperature usually 100.4°F or above
2. Shaking chills
3. Hematuria
4. Myalgia
5. History of loss of appetite, nausea, and vomiting
6. History of asymptomatic bacteriuria or cystitis
7. Urinary urgency due to associated cystitis
8. Urinary frequency due to associated cystitis
9. Dysuria due to associated cystitis
10. Low back (lumbar) pain
11. CVA tenderness (if infection is unilateral, it will most often involve the right side)
12. Lower abdominal (suprapubic) pain

Laboratory testing includes urinalysis, culture, and sensitivity, and CBC with differential. Findings from microscopic urinalysis and urine culture and sensitivity include the following:

1. Bacteriuria
2. Pyuria (with WBCs equal to or greater than 10 per high power field)
3. Hematuria
4. Proteinuria (value depending on the extent of renal damage)

The blood testing will usually demonstrate an increased WBC and a left shift in the differential.

The midwife should consult with the physician for management of pyelonephritis. Management of pyelonephritis requires hospitalization for intravenous therapy to correct dehydration and electrolyte imbalance, and for intravenous antibiotic therapy. Many clinicians maintain women on suppression therapy with antibiotics or nitrofurantoin until delivery. A urine culture should be done 6 to 8 weeks postpartum to assess for asymptomatic infection [25, 26, 28].

Anemias and Hemoglobinopathies

There are large numbers of anemias and hemoglobinopathies that may complicate or be complicated by pregnancy. If the woman's history or laboratory studies indicate an abnormality, the midwife evaluates the woman to determine the etiology of the anemia and then develops an appropriate management plan. This section will address the obstetric implications of common anemia and hemoglobinopathies. Refer to Chapter 7 for more general information.

Naturally occurring physiological changes in pregnancy affect normal blood count results in pregnant women. The increase in maternal blood volume results primarily from an increase in plasma rather than from an increase in red blood cells. Although there is an increase in the number of erythrocytes in circulation, it is not proportionate to the increase in plasma volume. The disproportion of erythrocytes to plasma exhibits itself in a lowered hemoglobin level. The increase in the number of erythrocytes is also one of the factors in the increased need for iron during pregnancy, along with fetal demand. This disproportion between erythrocytes and plasma is greatest during the second trimester, because the increase in plasma volume ceases toward the end of pregnancy while increased erythrocyte production continues.

Anemia is defined as either a decrease in the number of red blood cells or a decrease in the concentration of the hemoglobin in the circulating blood. The working definition of anemia is generally accepted to be a hemoglobin level of less than 12.0 grams per 100 milliliters (12 grams/deciliter) blood in nonpregnant women and less than 10.0 grams per 100 milliliters (10 grams/deciliter) blood in pregnant women. Iron deficiency anemia constitutes approximately 95 percent of anemias related

to pregnancy [31].

Although often asymptomatic, anemia may cause the following signs and symptoms:

1. Fatigue, drowsiness, malaise
2. Dizziness, weakness
3. Headaches
4. Sore tongue
5. Skin pallor
6. Pale mucous membranes, e.g., conjunctivae
7. Pale fingernail beds
8. Loss of appetite, nausea, and vomiting

History related to potential hematologic abnormalities include the following:

1. History of iron deficiency anemia
2. Sickle cell disease
3. Self or family history of thalassemia
4. Idiopathic thrombocytopenic purpura (ITP)
5. Bleeding disorders
6. Medication history
7. Previous pregnancy with increased bleeding (from episiotomy, cesarean incision, need for previous blood therapy, or bruising from IV sites)
8. If any previous infant had bleeding problems, e.g., after circumcision
9. History of HELLP syndrome
10. HIV infection (highly associated with anemias and an ITP-like syndrome)
11. Dietary history
    a. High iron source foods
    b. Pica—i.e., excessive craving for and ingestion of food substances, or such things as clay or dirt, starch, ice

Anemia is a sign of underlying illness rather than a disease entity itself [30]. In determining the etiology of an anemia, it is helpful to think of how the diagnosis is made by laboratory tests in order to categorize the possibilities and start the process of differential diagnosis. Initial laboratory evaluation for anemia determines the red cell size: microcytic, normocytic, or macrocytic. Further laboratory evaluation may be necessary to determine the specific anemia within a category (e.g., folate deficiency or B_{12} deficiency in macrocytic anemia). The following is a list of anemia etiologies by cell size category [30]:

Microcytic Anemias (Decreased Red Cell Size)

1. Iron deficiency anemia
2. Thalassemias
3. Hemoglobin E disorders (genetic hemoglobin variant common in Southeast Asia)
4. Lead toxicity
5. Chronic disease (infection, neoplasm)

Normocytic Anemias (Normal Red Cell Size)

1. Increased red blood cell loss or destruction
    a. acute blood loss
2. Hemolytic disorders
    a. hemoglobin SS disease (sickle cell disease)
    b. hemoglobin C disorders
    c. spherocytosis (common in Northern Europeans)
    d. glucose-6-phosphate dehydrogenase (G6PD) deficiency
    e. acquired hemolytic anemias (medication side effect)
    f. autoimmune hemolytic anemias
3. Decreased red blood cell production
    a. aplastic anemia (life-threatening bone marrow failure)
    b. chronic disease (liver disease, renal failure, infection, neoplasm)
4. Overexpansion of plasma volume pregnancy, overhydration

Macrocytic Anemias (Increased Red Cell Size)

1. Vitamin B_{12} deficiency
2. Folic acid deficiency
3. Hypothyroidism
4. Alcoholism
5. Chronic liver or renal disease

Iron Deficiency Anemia

Iron deficiency anemia is microcytic, and it is the primary cause of anemia in pregnancy. The cause may be dietary or due to chronic blood loss, with the vast majority of cases in pregnancy caused by dietary deficiency.

Women with a hemoglobin below 10 g/dL blood should be started on iron, folic acid (400 mcg, which is exceeded in prenatal vitamins), and vitamin supplements if they are not already taking all of these. Most midwives will supplement all women with iron and vitamins via prenatal vitamins. Controversy exists in the need for additional iron supplementation without evidence of iron deficiency. However, except for women with a medical contraindication such as hemochromatosis, supplementation has minimal if any side effects. (Refer to Chapter 22, p. 601 for further discussion.)

Dietary counseling is very important as iron is more readily absorbed from foodstuffs than from oral iron medication (see Table 24-9). High-iron foods include green leafy vegetables, collard greens,

TABLE 24-9 Tips to Increase Absorption of Iron

1. Take iron supplements between meals or 30 minutes before meals.
2. Avoid calcium ingestion with iron (milk, antacid, prenatal supplements).
3. Take with vitamin C (orange juice, vitamin C supplement).
4. Cook foods in a minimal amount of water, for the shortest possible time.
5. Eat meat, poultry, and fish—foods in which iron is absorbed and utilized more readily than the iron in other foods.
6. Eat a wide variety of foods.

red meat, egg yolks, raisins, prunes, liver, oysters, and some fortified cereals. Heme iron is contained in meat, fish, and poultry, and it is more completely absorbed than iron in other foods. Plant and dairy foods contain nonheme iron. Absorption of this form of the nutrient is affected by various components in food. Vitamin C and various compounds in meats, for instance, enhance the absorption of nonheme iron, while phytic acid (found in grains and soy proteins), coffee, and calcium phosphate hinder the body's ability to use the mineral [32]. In addition, iron from all food sources is better absorbed from meals that contain heme iron sources. Meals or food sources with vitamins A and C will also enhance absorption. Calcium sources, however, from foods or from medication will diminish the absorption of iron. The midwife should take a careful dietary history and analyze it. Attention should be paid to high iron content foods. Included in this history should be a thorough investigation into the possibility of pica, excessive craving and ingestion either of food substances or of clay or dirt, starch, ice, and other nonfoods. Such nonnutritive substances are filling; thus nutritive foodstuffs are neglected, resulting in malnutrition and its sequelae.

When the CBC demonstrates a low hemoglobin and hematocrit, below 10 mg/dL and 30 percent, respectively, iron supplementation should be initiated [30]. Iron is best absorbed when taken on an empty stomach, and it must be available to the body at several times during the day for best results. Table 24-10 shows the amount of elemental iron available in frequently prescribed iron preparations. These supplements can be provided in tablet, capsule, or liquid preparations.

If hemoglobin levels do not stabilize or continue to drop, a careful history should be taken to ascertain whether the woman is taking her iron supplement and following her dietary instructions. Ask about the color of her stools, as iron pills turn stools black and tarry. A stool specimen for occult blood should be taken. The possibility of pica should be reinvestigated. Iron replacement therapy has side effects such as nausea, dyspepsia, and constipation that may be uncomfortable or intolerable to women. Discussing these symptoms openly and offering dietary or medication changes may help the woman be compliant with iron use.

TABLE 24-10 Oral Iron Preparations

Preparation	Typical Dose	Elemental Iron/Dose
Ferrous sulfate	325 mg tid	65 mg
Ferrous sulfate, exsiccated (Feosol)	200 mg tid	65 mg
Ferrous gluconate	325 mg tid	36 mg
Ferrous fumarate (Hemocyte)	325 mg bid	106 mg

In addition to beginning iron replacement therapy, when the hemoglobin falls below 10 g/dL blood, the midwife should initiate the following laboratory tests directed at determining cell size and screening for the most common etiologies for anemia [33]:

1. Complete blood count (CBC) with differential
2. Reticulocyte count
3. Serum iron
4. Serum ferritin
5. Total iron-binding capacity (TIBC)
6. Platelet count
7. Hemoglobin electrophoresis

If these studies confirm iron deficiency anemia, continue iron replacement and monitor for improvement. If other than iron deficiency alone is suspected, evaluate the lab results according to Table 24-11. Physician consultation is recommended when iron deficiency anemia is recalcitrant, or if another etiology is identified or suspected.

Sickle Cell Disease (Hemoglobin S Disease) and Sickle-C Disease (Hemoglobin C Disease)

All African American women should be screened for the sickle cell trait at the initial prenatal visit. Those women with this trait should have genetic counseling along with the baby's father in order to rule out the presence of sickle cell disease in the fetus. In addition, these women have an increased risk of urinary tract infections during pregnancy and should be screened appropriately.

TABLE 24-11 Laboratory Diagnosis, Evaluation, and Management of Anemia

			Management	
Laboratory Test	*Result*	*Interpretation*	*Additional Data Needed*	*Treatment*
Hemoglobin	<10.0 g/dL	True anemia (hypochromic)	Management based on other indices	
Reticulocyte count	Elevated above 2.5%	Increased marrow activity due to blood loss or hemolysis	Review history for blood loss, hemolysis Order stool for ova and parasites	
	Absent to low (<0.5%)	Marrow failure due to iron or folate deficiency or effect of medications	Review medications for risk of marrow depression side effect	Change medication Supplement with iron and folic acid
Mean corpuscular hemoglobin (MCH)	Decreased	Iron deficiency (hypochromic)		Supplement with iron
Mean corpuscular volume (MCV)	Low value MCV <80 fl	Iron deficiency (microcytic) Confirms iron deficiency if serum ferritin is also low		Supplement with iron
	High value MCV >95 fl	Folate or vitamin B_{12} deficiency (macrocytic)	Order serum folate	If serum folate is low, supplement with folic acid If serum folate is high or normal, consider vitamin B_{12} deficiency Consult with physician for further evaluation
Serum iron	Elevated slightly	Mobilization of iron stores		Supplement with iron
	Low	Depleted iron stores		Supplement with iron
Serum ferritin	Elevated	Iron overload, inflammatory diseases, alcoholism, inflammatory liver diseases		Consult physician for further evaluation
	Normal or elevated	Chronic disease, thalassemia		Consult MD for further evaluation
	Low	Iron stores depleted		Supplement with iron
Total iron-binding capacity (TIBC)	Elevated	Response to fall in serum iron		Supplement with iron
Platelets	Mild decrease (100,000–149,000/mm^3)	Thrombocytopenia Gestational most likely	Antiplatelet antibody screen, peripheral smear Recheck platelet counts each trimester, 36 weeks, and in labor	No treatment needed Consult physician for further evaluation
	Moderate decrease (50,000–99,000/mm^3)	Thrombocytopenia Gestational most likely	As above	No treatment needed Consult physician for further evaluation and collaborative management
	Profound decrease (<50,000/mm^3)	Thrombocytopenia Gestational, ITP, HELLP	As above Preeclampsia labs	Medical management

TABLE 24-11 Laboratory Diagnosis, Evaluation, and Management of Anemia (*continued*)

			Management	
Laboratory Test	*Result*	*Interpretation*	*Additional Data Needed*	*Treatment*
Hemoglobin electrophoresis	AA	Normal		Inform woman
	AS	Sickle cell trait		Inform woman
		Carrier		Genetic counseling
				Monitor for urinary tract infections
	SS	Sickle cell disease		Inform woman
				Consult physician for further evaluation and collaborative management

Pregnancy increases the frequency and intensity of sickle cell crises in the woman with SS and SC hemoglobin. The midwife works collaboratively with a physician knowledgeable in the management of the complex hematologic problems when caring for a woman with sickle cell disease (see Chapter 7).

G6PD Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked genetic disease that affects an enzyme (G6PD) associated with red blood cells. G6PD deficiency is common in those of Mediterranean descent and in African Americans. Hemolysis occurs when the individual has an infection, undergoes surgery, or receives oxidant drugs. Oxidant drugs commonly used in pregnancy and women's health care that must not be given to individuals with G6PD deficiency include sulfa and sulfa derivatives, nitrofurantoin (Macrodantin), toluidine blue, and methylene blue. If a particular woman's care requires the use of any of these drugs and you do not know her G6PD status, you should obtain a G6PD screen. The woman should be informed of the results and genetic counseling should be offered, if indicated. In women with the Mediterranean variant of G6PD deficiency, fava beans will trigger hemolysis.

Management of care of women with G6PD deficiency includes avoidance of drugs (and fava beans, for Mediterraneans) that may cause hemolysis. Prompt diagnosis and treatment of infections such as urinary tract infections will minimize the risk of hemolysis from infection. Surgery can precipitate an episode of hemolysis. Therefore, the midwife should remind the woman to notify her surgeon and surgical team prior to any elective or required surgery. Genetic counseling and prenatal diagnostic testing should be offered to all women with G6PD deficiency. When caring for a pregnant woman with G6PD deficiency, the midwife should notify the consulting physician so that appropriate care can be provided in the event an operative delivery is needed or the woman requests postpartum surgical sterilization.

Thalassemia

In pregnancy, it is important to accurately diagnose anemia and not just to decide that all anemia is realted to iron deficiency. In the case of thalassemias, folic acid supplementation may be useful, but iron supplementation is not indicated and may cause hemosiderosis, an overaccumulation of iron. In addition, genetic counseling is indicated as this is a genetically inherited condition. (See Chapter 7 for discussion of thalassemia.)

Gestational Idiopathic Thrombocytopenic Purpura

A decrease in the platelet count below the lower limits of normal is considered to be thrombocytopenia. An increase in plasma volume during pregnancy will result in a slight dilutional effect in platelet levels, but they should not drop below normal (generally considered to be 150,000/millimeters^3. The most common cause of decreased platelets in pregnancy is gestational thrombocytopenia [30]. It is usually mild (platelets between 100,000 to 150,000/millimeters^3), and has no serious complications for mother or fetus. Immune thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS) are uncommon chronic hematologic diseases that may be encountered during pregnancy and must be ruled out when platelets are abnormally low.

Any woman who has an abnormally low platelet count, or a history of any bleeding problems during previous pregnancies, should have laboratory evaluation that includes antiplatelet antibody screening and a peripheral smear. Coagulation studies may also be requested. Consultation with a physician is required for making a management plan. In the majority of cases, no treatment will be necessary. If the mother's platelets are low, in rare instances, fetal platelets may also be depressed. In order to avoid problems for the fetus, internal scalp electrodes are not to be used unless considered of greater benefit than risk. Fetal scalp blood sampling and operative vaginal birth should be avoided if at all possible [30]. Vacuum assisted vaginal birth is contraindicated.

Von Willebrand's Disease

This genetic disease is responsible for an increased risk of bleeding in women (see Chapter 7 for discussion of the disorder). During pregnancy, there is increased risk for postpartum hemorrhage [30].

Heart Disease

The New York Heart Association (NYHA) [34] classification of cardiac status is the standard method used to classify heart disease. The purpose of the NYHA system is to provide a tool for communicating functional status in heart disease. The NYHA classification is shown in Table 24-12.

The normal physiologic changes of pregnancy increase cardiac output up to 40 percent above cardiac output during the nonpregnant resting state. This increase occurs early in pregnancy and peaks by 20 to 24 weeks. There is also marked fluctuation in cardiac output during pregnancy with changes in body position. Cardiac output increases further in labor, with an almost 50 percent increase during contractions. Cardiac output is highest immediately postpartum. During pregnancy, labor, and delivery, the increase in cardiac output places the woman with a history of heart disease at increased risk of cardiac decompensation [35]. A woman may enter pregnancy with Class I heart disease and become Class II or III with the physiological stress of pregnancy and delivery. Therefore, careful consideration must be made when there is any concern for cardiac status in pregnancy.

The most common cardiac abnormality in young women and therefore during pregnancy is mitral valve prolapse (MVP). This may be suspected on auscultation with the classic systolic click. Diagnosis is made by echocardiogram. The severity is based on whether there is evidence of valvular leaflet thickening or regurgitation. When no regurgitation is present, this is an innocuous problem during pregnancy, only requiring consideration of the need for antibiotic prophylaxis [36] (see Figure 24-1).

The American Heart Association's guidelines recommend that women with MVP without mitral regurgitation or thickened leaflets, do not require antibiotic prophylaxis for cesarean section or vaginal birth [36]. If a woman has additional cardiac complications, or if she develops chorioamnionitis or postpartum infection, she should be treated with an antibiotic appropriate for eradication of entero-

TABLE 24-12 The New York Heart Association (NYHA) Classification of Cardiac Status

Class	Summary	Characteristics
I	Uncompromised	Physical activity is not limited No symptoms of cardiac insufficiency No anginal pain
II	Slightly compromised	Slight limitation of physical activity Comfortable at rest Ordinary physical activity results in excessive fatigue, palpitation, dyspnea, or anginal pain
III	Markedly compromised	Marked limitation of physical activity Comfortable at rest Less than ordinary activity results in excessive fatigue, palpitation, dyspnea, or anginal pain
IV	Severely compromised	Inability to perform any physical activity without discomfort Symptoms of cardiac insufficiency or angina may develop at rest Any activity increases discomfort

cocci. If a woman requires antibiotic prophylaxis due to mitral valve regurgitation with mitral valve prolapse or another risk category, refer to Table 24-13 for the drug of choice.

Thyroid Disorders

During pregnancy, there is an increased demand for thyroid hormone secretion. When the thyroid gland is normal, this will not present a problem. However, if the woman is hypothyroid, or has a subtle, unrecognized degree of hypothyroidism, she may become symptomatic, resulting in concern for both herself and the fetus. Hyperthyroidism may also become symptomatic and has implications for both mother and fetus (see Table 24-14).

At the current time, there is not considered to be an adequate cost-benefit ratio to screening all women for thyroid disorders [37]. However, when indications exist (see Table 24-15), a serum TSH should be drawn and evaluated according to Figure 24-2. If the TSH is abnormal, then a free thyroxine 4 index (FT4I) should be drawn [38]. Consultation is required for abnormal testing results and need for medication. (Chapter 7 has further discussion of signs, symptoms, and management of thyroid disease.)

TABLE 24-13 Recommended Prophylaxis for Genitourinary Procedures

Risk Status	Medication/Dosage
High	Initial dose within 30 min of starting procedure: Ampicillin 2 gm IM or IV; and Gentamicin 1.5 mg/kg (not to exceed 120 mg) IM or IV 6 hr later: Ampicillin (only) 1 gm IM or IV
Moderate	2 hr before the procedure: Amoxicillin 2 gm orally or Within 30 min of procedure: Ampicillin 2 gm IM or IV
	If Penicillin Allergic
High	To be completed 30 min before procedure: Vancomycin 1 gm IV over 1–2 hr and Gentamicin 1.5 mg/kg (not to exceed 120 mg) IM or IV
Moderate	To be completed 30 min before procedure: Vancomycin 1 gm IV over 1–2 hr

Asthma

It is estimated that 1 to 4 percent of pregnant women have asthma. During pregnancy, the clinical course of asthma cannot be predicted. There is evidence that women with severe asthma before pregnancy will continue to experience severe problems and may get worse during pregnancy. In women with a history of asthma without recent acute episodes and women with occasional episodes, the pattern may continue, improve, or worsen. The experience of asthma in previous pregnancies may offer an indication of the course of asthma during the current pregnancy. Women generally return to

their prepregnant level of severity of asthma by 3 months postpartum. (Asthma as a medical disorder and in pregnancy is also discussed in Chapter 7.)

Asthma is associated with increased perinatal mortality, hyperemesis gravidarum, preterm delivery, chronic hypertension, preeclampsia, low birth weight infants, and vaginal hemorrhage. The incidence and severity of these adverse effects of asthma on pregnancy may be mitigated by good asthma control.

Medications commonly used to manage asthma are safe and effective during pregnancy. These include inhaled bronchodilators such as albuterol (Proventil), metaproterenol (Alupent), and terbutaline sulfate inhalation aerosol (Brethaire). Oral theophylline (Theo-Dur, Slo-Bid) may also be used. Anti-inflammatory agents that may be used include beclomethasone (Vanceril, Beclovent), flunisolide (Aerobid), and prednisone. The need for anti-inflammatory agents indicates severe asthma [39].

During labor and delivery, the woman should continue to take her regular medication. Care should be taken to ensure that she remains hydrated and that her pain is managed appropriately. These measures will help prevent bronchospasm. Medications to be avoided during labor and delivery include morphine and meperidine (Demerol), which can produce bronchospasm. If a prostaglandin is needed to manage fourth-stage postpartum hemorrhage, then prostaglandin E2 (PGE2), marketed as dinoprostone, should be used. The more common prostaglandin, 15-methyl prostaglandin F_2 alpha (PG F2α), marketed as Hemabate, Carboprost, or Prostin/15M, may trigger bronchospasm in women with a history of asthma.

Multiple Pregnancy

It is essential that a multiple pregnancy be identified as early as possible. A number of complications are associated with the pregnancy, labor and delivery, and puerperium of a woman pregnant with more than one fetus. No woman receiving antepartal care should enter labor with an undiagnosed multiple gestation. This statement, however, is not meant to advocate routine ultrasound screening. Rather, it emphasizes the importance of clinical skill and judgment.

The following are signs and symptoms indicative of a possible multiple pregnancy:

1. Large-for-dates uterine size, fundal height, and abdominal girth, associated with rapid uterine growth during the second trimester
2. Severe nausea and vomiting (associated with rapidly increasing hCG levels)
3. Familial history of twins (in and of itself not indicative)
4. History of recent use of ovulation-inducing drugs such as clomiphene citrate (Clomid) or menotropins (Pergonal)
5. Abdominal palpation of three or more large parts and/or multiple small parts, especially in the third trimester when these are more readily felt
6. Auscultation of more than one clearly distinct fetal heart tone (differing by more than 10 beats per minute and separate from the maternal pulse)

When there is discrepancy between the estimated gestational age and the uterine size at the initial prenatal visit, ultrasound evaluation is indicated to accurately date the pregnancy and to rule out the possibility of a twin (or greater) gestation. With multiple pregnancy, it is common for a woman to register in the first trimester and have that physical exam be consistent with the dates. Then, when she returns for a subsequent visit, the uterus will seem to have grown more than expected. This may be dramatic or it may only be slightly ahead of dates. The decision of when to do an ultrasound exam is based on clinical judgment. The midwife may wish to wait until the next visit if the uterine size is not dramatically larger, or may decide to reconfirm dating and rule out multiple pregnancy as soon as there is any suspicion of size greater than dates. Diagnosis is made on the basis of clinical findings and confirmed with ultrasound.

Midwifery management of multiple pregnancy depends on the setting. Twin gestations are considered to be at risk for the following [40]:

1. Fetal anomalies
2. Early pregnancy loss
3. Stillbirth
4. IUGR
5. Placenta previa
6. Preterm labor and birth
7. Gestational diabetes
8. Preeclampsia
9. Malpresentation
10. Dysfunctional labor

Therefore, if midwives plan to participate in management of twin gestations, they should have immediate access to consultative physician care and

anticipate birth in the hospital. Higher order multiples (triplets and greater) require medical management. For midwives who plan to care for women with multiple pregnancy, this chapter is not considered to be adequate instruction. Consider referring to a medical obstetric text for further information about the physiology and potential problems that may be encountered. It is important to develop a management plan with the consultant physician at the time of diagnosis of twins and at agreed upon times during the pregnancy.

Ultrasound diagnosis will be focused on fetal number, fetal anatomy, and placentation. In twins, the placenta is evaluated not only for position, but also for chorionicity of the twinning. In many cases, it is possible to determine if the twins are monozygotic or dizygotic. In addition, they will attempt to identify whether the twins are mono- or di-amniotic. These distinctions are necessary to help predict risks for complications. Figure 24-3 illustrates the possible combinations of chorionicity and amnionicity.

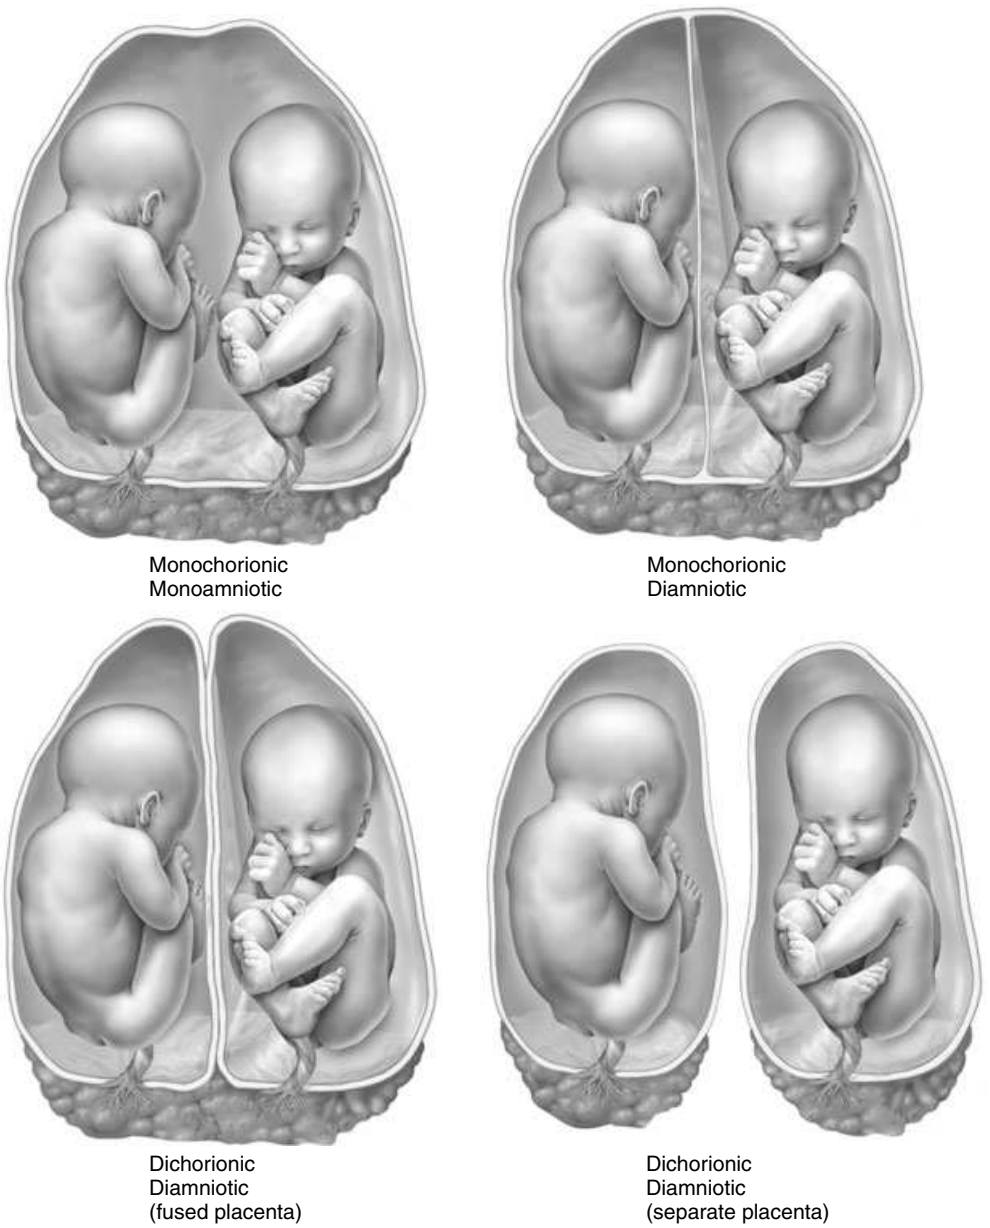

FIGURE 24-3 Placentation in twin pregnancies.

Once the diagnosis of twin pregnancy is made, the couple should be advised of this diagnosis and have a discussion about the changes in management of the pregnancy that will be necessary. This will include more frequent prenatal visits, increased surveillance for complications, at least monthly sonograms, physician consultation, and earlier changes in home and work responsibilities.

The first concern is that of fetal growth. Maternal nutrition is critical to the development of the fetuses. As explained in Chapter 22, protein and calories should be added to the diet for each fetus. Women should be evaluated carefully for the duration of their pregnancy for weight gain and fetal growth. Weight gain is essential for the woman to have the nutritional stores necessary for adequate fetal growth. After 24 weeks, the woman should be seen every 2 weeks until 36 weeks, and then weekly, unless there is a concern that indicates more frequent visits.

Fetal growth should be monitored by ultrasound as fundal height cannot give information about the individual fetus. It is generally accepted that ultrasound exams will be done every 3 to 4 weeks from 20 weeks until term for assessment of fetal growth. Of importance is not only the continued growth of each fetus but also consistency in size. If one of the twins becomes discordant, or if both twins are found to be lagging in growth, there will be heightened concern for intrauterine growth restriction (IUGR). Poor fetal growth may occur because of the tremendous demands of the mother for nutritional support or because of uteroplacental insufficiency. The large size of the placenta can stress the capability of uterine blood flow, especially when there is underlying pathology such as maternal hypertension, diabetes, or collagen vascular disease. If one or both fetuses have poor growth patterns, consultation is required as this then becomes a high risk pregnancy.

Due to the larger placental mass, the placental hormones are greater, which makes the risk for development of gestational diabetes higher. Glucose screening should be done at 24 to 26 weeks. The normative values for interpretation and the limits for glycemic control of the mother are the same as with a singleton pregnancy.

Increased surveillance of the woman with twins is indicated for evaluation of risks for preterm labor. Preterm labor symptoms should be carefully reviewed with the woman at each visit. In addition, ultrasound measurement of the cervix should be done with each scan for fetal growth [39]. Cervical examination should be performed as described in Chapter 29 for all women with an increased risk of preterm labor.

Preeclampsia has a higher incidence in women with multiple gestation, most likely related to increased placental mass and hormone production. Therefore, the woman and her family should be apprised of the symptomatology. Close observation of blood pressure measurement, weight gain, proteinuria, and edema in addition to development of headaches and scotomata must be carried out. The diagnosis and management of preeclampsia are discussed later in this chapter.

In multiple gestation, the physical discomforts of pregnancy are more extreme, body image may be even more distorted, preparations for baby care are multiplied, and finances may be more strapped. All of these factors pose additional stress, which requires the midwife to spend additional time in counseling and patient education. Midwifery management of multiple gestation can be very effective despite the increased risk for complications. Close rapport with the woman and her family, increased dietary counseling, and education regarding preterm labor and preeclampsia are critical to quality care of the multiple pregnancy.

Management also includes limiting activity and increasing rest periods throughout pregnancy. Bedrest has not been found to be an effective means to prevent preterm labor in multiple gestation. However, rest periods will become increasingly necessary and women should avoid exhaustion and long hours standing. Instruction regarding sexual activity should be based on cervical findings, previous obstetrical history, and strength of Braxton Hicks contractions. Advice may include the use of condoms because the prostaglandins in the semen can cause uterine irritability, or may extend to complete pelvic rest including avoidance of orgasm, based on individual findings.

Plans should be made for the physician to attend the birth. The midwife may have a key role in the vaginal birth of twins when the progress is normal. However, with twins, circumstances can change rapidly and the staff must be prepared to respond. In the event that the first twin is vertex, many physicians will proceed with a vaginal birth. Regardless of the second twin's position at the time of labor, once twin A is born, twin B can move freely in the vacated space and change position easily. Based on the resultant position of twin B, the physician's experience and preference, the baby may be delivered vaginally or by cesarean. If twin B

is vertex, a vaginal birth can be anticipated if the cervix remains dilated and allows the birth to proceed. If twin B is breech, some clinicians will allow the woman to give birth vaginally, either as a complete breech, or they may cause the fetus to become a double footling and guide the baby through a breech extraction. Other physicians will prefer to have a breech second twin, or a second twin who does not deliver quickly, to be born by cesarean. The decision-making is complex and must be in the hands of the physician.

Polyhydramnios (Hydramnios)

Polyhydramnios (hydramnios) is an excessive amount of amniotic fluid. Most polyhydramnios is of unknown etiology. The following conditions are likely to result in a higher incidence of polyhydramnios [41]:

1. Multiple pregnancy (especially with monozygotic twins)
2. Diabetes
3. Erythroblastosis
4. Fetal malformations (especially of the gastrointestinal tract—e.g., tracheoesophageal fistula—or central nervous system—e.g., anencephaly, meningomyelocele)

Polyhydramnios may produce the following additional complications [42]:

1. Preterm labor (due to overdistention of the uterus)
2. Maternal dyspnea and shortness of breath
3. Fetal malpresentations
4. Abruptio placentae
5. Cord prolapse
6. Uterine dysfunction during labor (due to overdistention of the uterus)
7. Immediate postpartum hemorrhage as a result of uterine atony from overdistention

The signs and symptoms of polyhydramnios include the following:

1. Uterine enlargement, abdominal girth, and fundal height far beyond that expected for gestational age
2. Tenseness of the uterine wall, making it difficult or impossible to auscultate fetal heart tones and to palpate the fetal outline and large and small parts
3. Elicitation of a uterine fluid thrill
4. Mechanical problems, if polyhydramnios is severe, such as dyspnea, lower extremity and vulvar edema; pressure pains in the back, abdomen, and thighs; heartburn, nausea, and vomiting
5. Frequent change in lie (unstable lie)

If the midwife suspects that a woman has polyhydramnios, the following workup should be done:

1. Obtain an ultrasound to confirm the diagnosis and identify any coexisting fetal or placental conditions or complications (see Chapter 23).
2. Screen for diabetes.
3. Screen for Rh alloimmunization.

When polyhydramnios is diagnosed, consultation with a consulting physician is indicated. The woman especially needs emotional support if congenital anomalies are present. Women with severe polyhydramnios have a number of mechanical difficulties and discomforts (listed above) for which the midwife can provide relief measures.

Oligohydramnios

Oligohydramnios is an abnormally small amount of amniotic fluid. The condition is frequently caused by uteroplacental insufficiency, which thereby means that a decreased fluid volume may be associated with a marked increase in perinatal mortality. The following conditions have a higher incidence of oligohydramnios [43]:

1. Congenital anomalies (e.g., renal agenesis, Potter's syndrome)
2. Viral diseases
3. Intrauterine growth restriction (IUGR)
4. Uteroplacental insufficiency
5. Early rupture of the fetal membranes (24 to 26 weeks)
6. Response to indocin as a tocolytic
7. Fetal hypoxia
8. Meconium-stained fluid and meconium aspiration
9. Postmaturity syndrome

The clinical signs and symptoms of oligohydramnios include the following:

1. "Molding" of the uterus around the fetus
2. A fetus that is easily outlined
3. A fetus that is not ballotable
4. Lagging fundal height

These clinical signs and symptoms are based on the fact that the amniotic fluid volume is below what is normally found for that particular gestational age. The amount of amniotic fluid is variable among women with normal pregnancies and may also fluctuate during the course of pregnancy. Generally speaking, amniotic fluid increases throughout pregnancy until it reaches around 1000 milliliters by the start of the third trimester, and then it gradually decreases, starting around 34 weeks' gestation, to about 800 milliliters by term. Amniotic fluid volume is measured by ultrasound and is a standard component of complete ultrasound examinations and the biophysical profile (see Chapter 23).

Oligohydramnios can be associated with multiple variable decelerations in the fetal heart rate, as reflected on a nonstress test [44]. The decelerations probably occur because less fluid "cushions" the cord, and fetal movement or uterine contractions may cause transient cord compression. Amnioinfusion has been shown to reduce the incidence of variable decelerations during labor.

Oligohydramnios is a significant finding suggestive of postmaturity syndrome in a postdate pregnancy. The combination of oligohydramnios and a fetus that has suffered intrauterine growth retardation increases the risk that the fetus will tolerate labor poorly and that operative delivery may be necessary.

Discussion with the consulting physician should include identification of the underlying etiology of the oligohydramnios and consideration of different management strategies based on etiology and gestational age. Conservative management includes bedrest, hydration, good nutrition, monitoring of fetal well-being (fetal movement counts, NSTs, biophysical profile, Doppler velocimetry), regular ultrasound measurement of amniotic fluid volume, amnioinfusion, and induction and delivery. (See Chapter 23 for detailed discussion of antepartum fetal assessment.)

Diabetes Mellitus

Diabetes is an increasing problem in the United States. The incidence continues to rise each year across ethnic and socioeconomic groups [45], although the incidence varies greatly by demographic groups. The CDC identified a 70 percent increase in the prevalence of diabetes in women between ages 30 and 39 and a 27 percent increased prevalence in women under the age of 45 between 1989 and 1996 [45]. Overweight, weight gain, and lack of physical activity are major risk factors for developing diabetes [45]. Clearly, these are considerations for all midwives when encouraging women to select healthy lifestyles. It is also a growing problem in women of childbearing age, and it must be screened for with all pregnant women.

Gestational diabetes mellitus (GDM) is defined as the presence of carbohydrate intolerance of varying degrees of severity with an onset or first recognition during pregnancy [46, 47]. The diagnosis of gestational diabetes is made regardless of the need for insulin or diet control or whether there is likelihood that the diabetes existed, but was yet undiagnosed, prior to pregnancy. Gestational diabetes is associated with an increased risk of both maternal and fetal complications both during pregnancy and potentially throughout life. The incidence of GDM in the United States varies between ethnic populations, but averages about 7 percent [47]. The prevalence of gestational diabetes is increased in women of Hispanic, African, Native American, South or Eastern Asian or Pacific Island ethnicity [46].

A pregnant woman with diabetes is classified according to when she was diagnosed with diabetes. If the diabetes antedated the pregnancy, the classification is *pregestational diabetes*; if she was first diagnosed with diabetes while pregnant, she has *gestational diabetes*. Pregestational diabetics, like all nonpregnant diabetics, are classified as either Type I or Type II. Type I diabetes is true insulin-dependent diabetes mellitus, typically develops prior to adolescence, and is therefore usually diagnosed prior to pregnancy. The White classification for pregnant women of Class B, C, D, F, and above is associated with pregestational diabetes [46]. All women who are pregestational diabetics, whether Type I or Type II, will require insulin during pregnancy and should have medical management. Pregnant women who have pregestational diabetes and who are on oral hypoglycemic agents will need to be placed on insulin. Oral hypoglycemic agents such as Tolbutamide (Diabenase) are possibly teratogenic and are associated with prolonged neonatal hypoglycemia. Research has shown some value in using glyburide orally during pregnancy but requires further research to extend this to general populations [46].

Type II diabetes is not necessarily insulin-dependent and usually begins when the individual is over age 40. Women with Type II diabetes are generally overweight and do not have the immune

markers of Type I diabetes. Because of its later onset, Type II diabetes is less common in pregnancy. Blood glucose levels in Type II diabetes mellitus can usually be controlled with diet, exercise, and oral hypoglycemic agents when women are not pregnant.

Physiology

Diabetes is caused by the absence or inadequate production of insulin, a hormone that is secreted by the beta cells in the islets of Langerhans within the pancreas. Insulin is responsible for transport of glucose into the cells. Cellular survival is dependent on this incoming glucose, which is then transformed into energy. In diabetes, there is no shortage of glucose in the blood, but it cannot be transported to the cellular level without an adequate supply of insulin, which results in hyperglycemia.

In classic Type I diabetes, there is an absence of insulin, thereby requiring the cells to metabolize fats and proteins for energy. Their breakdown forms ketones that are acidic, requiring mobilization of buffers for neutralization. Eventually, the acidosis overcomes the body, causing coma and eventually death.

In Type II diabetes, insulin is produced, but the cells are resistant to the insulin, requiring increasing amounts to be secreted. Eventually, the pancreas is not able to meet the increasing demand, and hyperglycemia results. Overwhelming ketosis is an uncommon problem with Type II diabetes.

Gestational diabetes is similar to Type II diabetes, in that there is insulin available. However, hormonal changes of pregnancy alter the body's receptivity to insulin. In early pregnancy (prior to 20 weeks) the cells are more responsive to insulin and circulating glucose levels may be lower than usual. This may be a reason for some women to experience nausea and vomiting when they have gone without food for a long period of time, such as through the night.

As the placenta grows, the production of pregnancy hormones, specifically human placental lactogen (HPL) increases. HPL increases cellular resistance to insulin, causing a diabetogenic state [46]. In most women, the pancreas is able to increase the supply of insulin to meet this increased demand. But when the pancreas is unable to produce adequate insulin, hyperglycemia results. The peak effect of HPL occurs around 26 to 28 weeks of pregnancy, the suggested timing for screening.

Hyperglycemia is responsible for many adverse effects during pregnancy. For Type I or Type II pregestational diabetics, in poor glycemic control during organogenesis, elevated glucose and ketone levels have been found to have teratogenic properties resulting in congenital anomalies such as cardiac defects, central nervous system defects, and caudal regression syndrome. Spontaneous abortion and stillbirth are also increased. The vasculopathy of Type I diabetes may cause decreased blood flow to the uterus and placenta, thereby increasing the incidence of uteroplacental insufficiency resulting in IUGR and its related complexities. Hypertension and preeclampsia are also found in greater numbers of diabetic women.

For gestational diabetics, whose early pregnancy blood sugars were most likely not elevated, the risk of congenital anomalies is the same as the general population. Instead, as the demand for insulin increases, hyperglycemia also increases. Insulin is a hormone very similar to human growth hormone (HGH). As maternal blood sugar elevates, it crosses the placenta to the fetus. The fetus does not have diabetes, but must increase its own production of insulin in order to metabolize the glucose. This response to elevated glucose and insulin levels causes a dramatic growth profile in the fetus resulting in a macrosomic infant [46]. Macrosomia is caused by hyperplasia, an increased number of cells, and hypertrophy, an enlargement of the infant's cells. Thus, this is a lifelong change for the fetus that has been shown to increase the likelihood of childhood and adult obesity as well as an increase in the risk for diabetes later in life [48]. Macrosomia is a known complication of the intrapartum period, placing the mother and fetus at increased risk for protracted labor, shoulder dystocia, and operative delivery.

For gestational diabetic mothers, there is an increased incidence of hypertension and preeclampsia complicating the intrapartum course. There is also an increased risk of Type II diabetes developing later in life.

Screening

Every pregnant woman should be screened for diabetes. The guidelines used here are from the American Diabetes Association [47], and the Fourth International Workshop-Conference on Gestational Diabetes [47]. Each midwife must be aware of the screening guidelines and the laboratory assessments that are used in their own clinical site. With all methods, the initial screening for gestational diabetes begins with the first visit and history taking.

For the subset of women who have no identifiable risk factors, the ADA suggests that no laboratory screening is indicated. This includes women who meet *all* of the following criteria:

1. Age <25 years
2. Weight normal before pregnancy
3. Member of an ethnic group of low prevalence of GDM (white American or Western European)
4. No known diabetes in first-degree relatives
5. No history of abnormal glucose tolerance
6. No history of poor obstetric outcome [47]

Conversely, if a fasting glucose is found to be >126 mg/dL or a nonfasting glucose sample is found to be > 200 mg/dL, then the diagnosis of gestational diabetes can be made without further screening tests [47]. For all other women, a stepwise screening process applies.

When high risk symptoms or historical factors exist at the initial prenatal visit, or become evident in a subsequent visit, a laboratory screening test should be performed at that time. The criteria for early screening are as follows:

1. Marked obesity
2. History of GDM in a prior pregnancy
3. Strong family history of diabetes (parents, siblings, grandparents)
4. Previous infant >4000 grams
5. History of previous unexplained stillbirth
6. Poor obstetrical history (e.g., spontaneous abortions, congenital anomalies)
7. Recurrent glycosuria (two positive tests) in clean-catch specimens, not explained by dietary intake. Glycosuria secondary to dietary intake illustrates the lowered renal threshold for glucose, which is a normal physiologic change during pregnancy.

The midwife should screen all pregnant women for whom there are no initial risk factors for diabetes mellitus between 26 and 28 weeks' gestation. In addition, all women who had risk factors and normal screening results early in pregnancy, should be rescreened between 26 and 28 weeks. If the screening test is normal, no further testing is needed unless new risk factors develop.

If secondary risk factors such as preeclampsia, polyhydramnios, or a large-for-gestational-age fetus are identified, rescreening when these risk factors are first noted should be considered.

Screening has become virtually standardized with the use of a glucose challenge test (GCT). The GCT is a random, nonfasting, oral 50-gram glucose load followed in one hour by a blood glucose draw. A glucose threshold of >140 mg/dL will successfully lead to diagnosis of 80 percent of women with carbohydrate intolerance consistent with gestational diabetes. A cut-off of >130 mg/dL will increase the yield to 90 percent. For those women who have a screening test result over the stated norm (>140 or >130 mg/dL), a 3-hour oral glucose tolerance test (OGTT) is the diagnostic study that must be done. The exception to this is that, if the screening GCT glucose value is > 200 mg/dL, then the diagnosis of GDM is made without further testing.

Procedure for an OGTT

1. Three days prior to the test, the daily intake of carbohydrate must exceed 150 grams, and physical activity should be unrestricted.
2. Perform the test in the morning after an 8 to 14-hour fast (except water).
3. Administer the glucose mixture—to be ingested within 10 min.
4. There should be no eating or drinking (other than water) and no moderate or vigorous exercise or smoking for the duration of the test.

Most laboratories have established their laboratory values on the basis of using 100 grams of the glucose solution for diagnosis in pregnancy. The criteria for normal values are based on work by O'Sullivan and Mahan, which has been modified by Carpenter and Coustan [47]. The upper limits of normal are listed in Table 24-16.

Management

The goal of management of GDM is to maintain a normal fasting blood sugar. Most women with gestational diabetes can control this condition with a combination of diet and exercise. The following is a summary of the American Diabetes Association's Clinical Practice Recommendations for Gestational Diabetes [47].

Every woman with GDM should have a visit with a nutritionist or a nurse or midwife with detailed knowledge of medical nutritional therapy (MNT). This visit must include careful explanation of the exchange food list and the caloric intake necessary to meet the maternal and fetal nutritional needs, but avoid fasting and postprandial hyperglycemia, as well as ketonemia [49, 51]. Controversy exists in the literature and between organizational guidelines regarding the ideal division of calories between carbohydrate, fat, and protein sources as well as the required overall daily caloric intake. The ADA suggests that nutrition requirements during preg-

TABLE 24-16 Diagnostic Criteria for Gestational Diabetes

3-hr, 100 g OGTT

Abnormal, or diagnostic for GDM: two or more of the following plasma glucose values are met or exceeded:

Fasting	95 mg/dl
1 hr	180 mg/dl
2 hr	155 mg/dl
3 hr	140 mg/dl

—OR—

2-hr, 75 g OGTT (an alternative diagnostic test)

Abnormal, or diagnostic for GDM: two or more of the following plasma glucose values are met or exceeded:

Fasting	95 mg/dl
1 hr	180 mg/dl
2 hr	155 mg/dl

—OR—

If the screening GCT glucose value is > 200 mg/dl, then the diagnosis of GDM is made without a 2- or 3-hr OGTT.

Note: When processing the serum samples, the vast majority of laboratories will spin the blood down and use the plasma for evaluation of the glucose levels. Therefore, the values used here reflect the norms for plasma. If the testing is done in an office setting using whole blood samples with a glucometer, the normative values should be approximately 15 percent lower than listed above for plasma samples.

Source: American Diabetes Association. Gestational diabetes mellitus. Clinical Practice Recommendations 2002: Position Statement. *Diabetes Care* 25 (suppl.), 1:S95 (January) 2002.

nancy and lactation are the same for women with or without diabetes [49].

Home glucose monitoring by finger stick is widely available and has been shown to be an adequate measure of glycemic control. If possible, every woman with diabetes in pregnancy should have and be instructed in the use of a home glucose monitor. Daily self-monitoring of blood glucose (SMBG) has been shown to be a better method of tracking blood sugar values than intermittent office monitoring of plasma glucose. If a glucometer is not available, or if the woman cannot handle doing SMBG, then monitoring in the office or laboratory is an acceptable alternative. It may be prudent to occasionally test a woman in the laboratory setting, particularly if she is not consistent with SMBG. The target blood glucose values for whole blood with a glucose monitor should be as follows:

Fasting	<95 mg/dl
1 hour postprandial	<140 mg/dl
2 hour postprandial	<120 mg/dl

If a laboratory sample is performed with plasma, the values should be as follows [47]:

Fasting	<105 mg/dl
1 hour postprandial	<155 mg/dl
2 hour postprandial	<130 mg/dl

There is no absolute agreement regarding the best times for testing women with diet-controlled GDM. Some feel that fasting values are the best predictors of overall glycemic control, while others prefer postprandial [46]. The most important factor is consistency. A common practice is to perform fasting and 2-hour postprandial samples once or twice a week, and, if normal, only use one sample the remaining days.

Urine glucose monitoring in GDM is not useful, as there is very poor correlation between blood glucose levels and urine glucose levels in pregnancy due to the lowered renal threshold for glucose. If there is concern about inadequate caloric intake, urine sampling for ketonuria may be helpful.

For the woman who is maintained with dietary therapy alone, daily self-testing should be started at the time of diagnosis. If there is difficulty with glycemic control, or an upward trend in the values, then daily testing should continue until labor begins. If, however, fasting and postprandial blood sugar levels are routinely maintained in the normal ranges, a woman with diet-controlled GDM, may decrease the frequency of testing to every other day or twice a week, as long as the values remain normal [46]. A record of the blood glucose values should be maintained and brought to each prenatal visit.

If a woman is unable to maintain her blood sugar values within these ranges on medical nutrition therapy (MNT), then she should have a physician consult to evaluate her need for insulin. A thorough history is needed to evaluate the adherence to the dietary plan, as well as to identify other factors such as illness or severe stress that may be causing difficulty in management of euglycemia (normal blood sugar).

Exercise is known to improve glucose metabolism. Mild to moderate exercise may be of benefit in both pregestational and gestational diabetes and has no adverse fetal effects [46]. Women should be encouraged to continue mild to moderate exercise, such as walking, but to avoid exercise while in the fasting state (e.g., before breakfast). Exercise when fasting increases the risk of hypoglycemia for insulin-dependent diabetics.

Women with diet-controlled GDM may be managed by the midwife with appropriate medical

consultation. In addition to close observation of blood glucose levels, the midwife will observe for macrosomia, polyhydramnios, and hypertension or preeclampsia, as these are common complications of GDM.

As in routine prenatal care, careful abdominal palpation should be performed at each prenatal visit. A fundal height measurement greater than dates may indicate macrosomia or polyhydramnios. Ultrasound examination is indicated in this situation for evaluation of both fetal size as well as an amniotic fluid index. If the scan shows normal growth and fluid volumes, then prenatal care should proceed routinely.

Management of polyhydramnios is discussed earlier in this chapter, and Chapter 25 covers management of the large for dates fetus. If the fetus is shown to be large for dates, or if there is an excessive amount of amniotic fluid, physician consultation is advised. In either case, repeat ultrasound will be recommended for accurate, ongoing evaluation. In addition, the woman should be kept informed of the testing results and implications.

Fetal movement counting may be initiated by 34 to 36 weeks for diet-controlled GDM. If fetal growth remains within a normal range, amniotic fluid volumes appear to be normal, there is no hypertension, and no history of unexplained stillborn, no specific antepartum testing is required prior to term. At 40 weeks, a biophysical profile should be performed twice weekly until delivery.

For the gestational diabetic with an apparently appropriately grown infant and no evidence of hypertension, it is advisable to await spontaneous labor [46]. If there is concern for macrosomia or preeclampsia, or if there is a history of term stillbirth, induction at 40 weeks should be considered. Any increase in maternal blood pressure or evidence of preeclampsia should be managed as they would be for any pregnant woman, and the physician should be notified of abnormal findings.

Management of labor in women with diet-controlled gestational diabetes is no different from management of labor for any other woman. If intravenous fluids are necessary, a glucose mixture should not be used. Since the incidence of macrosomia is higher among women with diabetes, the midwife should carefully evaluate the estimated fetal weight and progress of labor with a higher level of suspicion for shoulder dystocia. The pediatrician should be informed when the woman goes into labor. Some babies may develop hypoglycemia following birth, especially if they are macrosomic.

Once birth has occurred, placental hormones are no longer present, and the gestational diabetes is no longer an issue. No further glucose testing is needed in the immediate postpartum period. All women with the diagnosis should have a 2- or 3-hour OGTT after their 6-week postpartum visit to determine if the abnormal carbohydrate metabolism was strictly related to pregnancy hormones or if she is indeed diabetic.

A woman with a diagnosis of gestational diabetes in one pregnancy will usually develop gestational diabetes in another pregnancy. Therefore, early testing is indicated in subsequent pregnancies. It is prudent to advise women of this and to recommend that they initiate the ADA dietary guidelines early in the next pregnancy.

An abnormal glucose tolerance test in pregnancy may also be predictive of later nonpregnant glucose intolerance. Approximately 60 percent of these women may develop glucose intolerance later in life [46, 47]. Therefore, the midwife should inform the woman with gestational diabetes of this potential and encourage her to develop a healthy lifestyle in order to delay or avoid adult onset diabetes. This emphasis on healthy lifestyle choices is also important because the children of mothers with GDM are at increased risk for obesity, glucose intolerance, and diabetes in their late teens and early twenties [48].

Women with diabetes confirmed at the postpartum visit or interconceptionally should be encouraged to seek preconception counseling prior to future pregnancy, as should all pregestational diabetics [47, 50]. They should understand that risks of abortion and fetal anomaly are reduced if they enter pregnancy with their diabetes well under control [46, 51].

Rh(D) Isoimmunization

All human blood is designated by an ABO blood group. The majority of humans have an antigen against an erythrocyte surface antigen of the rhesus blood group system. Those who have the antigen are considered to be Rh(D)-positive. Those without the Rh factor are termed Rh(D)-negative. The Rh antigen is further categorized into a complex of antigens, C, D, E, c, e, with the D antigen being the one most frequently associated with serious hemolytic disease of the fetus and newborn [52]. It is the presence or absence of the D antigen that is

most important aspect of the categorization of the Rh factor and associated antigens. Thus the term "Rh(D)-positive" reflects the presence of the D antigen, with absence of a D antigen correlating with an Rh(D)-negative type. For the purpose of this text, the terms Rh(D)-positive or Rh(D)-negative will be used. The incidence of Rh(D)-negativity differs between ethnic groups. European Whites have an incidence of about 15 percent, American Blacks 5 to 8 percent, and Asians and Native Americans 1 to 2 percent [52, 53].

If a woman does not have antigens to the rhesus D antigen—if she is Rh(D)-negative—she will develop antibodies against the Rh factor if it is introduced into her blood. The times when this can occur are when a blood transfusion of Rh(D)-positive blood is given or if she is pregnant with an Rh(D)-positive fetus and there is a bleed of fetal blood into the maternal circulation. Because the maternal and fetal blood supplies are entirely separate, this is not always a problem for Rh(D)-negative women with an Rh(D)-positive fetus.

In order for Rh(D) isoimmunization to occur, the mother must be Rh(D)-negative and the fetus must be Rh(D)-positive. A sufficient quantity of fetal red blood cells must enter the maternal circulation. A quantity as small as 0.1 milliliters of Rh(D)-positive red blood cells has been shown to trigger sensitization of some women. In addition, the woman must have the immunogenic capacity to produce antibody to the D antigen [52]. The most common time of feto-maternal hemorrhage is at the time of birth (see Table 24-17).

When Rh(D)-positive cells are introduced in the serum of an Rh(D)-negative woman, she may develop anti-D antibodies. The transfer of fetal blood to the mother during one pregnancy can thereby stimulate development of antibodies that may cause fetal red blood cell hemolysis in a subsequent pregnancy. When the mother has anti-D antibodies, they can be transferred across the placenta to the fetal circulation. Destruction of fetal erythrocytes ensues, followed by severe fetal anemia, cardiac decompensation, and eventual hydrops and possible fetal or early neonatal death, dependent upon the severity of the reaction and effectiveness of treatment.

Prior to the use of Rh(D)-immune globulin (RhoGAM), erythroblastosis fetalis was more frequent, occurring in about 10 in 1000 births [53]. Since the early 1960s, the incidence of fetal or neonatal death has fallen to approximately 4 to 5 per 100,000 births [53]. This remarkable improvement in perinatal health is attributed to a combination of the use of RhoGAM, decrease in the size of families, and tremendous strides in interventions such as amniotic fluid spectrophotometry, cordocentesis, ultrasound imaging, intrauterine fetal transfusion, neonatal exchange transfusion, and improved neonatal and maternal care. Unfortunately, many of the current cases are the result of missed opportunities to use Rh(D)-immune globulin after first trimester pregnancy loss, procedures or trauma during pregnancy, or postpartum [54]. It is a strong reminder that this disease process can only be halted by steadfast adherence to the recommendations for use of Rh(D)-immune globulin.

Introduced in the 1960s, Rh(D)-immune globulin (RhoGAM) is a passively administered antibody that prevents active maternal isoimmunization. It is manufactured from human plasma. The processing and filtration, in addition to rigorous screening of donors, make the risk of transfer of viruses (e.g., HIV, hepatitis C) a theoretic risk that has not been demonstrated [55]. The RhoGAM should be given in a dose related to the amount of the fetal blood that has entered the maternal circulation. During the second and third trimester, the full 300 micrograms dose is given, which can cover up to 15 milliliters of fetal blood. Fewer than 1 percent of births will result in a feto-maternal hemorrhage greater than 15 milliliters. If a hemorrhage greater than 15 milliliters is suspected, the RhoGAM dosage should be adjusted to the rate of 20 micrograms/ milliliters of fetal blood. (See later discussion of relevant laboratory studies.) In early pregnancy, the risk of feto-maternal hemorrhage is markedly less than during later pregnancy, and the total volume of fetal blood is very small. Therefore, small doses of Rh immune globulin (MICRhoGAM) are used in the amount of 50 micrograms (see Table 24-17). Adverse reactions to Rh(D)-immune globulin are rare (1:60,000) and include formation of anti-D antibodies despite treatment, and localized reaction at the site of injection [55].

Clinical Considerations

At the first prenatal visit, both history and laboratory examinations are important for screening for Rh(D) incompatibility. It is imperative that women presenting to emergency clinics for threatened or spontaneous abortions and ectopic pregnancies be similarly screened. In addition, elective termination of pregnancy in the first or second trimester must also be considered at risk for feto-maternal hemorrhage. History that may be relevant to Rh incompatibility includes the following:

TABLE 24-17 Opportunities for Feto-Maternal Hemorrhage and Dose of Rh(D)-Immune Globulin

Cause of Feto-Maternal Hemorrhage	Dose of Rh(D)-Immune Globulin (RhoGAM)
First trimester	
Abortion (spontaneous or elective)	50 μg
Ectopic pregnancy	50 μg
Chorionic villus sampling	50 μg
Second trimester	
Ectopic pregnancy	300 μg
Amniocentesis	300 μg
Second or third trimester	
Blunt abdominal trauma	300 μg
Fetal death, stillbirth	300 μg
Fetal manipulation—e.g., external cephalic version	
Vaginal or cesarean birth	300 μg
Major hemorrhage—e.g., placental abruption, uterine rupture	20 μg/ml estimated fetal whole blood (refer to Kleihauer-Betke)

1. Previous blood transfusion
2. Previous baby needing a blood transfusion
3. Stillbirth or neonatal death resulting from causes unknown to the mother
4. Receiving RhoGAM after previous deliveries or abortions
5. Known Rh(D)-negative blood type

Determination of the mother's ABO type and Rh group is made through routine laboratory work ordered during the initial prenatal visit. If the Rh(D) is positive, no further evaluation is necessary. If the Rh(D) is negative, the results of the antibody screen will be critical to further management.

An antibody screen should also be performed routinely at the first visit for all women (regardless of Rh group) to screen for anti-D as well as other possible antibodies. If the antibody screen is positive, a titer will be done automatically by most labs. A normal antibody screen will be negative. If anti-D antibodies are present—a titer of greater than 1:4—the woman is considered to be Rh(D)-sensitized. Referral for medical management is indicated for any woman who is Rh(D)-sensitized and the fetus is determined to be Rh(D)-positive.

For the woman who is Rh(D)-negative, there is a high likelihood that the fetus will be Rh(D)-positive. Due to the pattern of genetic inheritance, the Rh(D)-negative trait is autosomal recessive. Therefore, both parents must contribute the gene for an Rh(D)-negative blood group for the child to be Rh(D)-negative. If either parent contributes an Rh(D)-positive gene, then the fetus will be Rh(D)-positive. Occasionally, a couple will present who are both Rh(D)-negative. In this case, if paternity is certain, the fetus will be Rh(D)-negative, and Rh-immune globulin is not required. The concern is that no one can be certain about the paternity except for the woman herself. In most cases, the father's blood type is not known, and the antepartum dosage of Rh(D)-immune globulin is given as a routine for Rh(D)-negative women. If, however, the couple wishes to have documentation of the father's Rh(D)-negative blood type and desire to avoid antepartum RhoGAM—understanding the potential risk—then this is an acceptable option.

When the blood type is Rh(D)-negative, Rh(D)-immune globulin is given prophylactically at approximately 28 weeks' gestation. This timing is selected in order to protect against sensitization to feto-maternal bleeds in the third trimester, and because the duration of action of a single dose of Rh(D)-immune globulin is 12 weeks, which means that the pregnancy is protected throughout the third trimester. If the pregnancy extends longer than 12 weeks after the dose of Rh(D)-immune globulin was given, another dose should be given. If a woman then gives birth within 3 weeks of the second dose, an additional dose should not be necessary. If birth occurs longer than 3 weeks later, an additional dose of RhoGAM is to be given if the baby is Rh(D)-positive [55].

There is controversy regarding the need for an antibody screen at the time of the 28-week antepartum Rh(D)-immune globulin. The screen is recommended by the American Association of Blood Banks, with the thought that sensitization that has occurred early in pregnancy would be detected. However, this is a rare event, especially in pregnancies that have not had an incident of trauma or a procedure performed (e.g., amniocentesis). It is now common practice to administer Rh(D)-immune globulin (300 mcg) without a simultaneous antibody screen. An antibody screen at 35 to 36 weeks is also not indicated.

If a blood sample is taken within the active time frame of the immunization (12 to 14 weeks)—for example, on admission in labor—there may be titers of anti-D present that indicate passive immunity as a result of the RhoGAM. These titers should be 1:8 or less by 38 to 40 weeks' gestation. Titers greater than 1:8 suggest that active immunization because of Rh incompatibility has occurred.

After the birth, the infant will have its ABO and Rh type done from the cord blood sample. If the baby is found to be Rh(D)-positive, then Rh(D)-immune globulin (300 mcg) should be administered to the mother within 72 hours of the birth. This 72-hour time frame is not absolute. It is important to administer the Rh(D)-immune globulin before the woman mounts an antibody response to the Rh(D)-positive fetal cells. In the event that the dose is inadvertently not given, it may be given at any time up to 28 days following the birth in an attempt to prevent sensitization. If typing of the infant is delayed, it is preferable to administer the RhoGAM prophylactically that to risk subsequent sensitization.

If the fetus is shown to be Rh(D)-positive, the mother should also be screened for excessive feto-maternal bleeding, which occurs in about 1 percent of births. Risk factors for excessive feto-maternal bleeding are cesarean section, multiple pregnancy, placenta previa, abruptio placentae, manual removal of the placenta, and intrauterine manipulation [52]. However, excessive feto-maternal hemorrhage is not limited to births where risk factors are present. When Rh(D)-immune studies are ordered postpartum, most labs will run an erythrocyte rosette test to identify excessive feto-maternal bleeding. In the event that this test is positive, a Kleihauer-Betke test must be done to quantify the fetal blood in maternal circulation. This then becomes the guide to dosage of Rh(D)-immune globulin at a dose of 1 μg/ml of fetal blood.

Screening for Other Antigens

The D antigen is the most commonly occurring and the most responsible for fetal hemolytic disease. However, there are many other antigens on the erythrocyte that are referred to as minor or atypical antibodies. The incidence of these antibodies varies among ethnic groups and is frequently the result of a previous incompatible blood transfusion. Most of these antibodies cause minimal if any impact during pregnancy. Those that can produce fetal hemolysis are anti-E, anti-Kell, anti-c, anti c+E, and anti-Fy^a (Duffy) [50]. These antibodies will be identified on the initial antibody screen. Consultation is suggested for management of these atypical antibodies.

Placenta Previa

Placenta previa is the malposition of the placenta in the lower uterine segment, either anteriorly or posteriorly, so that the fully developed placenta extends to the cervical os. In a complete or central placenta previa, the body of the placenta fills the lower uterine segment, entirely overlying the cervical os. In a partial placenta previa, the placental edge covers (totally or partially) the cervical os. A marginal previa will have the edge of the placenta near, but not actually over the internal cervical os (see Figure 24-4).

Placenta previa may be a serious cause of antepartal hemorrhage in the third trimester. It is

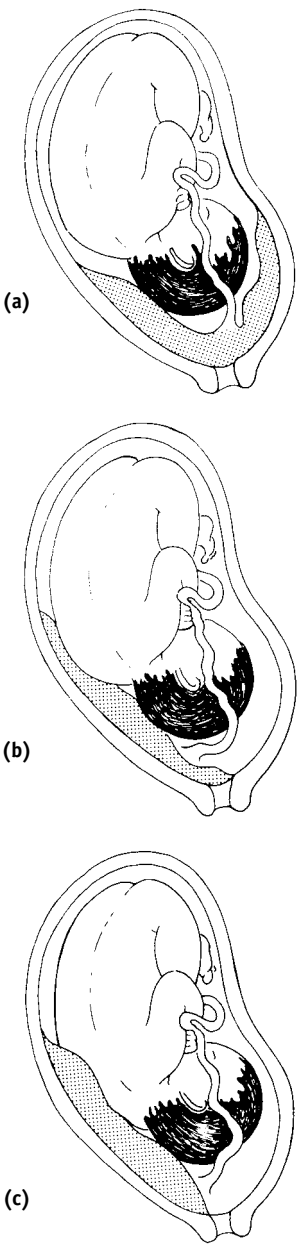

FIGURE 24-4 Placenta previa: (a) complete; (b) partial; (c) marginal.

more common in women with the following conditions [56–58]:

1. Multiparity
2. Maternal age greater than 35
3. Previous placenta previa
4. Previous uterine surgery, including cesarean section (risk increases with increased number of cesarean sections)
5. Multiple pregnancy (larger placenta)
6. Smoking (possible larger placenta)

The cardinal sign of placenta previa is painless vaginal bleeding with a sudden onset. It occurs during the third trimester and may be accompanied or precipitated by uterine irritability. A woman who is not in labor who experiences painless vaginal bleeding in the third trimester must be suspected of having placenta previa. Malpresentations (breech, transverse lie, floating head) are a common finding as the fetal head is prevented from entering the pelvis by the presence of the placenta in the lower uterine segment.

Placenta previa may be diagnosed by ultrasound prior to any symptomatology. If a sonogram demonstrates a low-lying placenta prior to 28 weeks, a repeat scan will be necessary in the third trimester to further document the position of the placenta in relationship to the cervix as the lower uterine segment grows in the last few weeks of pregnancy. It is common to see a placenta extending into the lower segment early in pregnancy. Most often, as the uterus grows, the distance between the cervix and the border of the placenta will increase. If the placenta remains encroaching over the cervix or if it is indeed a central placenta previa, then vaginal birth will be contraindicated.

If a woman presents with painless vaginal bleeding in the third trimester, it is imperative that the midwife not perform a vaginal examination until placental position is identified. Evaluation and stabilization of maternal and fetal status are the immediate goals of management. Reference to previous ultrasound reports may be useful and an emergent scan in the labor and delivery suite will be indicated. Only when a placenta previa is ruled out is it safe to perform a digital vaginal examination.

When placenta previa is diagnosed prior to any symptomatology, no intervention is necessary. The woman should be informed to call immediately with any evidence of vaginal bleeding. Ultrasound in the third trimester should be confirmatory if placenta previa is still present.

If a woman has bleeding associated with the placenta previa, management will be dictated by the gestational age, severity of bleeding, and fetal status [56–58]. When the dating criteria are certain, and the fetus is at 37 weeks or greater, cesarean section is indicated.

It is common for the woman to experience an episode of bleeding which then subsides. Close attention must be paid to the fetal response and maternal hemostasis. If there is unresolving fetal distress, delivery may be indicated. Usually, there is stabilization of the fetal heart rate patterns and the bleeding stops. Maternal intravenous hydration is indicated and tocolytics may be used as necessary. If maternal blood loss is significant, blood replacement may be required.

If the bleeding stops and the uterus remains quiet, the woman may be discharged to bedrest at home. It is necessary that she have 24-hour access to emergency transport to the hospital in case of bleeding. For some women, hospitalization with or without the use of tocolytics may be required until fetal maturity when a cesarean section can be performed [57, 58]. These women must observe pelvic rest; nothing should be inserted into the vagina (for example, vaginal therapeutics, douches, penis). In addition, the woman should be counseled to avoid orgasm, because orgasm results in uterine contractions that may exacerbate bleeding.

For women with a partial or marginal placenta previa, the degree of occlusion of the cervical os may depend on the degree of cervical dilatation. Therefore, if she presents in labor without uncontrollable bleeding, tamponade of the placenta by the fetal head may allow vaginal birth for some women.

Abruptio Placentae

Abruptio placentae is the premature separation of the normally implanted placenta (Figure 24-5). It can be a serious cause of antepartal hemorrhage in the third trimester. Hemorrhage may be concealed if the separation and bleeding are from an area central to the placenta, or it may be obvious if the separation or bleeding are at the borders of the placenta or cause a disruption of the edges of the placenta.

Specific etiological factors are unknown, but abruptio placentae is associated with the following conditions [56]:

1. Maternal hypertensive disorders
2. Advanced maternal age or parity

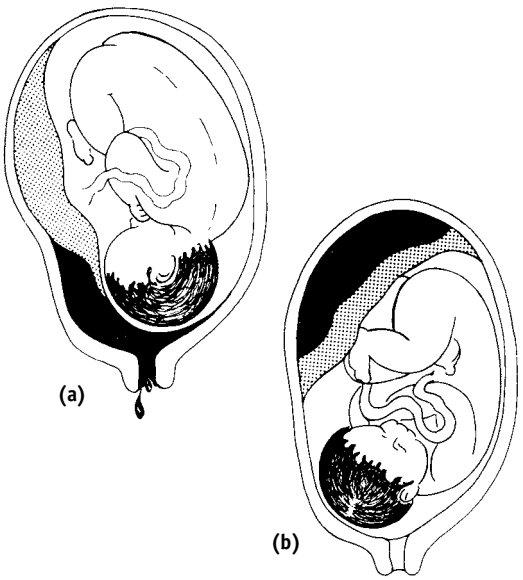

FIGURE 24-5 Abruptio placentae: (a) marginal separation with obvious bleeding; (b) central separation with concealed bleeding.

3. Maternal smoking
4. Poor maternal nutrition
5. Chorioamnionitis
6. Maternal blunt abdominal trauma
7. History of previous abruptio placentae
8. Sudden decrease in uterine volume or size (for example, with rupture of the membranes in polyhydramnios or between delivery of babies in multiple gestation)
9. External cephalic version
10. Cocaine, particularly crack cocaine, usage

The signs and symptoms of abruptio placentae depend on the degree of separation. They may be very mild, with generalized back pain and colicky, discoordinate uterine activity interspersed with relaxation of the uterus. Bleeding may be either concealed or obvious. It is common to mistake early signs of abruption as premature or false labor. The woman's perception of pain may be out of proportion to what the examiner feels; there may be increased uterine tone between what feel like contractions, and the woman may experience painful localized or generalized uterine tenderness. The classic hypertonic, boardlike uterus and uterine rigidity will usually occur only with a large abruption (Grade 2–3) [56], as shown in Table 24-18.

Other signs and symptoms vary according to the degree of separation. The fetal heart rate pattern may be normal with a small degree of abruption. A greater degree of separation will produce abnormal fetal heart rate tracings of variable or late decelerations, loss of beat-to-beat variability, or a sinusoidal pattern. Fetal movements may be decreased or absent for up to 12 hours prior to any obvious signs of an abruption. Other women may have violent fetal movement when there is a large abruption and massive hemorrhage. If a cesarean section is done within minutes of this occurrence, the baby may be born alive. Otherwise, fetal movement ceases.

Other signs and symptoms of a significant abruption include uterine enlargement (concealed hemorrhage only) and the signs and symptoms of maternal shock. The severity of maternal shock depends on the severity of the abruption. You should not make the mistake of thinking the blood loss from obvious bleeding is always the total actually lost, because there may be concomitant concealed hemorrhage. Uterine enlargement from concealed hemorrhage is measured by marking the abdomen at the level of the fundus, checking every 15 minutes for an increase, and remarking accordingly.

TABLE 24-18 Severity of Abruptio Placentae and Associated Clinical and Laboratory Signs

	Bleeding	Contraction	Fetal Heart Rate	Maternal Vital Signs	Labs
Grade 1	Slight	Uterine irritability	Normal	Unaffected	Normal
Grade 2	Mild to moderate external	Uterus irritable, tetanic or frequent contractions may be present	May show signs of compromise	↑ pulse, stable blood pressure	↓ Fibrinogen
Grade 3	Moderate to severe, but may be concealed (20%)	Tetanic contractions, painful, rigid abdomen	Fetal death	Hypotension	↓ Fibrinogen (<150 mg/dl) thrombocytopenia, factor depletion

Source: Adapted from Benedetti, J. J. Obstetric hemorrhage. In Gabbe, S. G., Niebyl, J. R., and Simpson, J. L. *Obstetrics: Normal and Problem Pregnancies*, 4th ed. New York: Churchill Livingstone, 2002, ch. 17.

Ultrasonography for a retroplacental clot will yield information only if the bleed is of significant size and in a position that can be easily identified. A negative finding on ultrasound does not preclude the diagnosis of an abruption. In most cases, ultrasound may be useful to identify or rule out a placenta previa as the source of bleeding. It is usually not of value in identifying a placental abruption.

The management for abruptio placentae is delivery. If the woman is stable and there is no evidence of deterioration in the fetal or maternal condition, delivery may be vaginal. Management includes rupture of the membranes, internal monitoring of the fetus, and pitocin induction or stimulation. In cases where the fetus is very immature and the maternal and fetal vital signs are stable, the use of tocolytics may be useful to maintain uterine quiescence for at least 48 hours [56, 57].

The diagnosis of abruptio placentae should be considered for any woman who presents with back pain and colicky uterine activity. If she has sustained known uterine trauma, such as a motor vehicle accident or been the victim of maternal battering, an observation period of up to 24 hours may be indicated. Cervical findings, fetal movement history, fetal heart rate pattern, vital signs, urine for proteinuria, and maternal vital signs should be obtained. Uterine activity should be monitored by fetal monitor, but should always be palpated by hand as well. Particularly in preterm pregnancies, the external uterine monitor is not a good evaluator of the intensity of uterine contractions. In addition, it is important to monitor the woman's response to the contractions in relationship to the actual tensing and relaxation of the uterus. If an abruption is occurring, it should become apparent during this period of observation.

Management of Hemorrhage Due to Placenta Previa or Abruptio Placentae

Particularly with an abruptio placentae, diagnosis of the source of hemorrhage may not be identified until the birth. Management of a woman who is hemorrhaging from either placenta previa or abruptio placentae is the same and consists of the following:

1. Call for help and request that your physician consultant be notified.
2. Start 5% dextrose in Ringer's lactate intravenously with a 16-gauge intracatheter.

TABLE 24-19 Rapid Fibrinogen Assay—Use in the Presence of Hemorrhage for a Rapid Assessment for Coagulation Defect

Draw a red top tube of whole blood.
Tape to the wall; note time of blood draw.
If a clot has not formed in 6 min, or if a clot forms and lyses within 30 min, the fibrinogen level is < 150 mg/dl.

3. When starting the IV, obtain blood for type and cross-match for four or more units, CBC, platelets, prothrombin, partial prothrombin, fibrinogen, and a tube for clotting time to hang on the wall (see Table 24-19).
4. Place the woman in Trendelenburg position.
5. Monitor the woman's vital signs (blood pressure, pulse).
6. Monitor the fetal heart tones (use an external monitor).
7. Administer oxygen to the woman.
8. Cover the woman with warm blankets.
9. Start a second IV. Two intravenous infusion routes are needed: one for electrolyte solutions and the other for blood transfusion. Keep the IV line for blood transfusion open until the blood is obtained.
10. Inform the mother and her partner of the emergency nature of treatment as well as possible need for cesarean birth, blood transfusion, and neonatal resuscitation.
11. Have the operating room set up for an emergency cesarean section.
12. Insert a Foley catheter to measure output and in preparation for possible surgery.

Hypertensive Disorders of Pregnancy

The most common medical disorder of pregnancy is hypertension. Presenting in one or more of several ways, the incidence ranges between 5 and 10 percent. Over the past several decades, the nomenclature as well as identified symptomatology, methods of diagnosis, and approach to management have changed. Meanwhile, voluminous research has yet to clearly identify etiology or definitive means of predicting or treating the hypertensive disorders. The National Institutes of Health, through the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy [59] has established some guidelines for definition and management that will be the reference for many aspects of the discussion in this chapter.

Not only are hypertensive disorders common in pregnancy, but they are responsible for significant maternal and fetal morbidity and mortality. Abruptio placentae, disseminated intravascular coagulation, cerebral hemorrhage, hepatic failure, and acute renal failure are all potential maternal complications. The fetus has the risk of IUGR, prematurity, and death.

Definitions [59]

1. Chronic hypertension
   a. Hypertension is considered chronic if it is observed before pregnancy or by the 20th week of gestation.
   b. Blood pressure is measured as >140 mm Hg systolic or >90 mm Hg diastolic.
   c. If hypertension is diagnosed during pregnancy but unresolved postpartum, it is also considered chronic hypertension.
2. Preeclampsia is a pregnancy-specific syndrome that usually occurs after 20 weeks (except with trophoblastic disease) and can be diagnosed by any of the following criteria:
   a. There is gestational blood pressure elevation (≥140 mm Hg systolic or ≥90 mm Hg diastolic) in a previously normotensive woman accompanied by proteinuria (≥0.3 grams protein in a 24-hour specimen or ≥30 mg/dL (≥1+ reading on dipstick).
   b. If gestational hypertension is present without proteinuria, preeclampsia should be highly suspected with increased gestation if accompanied by headache, blurred vision, abdominal pain, low platelets, or abnormal liver enzymes.
3. Severe preeclampsia
   a. blood pressure ≥160 mm Hg systolic or ≥ 110 mm Hg diastolic
   b. proteinuria of >2.0 grams in 24 hours (2+ or 3+ dipstick), occurring for the first time in pregnancy and regresses after delivery
   c. serum creatinine increased (>1.2 mg/dl unless known to be previously elevated)
   d. platelet count <100,000 cells/mm^3
   e. hepatic enzyme activity elevated (alanine aminotransferase, aspirate aminotransferase or both)
   f. neurologic symptoms: persistent headache, visual disturbances
   g. persistent epigastric pain
   h. oliguria ″400 milliliters in 24 hours
4. Eclampsia
   a. presence of seizure in addition to preeclampsia (if seizures cannot be attributed to another cause)
5. Gestational hypertension
   a. gestational blood pressure elevation (≥140 mm Hg systolic or ≥90 mm Hg diastolic) after 20 weeks (previously referred to as pregnancy-induced hypertension) without proteinuria or abnormal laboratory evaluation during pregnancy and which returns to normal by 12 weeks postpartum
   b. final determination of gestational hypertension versus preeclampsia made only in the postpartum period.
6. Preeclampsia superimposed on chronic hypertension
   a. commonly occurs with chronic hypertension
   b. worsens prognosis for mother and fetus
   c. any new evidence of proteinuria
   d. sudden increase in blood pressure when previously well controlled
   e. thrombocytopenia (>100,000 platelets)
   f. increase in hepatic enzymes
7. HELLP (Hemolysis-Elevated Liver enzymes-Low Platelets) syndrome
   a. controversy as to whether this is a separate syndrome from severe preeclampsia
   b. perinatal morbidity similar to severe preeclampsia

Two notable changes have been made from the classic guidelines regarding diagnosis of preeclampsia. Edema is no longer considered to be a part of the diagnostic trio for preeclampsia [59–61]. The presence of edema is normative during pregnancy for many women without any other evidence of preeclampsia. In addition, it is sometimes not present even in the face of abnormal liver or renal function. Therefore, the new guidelines consider preeclampsia a diagnosis of gestational hypertension and proteinuria.

The other change regards the definition of hypertension. In the past, this was defined using an elevation of 30 mm Hg systolic and/or 15 mm Hg diastolic rise over the registration baseline blood pressure. This definition has not proved to be linked with evidence in defining preeclampsia. Therefore, the definition of gestational hypertension has been newly stated as being ≥140 mm Hg systolic or ≥90 mm Hg diastolic after 20 weeks of pregnancy. However, the NIH Working Group recommends close observation of women with a blood pressure elevation of 30/15 especially if there is associated proteinuria or hyperuricemia [59].

The role of the midwife in relation to the hypertensive disorders of pregnancy lies in meticulous screening, in early identification, and in knowing

when to consult or collaborate with the physician. Preeclampsia can be a very serious disease for both mother and fetus. Therefore, maintaining a high index of suspicion and avoiding overnormalization of findings will assist in appropriate diagnosis.

It is important to differentiate chronic hypertension from preeclampsia. It is even more important to recognize when preeclampsia is superimposed on chronic hypertension. Chronic hypertension, by strict definition, either precedes pregnancy or occurs before the twentieth week of gestation. A chronically hypertensive woman may be receiving an antihypertensive drug. Her blood pressure should remain stable during pregnancy. If the blood pressure rises above what is normal for her or if she suddenly develops proteinuria, these should be recognized as signs of superimposed preeclampsia or renal disease and not as part of the course of chronic hypertension. Collaborative management of these women is indicated. A baseline set of liver and kidney function tests and a diabetes screen should be obtained on the initial visit. A careful ophthalmic examination adds to the database regarding the severity of this disease process. (See Chapter 7 for discussion of chronic hypertension in the nonpregnant woman.)

Prevention of preeclampsia is limited primarily due to an unknown etiology. In addition, screening tests have not been demonstrated to have accurate prediction in low-risk populations. Therefore, the most judicious approach is identification of women with risk factors or development of any symptomatology. Conditions associated with or that predispose a woman to the development of preeclampsia include the following:

1. Nulliparity
2. Trophoblastic disease (occurs in up to 70 percent of women with hydatidiform mole)
3. Multiple pregnancy, regardless of parity
4. Preexisting medical disease
   a. Chronic hypertension
   b. Chronic renal disease
   c. Pregestational diabetes mellitus
5. Family history of preeclampsia or eclampsia
6. Previous history of preeclampsia
7. Increased risk for multipara with a new sexual partner
8. African-American or Asian ethnicity

The signs and symptoms of preeclampsia form the basis of a routine history, physical, and laboratory screening that are done on each prenatal visit. If any signs or symptoms are positive, then follow up is necessary.

1. History
   a. persistent headaches unresponsive to usual remedies, careful history regarding the headaches and visual disturbances to rule out migraine headaches, need for glasses, and stress and tension in the woman's personal life
   b. dizziness, blurring of vision, spots before the eyes, or scotomata
   c. persistent epigastric pain
2. Physical examination
   a. blood pressure elevation ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic
   b. most accurate blood pressure taken
      (1) with an appropriate sized cuff (bladder covers more than 80 percent circumference of the arm)
      (2) patient sitting, or lying with left tilt, using right arm approximately at the level of the heart
      (3) after period of rest
      (4) best when two episodes are identified 4 to 6 hours apart
      (5) auscultated to hear last sound for diastolic pressure, not the diminishing sound (this is Korotkoff phase V)
   c. ophthalmic examination
      (1) papilledema
      (2) A-V nicking
      (3) vessel narrowing
      (4) hemorrhagic areas
3. Laboratory test
   a. urine for protein ≥ 1+ dipstick followed by 24-hour urine
   b. hemoglobin and hematocrit
   c. platelet count: if platelets <100,000 cells/mm^3, order coagulation labs
      (1) fibrinogen
      (2) fibrin split products
      (3) PT (prothrombin time)
      (4) PTT (partial prothrombin time)
   d. liver function tests
   e. renal function tests
      (1) 24-hour urine for total protein, creatinine clearance
      (2) serum creatinine
      (3) serum uric acid

As precise ranges vary from laboratory to laboratory, it is necessary to check the standard values for the laboratory from which you obtain test results. Table 24-20 provides an interpretation of laboratory findings in preeclampsia. You need to

TABLE 24-20 Interpretation of Laboratory Findings in Preeclampsia

Laboratory Test	Finding	Interpretation	Comment
Hemoglobin and hematocrit	Increased	Hemoconcentration	Fluid moves from intravascular to extracellular, causing edema
Platelet count	Decreased	Cause unknown	Falling platelets indicate progressive disease
		Reflects severity of preeclampsia	<100,000 platelets is severe disease
Serum uric acid	Increased	Decreased renal clearance	Serum uric acid increases as renal excretion of uric acid decreases
Blood urea nitrogen (BUN)	Normal	Mild preeclampsia	
	Increased	Decrease in renal blood flow and glomerular filtration rate indicates increasing severity of preeclampsia	Doubling of BUN represents 50 percent reduction in renal blood flow
Serum creatinine	Normal	Mild preeclampsia	
	Increased	Decrease in renal blood flow and glomerular filtration rate indicates increasing severity of preeclampsia	Doubling of serum creatinine represents 50 percent reduction in renal blood flow
Creatinine clearance	Decreased	May be normal in less severe preeclampsia; is decreased in severe preeclampsia	More useful measure than a single serum creatinine value
Liver function tests:	Elevated	Liver cell damage	Serious complication of preeclampsia is subcapsular hemorrhage in the liver
LDH (lactate dehydrogenase)		Indicates severe disease	
AST (SGOT)—serum glutamic oxalacetic transaminase			
ALT (SGPT)—serum glutamic pyruvic transaminase			
Coagulation profile:		Measures blood clotting ability; abnormal clotting function is indicative of severe disease	
Fibrinogen		Low	
Fibrin split products		Present	
PT—prothrombin time		Prolonged	
PPT—partial prothrombin time			
Urine protein (dipstick)	Increased	3+ and 4+ in severe disease	2+ indicates need for 24-hour collection
Urine protein (24-hr)	Increased protein	Renal compromise with increased permeability	300 mg in 24 hr, or 1 g/L in preeclampsia; 5 g/L in 24 hr in severe disease
	Decreased urine volume	Hypovolemia, hypoperfusion, renal compromise	Less than 400–500 mL in 24 hr in severe disease

discuss any abnormal values and an appropriate management plan with your consulting physician, even if hypertension is minimal or absent.

Preeclampsia is a disease that begins early in pregnancy and develops gradually, only demonstrating distinct symptomatology as the disease worsens. It is common to see subtle signs of preeclampsia prior to definitive diagnosis. In addition, all women do not necessarily have significantly elevated blood pressure. Although hypertension is a primary diagnostic symptom in preeclampsia, it is not present in all preeclamptic women and does not necessarily correlate with severity of disease [59–61].

Therefore, it is important to have a critical awareness when screening for symptoms. The woman may have mildly elevated blood pressure, or may develop edema of the hands and face that are not diagnostic but may indicate the sodium retention of preeclampsia and warrant close observation [59]. For women who are "tending toward" preeclampsia but do not meet the criteria for diagnosis, it is reasonable for the midwife to draw a panel of baseline lab studies (hemoglobin, hematocrit, platelets, LDH, AST, ALT). This baseline set of labs will be useful in making an early diagnosis of preeclampsia as well as determining the progression and severity of disease.

In addition to laboratory evaluation, the woman should be encouraged to decrease the stresses in her life and to increase rest periods. Fetal movement counting should be reinforced. If there is real suspicion of impending preeclampsia, more frequent office visits may also be encouraged. Increased fluid intake and a diet high in protein and with minimal excess sodium are healthy for all women and may help diminish symptomatology. Restriction of salt and the use of diuretics have no place in the management of impending or actual preeclampsia or eclampsia.

Management

When the diagnosis of preeclampsia is made or is strongly suspected, physician consultation is required. The only cure for preeclampsia is delivery. It is in the mother's best interest to facilitate delivery as soon as possible. However, gestational age may make this a life-threatening risk for the fetus. Therefore, management of preeclampsia is a balancing act between the best interests of mother and infant. If delivery is not indicated for fetal well-being, then the goal of treatment is to mediate maternal condition in order to allow for maturity of the fetus.

Evaluation of fetal well-being is done by assessment of fetal growth by ultrasound. As the pathophysiology of preeclampsia causes utero-placental insufficiency, the fetus is at risk for chronic hypoxia and IUGR. It is also at risk for acute episodes of hypoxia if the maternal condition is worsening or labile. Therefore, periodic biophysical profile scoring can be useful in assessing fetal status. (See Chapter 23 for discussion of fetal testing with maternal hypertensive disorders.)

If preeclampsia is mild and appears not to be taking a fulminate course, the woman may remain at home. This would include modified bedrest, home assessment of urine protein, and frequent office or home visits for assessment of blood pressure and other symptomatology. Women and their families must be educated in the signs and symptoms of worsening preeclampsia. In addition, the woman must be able to access medical attention 24 hours a day. Therefore, home care is dependent upon the availability of someone to bring her to the hospital. She must also be able to rest and carry out her own care at home. This means she cannot be primarily responsible for child care and care of the home environment. If this cannot be met at home, then hospitalization may be necessary.

If the woman's blood pressure continues to elevate, proteinuria progresses, laboratory studies indicate worsening disease, or fetal assessment testing is nonreassuring, hospitalization is required for management of the duration of the pregnancy. The decision to prolong pregnancy must be revisited daily, based on progression of maternal disease and fetal status.

Prior to birth, management focuses on bedrest, frequent assessment of maternal blood pressure, laboratory assessment of hematologic, renal, and hepatic function, and fetal well-being. In the presence of stability in all of these areas and the continued need for additional fetal maturity, close observation continues to be indicated. Magnesium sulfate is often used in order to prevent seizures in the preeclamptic woman. Dosages and monitoring of magnesium should be managed by the physician.

Table 24-21 lists indications for delivery based on maternal and fetal risk factors. The preferred route of delivery is vaginal in order to avoid the additional stresses and risk of surgery to mother and fetus. When the decision is made to progress to delivery, then aggressive induction of labor should

TABLE 24-21 Indications for Delivery in Preeclampsia

Maternal	Fetal
Gestational age > 38 weeks[a]	Severe fetal growth restriction
Platelet count < 100,000 cells/mm^3	Nonreassuring fetal testing
Progressive deterioration in hepatic function	Oligohydramnios
Progressive deterioration in renal function	
Suspected abruptio placentae	
Persistent severe headaches or visual changes	
Persistent severe epigastric pain, nausea, or vomiting	

[a] Delivery should be based on maternal and fetal conditions as well as on gestational age.

Source: National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. Report of National High Blood Pressure Education Program Working Group on high blood pressure in pregnancy. *Am. J. Obstet. Gynecol.* 183(1):S1–S22, 2000. Reprinted by permission.

ensue [59]. If vaginal birth cannot be accomplished in a reasonable period of time or is contraindicated for another reason, cesarean birth may be performed. Epidural anesthesia is the labor anesthetic of choice if needed for labor or cesarean birth. General anesthesia carries increased risks and should be avoided if possible.

Eclampsia

Eclampsia is diagnosed when preeclampsia progresses to convulsions. Eclamptic seizures are most common prior to delivery but may occur up to 10 days postpartum. Premonitory signs and symptoms—including headache, visual disturbances, epigastric or upper right quadrant pain, and restlessness—may alert the midwife to an impending seizure.

The following are the appropriate steps in emergency management of care of a woman with an eclamptic seizure:

1. Call for help; notify the physician to respond emergently.
2. Observe the seizure, but do not attempt to stop it. Eclamptic seizures will last 30 to 90 seconds, regardless of intervention. Observation is critical to assist with differential diagnosis of the seizure etiology. Eclamptic seizures are generalized tonic-clonic seizures. The seizure from an intracranial event, such as a ruptured aneurysm, may produce focal seizures—i.e., seizures affecting one side of the body only.
3. Prevent injury:
   a. Put up side rails.
   b. Turn the woman on her side to prevent aspiration.
   c. Do not attempt to restrain the woman except to keep her in bed; forced restraint could result in injury.
   d. Insert a soft airway or padded tongue blade early in the seizure, to prevent injury to the tongue; do not attempt to place the airway or tongue blade once the seizure is well established and the jaws are clenched. Avoid stimulation of a gag reflex.
4. Prepare to administer magnesium sulfate as soon as the seizure is over, or start immediately if the woman has a patent IV. Nothing will stop the current seizure. Magnesium sulfate is the drug of choice to prevent future seizures [59, 61].

Meanwhile, the woman must be carefully stabilized and evaluated as follows:

1. Clear the airway; suction thoroughly. Place a soft airway to maintain patent airway and facilitate suctioning until the woman is conscious.
2. Administer oxygen by facemask at 8 L/min—the woman had no respirations during the seizure.
3. Initiate or reestablish electronic fetal monitoring to evaluate fetal status. It is common for the fetus to display a bradycardia during the hypoxic phase of the seizure, then recover with a rebound tachycardia, and gradually return to preseizure baseline. A compromised fetus may be unable to tolerate the hypoxic episode, and you may observe signs of fetal compromise—i.e., sustained bradycardia, late decelerations, or sustained severe tachycardia.
4. Evaluate the woman's contractions and labor status. Uterine contractions usually increase in frequency and intensity for up to 15 minutes following a seizure. If the woman was in active labor when the seizure occurred, her labor may progress rapidly after the seizure as a result of the hypertonicity.
5. Examine the woman for injury.
6. Carefully document the course of events including timing, specific occurrences associated with the seizure, any interventions, maternal and fetal vital signs prior to and following the seizure, who was notified, and what follow-up actions were taken.
7. A woman with eclampsia is critically ill and will require intensive nursing care and medical

management to prevent further complications such as intracranial hemorrhage, pulmonary edema, renal damage, and detached retina. The decision to expedite delivery will be based primarily on maternal indications. The mother's condition must be stabilized before induction or cesarean section can be considered. When the woman is stable, fetal indications for delivery may be considered. Management of a woman with eclampsia must be by the obstetrician-gynecologist. Midwifery support may be very helpful to the woman and her family members.

Fetal Death

Pregnancy loss in the first half of pregnancy is considered to be a spontaneous or missed abortion. After the expected age of viability (22 to 24 weeks), it is classified as a fetal death. Signs and symptoms of fetal death include the following:

1. Cessation of uterine growth or decrease in uterine size—fundal height stationary or decreasing over time
2. Cessation of fetal movement
3. Cessation of fetal heart tones—i.e., FHT not heard with a Doptone; items 2 and 3 constitute the so-called silent uterus, which gives rise to an ominous feeling of fetal death
4. Cessation of maternal weight gain or decrease in weight
5. Retrogressive breast changes
6. Collapsed fetal skull felt upon examination
7. Sonographic signs
   a. no heart movement
   b. no fetal movement
   c. overriding skull bones; occurs several days after death as a result of liquefaction of the brain
8. Radiologic signs (x-ray ordered if ultrasonography is not available)
   a. Spalding's sign, overlapping of the skull bones
   b. exaggerated curvature of the fetal spine; occurs several days after death due to maceration of the spinous ligaments
   c. gas formation in the circulatory system of the fetus

The midwife consults with the physician when the possibility of fetal death is suspected. The decision to induce labor or wait for labor to occur spontaneously will depend on the woman and her partner's feelings and desire, the cervical status, and any medical issues that need to be addressed—for example, preeclampsia or disseminated intravascular coagulation (DIC).

Expectant management involves awaiting the onset of labor, which can be anticipated within 2 to 3 weeks of fetal death; onset of labor is thought to be due to cessation of placental functioning. The risk involved in expectant management is the potential development of DIC. Coagulation studies consisting of prothrombin, partial prothrombin, fibrinogen, and platelets are done every week to screen for DIC. If these tests remain within normal range, it is acceptable to continue to wait for spontaneous labor to begin. If there is a drop in platelets or fibrinogen, and/or an increase in the partial prothrombin or prothrombin, consultation with the physician is indicated for induction of labor.

Emotional support is extremely important antepartally, intrapartally, and during the postpartal course. The midwife should help the woman explore her own or other family members' feelings of guilt or ambivalence during the first trimester (see Chapter 21) and her beliefs about possible causes of the death. Information should be supplied to counteract "old wives' tales" concerning possible causes of the fetal death (e.g., falling down stairs, raising arms over head, lifting heavy object). The midwife may need to initiate this discussion in order to elicit specific beliefs held by the woman or family members or significant others.

Support during labor will be difficult if the midwife does not examine her own personal feelings and reactions to an intrauterine death. If you keep in mind that the woman is still giving birth to a child, then you will not be tempted to offer her drugs to block out the experience. The woman, the baby's father, and other supportive family members should be encouraged to view, touch, and hold the infant. This may be difficult for the woman to do for a variety of reasons, including drowsiness secondary to medication or emotional reasons. The option to view the baby should be kept open and arrangements made with the morgue to allow the woman, the baby's father, and the family to view the baby whenever and as often as the may need to. This reality orientation is an essential ingredient in facilitating the grief process.

You should avoid making a false diagnosis of the cause of death but should point out to the parents even the smallest deviations from normal, if any (e.g., nuchal cord, twisted cord). Most intrauterine deaths cannot be attributed to a known cause, even after autopsy. These are the most difficult for women to handle.

The midwife should assist the family in decisions regarding autopsy and burial. If an autopsy is performed, she should arrange to meet with the woman and significant others as soon as the preliminary results are available. They need to be informed that the final results usually take 6 weeks to 3 months.

The midwife must evaluate and assess her own value system and responses to death and grieving before she can begin to understand and assist a woman through the grief process. The first stage of grief manifests itself in extreme emotion. These emotions should not be denied or hampered with well-intentioned but inappropriate and often destructive platitudes (e.g., "It's all right, you can have another baby"; "It's God's will, just accept it"; "Aren't you fortunate to have other children?"). For a discussion of the grief process, see Chapter 42.

The determination of whether and when a woman (or couple) should have another child should be based on the resolution of the grief process and her (or their) ability to see a subsequent child as a separate individual, not a replacement. If another pregnancy occurs, the midwife will need to provide anticipatory guidance regarding the woman's fears of another disastrous outcome.

CHAPTER

25

Complications of Gestational Age Assessment and the Postdate Pregnancy

CAROL L. WOOD, CNM, EdD

Fetal Age Determination

Accurate assessment of gestational age is one of the most critical judgments a midwife makes during the course of a pregnancy. Incorrect estimation of the duration of a pregnancy can lead to inappropriate timing for screening, misinterpretation of data, unnecessary intervention, or a failure to intervene when indicated [1]. Gestational age at the time for birth is the single most valuable predictor of infant health, and timing of delivery is often determined by assessment of gestational age [2]. The midwife has the responsibility of obtaining all available data related to establishing an accurate gestational age as early in the pregnancy as feasible. In general, the opportunity for accurate assessment of gestational age decreases with the passage of time.

Terminology for fetal age is somewhat confusing as gestational age, menstrual age, fetal age, conceptual age, ovulatory age, months of pregnancy, and weeks of pregnancy are all used to refer to advancement of embryonic and fetal development. The tradition of timing pregnancy from the first day of the last menstrual period (LMP) is in wide use since more women are aware of when menses last began than when they ovulated or when conception occurred. Gestational age is typically 2 weeks longer than ovulatory age in a 28-day cycle, and will be the default method of referring to fetal age within this chapter. Some helpful term equivalencies for gestational age are offered in Table 25-1.

TABLE 25-1 Gestational Age Equivalencies

Term	Days	Weeks	Months
Menstrual age	280	40	10 lunar, 9 calendar
Gestational age	280	40	10 lunar, 9 calendar
Fetal age	280	40	10 lunar, 9 calendar
Conceptual age	266	38	9 lunar, 8 calendar
Ovulatory age	266	38	9 lunar, 8 calendar
Postdate	>294	>42	>10 lunar

At the first prenatal visit, the midwife collects data that will be the basis for assessment of gestational age. The database will also include information about factors that may be responsible for variation in fetal growth as the pregnancy progresses. Data to be collected at the first visit should include the following:

1. First day of LMP
2. Normalcy (duration, amount of flow) of LMP (last normal menstrual period)
3. Menstrual history (frequency, duration)
4. Contraceptive history (use or not)
5. Pregnancy test—when positive? Urine or blood? Home or office test?
6. Previous pregnancy history, when, size of infants, gestational age at birth, route of delivery, complications of birth
7. Maternal chronic medical illness (e.g., diabetes, lupus, sickle cell anemia, hypertension)

8. Lifestyle practices (e.g., smoking, drug, alcohol use)
9. History of eating disorder

The database for reliable assessment of gestational age should include one or more of the first five criteria listed in Table 25-2. Criteria for dating are listed in descending order of accuracy, with the more reliable (smaller margin of error) methods of dating pregnancy listed first. Criteria 6 and 7 are considered unreliable means of establishing gestational age. Each criterion for dating will be considered in further detail. When available, any written record of the dating criteria will help validate the client's memory. If pregnancy tests have been done in a laboratory elsewhere, written confirmation of results should be requested.

During the prenatal visit in which the estimated date of birth (EDB) is calculated, the midwife should stress that the date is an estimation that represents the midpoint in a 4-week range, that some variation is not only normal but expected, and that approximately one woman in ten will have a pregnancy that will continue more than 2 weeks beyond that estimate [1, 2, 6, 9, 10]. Reassure the woman that you will follow established protocols for safe management of the postdate pregnancy if that should become necessary.

Basal Body Temperature

A few women keep basal body temperature (BBT) and coital records, particularly when actively attempting to conceive. Such records can be helpful in calculating the EDB, but it is rare that women enter a prenatal setting with this information. Conversely, if the woman has not followed instructions carefully, the data may be misleading. Whenever possible, several months' records should be reviewed when considering historical information, so that cycle length and regularity can be accurately assessed. Carefully recorded BBT records in infertility studies have established that this is a highly reliable (± 2 to 5 days) method of diagnosing pregnancy in its earliest stages [3]. Additionally, BBT records can reveal the prolonged preovulatory phase associated with almost 70 percent of postdate pregnancies, as well as those pregnancies exceeding 280 postconception days, which would have been undiagnosed due to a shortened preovulatory phase [11, 12]. Very few women are motivated to take daily temperatures and record them, so while accurate, the use of BBT records to establish gestational age is not a practical recommendation for most women. An added disadvantage is that the recording of daily temperatures for this purpose would have to take place in anticipation of pregnancy, and the majority of pregnancies are not planned. (See Chapter 17 for full instructions for recording BBT.)

Ultrasound

Increasing use of ultrasound technology early in pregnancy has reduced the frequency with which the midwife will be caring for a woman without reliable dates. If a woman presents without a reliable menstrual history, or if a size/date discrepancy is noted on the first visit, ultrasound information can add objective data from which an EDB can be calculated [4, 7, 11, 12]. Reliability of ultrasound results will be dependent upon the gestational age at assessment, skill of the examiner, technology available, and position of the fetus. First trimester ultrasound estimates based on crown-rump length are accurate to within 3 to 5 days [4]. Second trimester ultrasound estimates of fetal age are based on combined measurements of the biparietal diameter, femur length, and abdominal circumference to give the most reliable estimate (± 7 to 10 days) [7]. When ultrasound studies are ordered, the midwife should assess the level of reliability determined by that facility—i.e., the margin of error at each gestational age. The clinician must make a judgment about reliability of ultrasound data in comparison

TABLE 25-2 Criteria and Range of Accuracy for Dating Pregnancy

Criteria	Range of Accuracy
Basal body temperature chart with coital record, ovulation, and temperature elevation, combined with previous menstrual record	± 2–5 days [3]
First trimester ultrasound	± 3–5 days [4]
Serum beta hCG <10,000, 2 values, 1 week apart, rising appropriately	± 3–5 days [5]
LMP that is certain, normal, regular, and consistent with a first trimester examination	± 1–2 weeks [6]
Second trimester ultrasound	± 1–2 weeks [7]
Third trimester ultrasound	± 2–3 weeks [7]
Physical examination after 20 weeks	± 2–3 weeks [8]

to objective or historical data, keeping in mind that as pregnancy progresses, all methods of dating pregnancy become less reliable. Variability in fetal size increases as term approaches, and after 26 weeks the 2- to 3-week margin of error reflects increased variation in fetal growth rather than accurate correlates of gestational age [7].

Controversy remains concerning the wisdom of obtaining routine ultrasound measurements for all pregnancies [4, 7, 11, 12, 14, 15]. Proponents of routine ultrasound argue that there would be fewer errors in estimating gestational age of pregnancy with reduction in consequent misjudgment (e.g., misdiagnosed postdate pregnancy with resultant unnecessary inductions), earlier diagnosis of fetal anomaly or multiple pregnancy, and earlier identification of conditions that warrant increased fetal or maternal surveillance (e.g., placenta previa, low fluid volume). Critics point out that research findings have failed to conclusively demonstrate improved outcomes in low-risk women who receive routine ultrasound screening. (See Chapter 23 for full discussion of routine ultrasound and indications.)

When a significant discrepancy exists between the size of the uterus at clinical examination and the size expected based on estimated gestational age, ultrasound imaging is indicated to clarify gestational age. In addition, ultrasound will assist in ruling out fetal anomalies, multiple pregnancy, early pregnancy loss, ectopic pregnancy, uterine fibroids, or other pathology [4, 7, 11, 12, 14, 15].

Human Chorionic Gonadotropin

Measurement of human chorionic gonadotropin (hCG) or a subunit is the basis of endocrine-based tests for pregnancy. Highly sensitive serum testing can detect elevated hCG levels within 1 to 2 days of implantation (8 or 9 days after ovulation), and peak levels are reached at 60 to 70 days (8 to 10 weeks). Serum hCG levels double every 1.4 to 2.0 days during early pregnancy and can be used to assess viability, intrauterine implantation, and gestational age, particularly when there are two values under 10,000, which rise appropriately [5]. Individual laboratories can provide clinicians with guidelines for interpretation of quantitative results.

Commercially available urine pregnancy tests can be highly reliable if used correctly and may be a valuable adjunct in the determination of gestational age. Theoretical effectiveness of home pregnancy tests is superior to testing with actual patients, however, and some reports indicate sensitivity as low as 75 percent. False-negative results are more likely if the test is performed prior to the first day of the expected menstrual period [5].

Last Menstrual Period

When the first day of the LMP is known, a calculation of the EDB is made using Naegele's rule. The prediction of a 40-week gestation (LMP plus 1 year, subtract 3 months, add 1 week) originated in the nineteenth century with Dr. Frederich Naegele. Naegele authored a German text published in 1812 that contained the advice to estimate that a pregnancy would terminate approximately 40 weeks (280 days) after the first day of the last menstrual period [15]. Although this theory is not based on any modern concept of research, it remains widely accepted today. Subsequent research has indicated that the mean gestational age (i.e., menstrual age) for spontaneous labor in primigravid women is 41 weeks from LMP (287 days), or 40 weeks 3 days (283 days) for the multiparous woman [6, 8, 16]. Estimates based on pooled data are consistent with this finding and suggest that the mean menstrual age for pregnancy is 283 to 284 days [6, 8–10, 16].

The use of the LMP in calculation of the EDB is somewhat reliable (with a 2-week margin of error) if the woman has had regular cycles, has recorded her menstrual history, and has not used oral contraceptives for at least 3 months prior to conception [2]. However, studies have indicated that many women do not record their menstrual history, and light flow referred to as spotting renders the LMP invalid [1, 2, 6]. All menstruating women should be encouraged to keep a record of menses, and midwives should routinely consider cycle length when calculating the EDB. For example, if the cycle length is 30 days, add 2 days to the calculated EDB. The disadvantage of basing the EDB on menstrual history is that it may be notoriously unreliable, and there may be considerable variability in preovulatory interval in any case. Errors in calculation of the EDB, which is based on history, are primarily the result of errors in the woman's recall [1, 2, 6]. The midwife must also be aware that a woman may inaccurately report the LMP as a result of her strong desire for conception to have taken place on a particular date. Information that is supplemental to the LMP, and helpful in validating the EDB, includes coital timing (inclusion or exclusion dates for exposure to conception), use (or not) of contraception (type, timing, consistency, etc.), and date(s), type, and result(s) of any home pregnancy testing that the patient has done prior to seeking prenatal care.

Less Reliable Methods of Dating Pregnancy

Careful review of the literature reveals that uterine size does correlate positively with gestational age, but fundal measurement is a much less reliable predictor of EDB than the LMP [8, 17–19]. Clinical assessment of uterine size may be affected by distension of the bladder (up to 7 cm), maternal build, retroversion or retroflexion of the uterus, presence of fibroids, uterine anomaly, length of the cervix, position and presentation of the fetus, location of the placenta, amniotic fluid volume, clinician experience, and missing or incorrect data concerning menstrual dates (as high as 43 percent) [1, 2, 6, 17–19]. There is a common tendency to assess the uterine size as "appropriate for dates" if the menstrual history is known [19]. The closest correlation of the fundal height (measured in centimeters) and gestational age (expressed in weeks from the LMP) is between 20 and 30 weeks, with a margin of error of up to 3 weeks [8]. Thus, if the midwife finds that the uterus measures 26 centimeters at 28 weeks, consistent fundal growth has occurred to date, *and there are no other indications that the woman or fetus is not adequately nourished*, the uterine size may be considered consistent with the gestational age.

Research aimed at standardizing methods for calculation of gestational age has discredited quickening and the 20-week landmark "uterus at the umbilicus," as both have an unacceptably high margin of error. The clinician's notation of first fetal heart tones whether by ultrasound or fetoscope, and the client's signs and symptoms of pregnancy are likewise poor predictors of gestational age with an unacceptably high margin of error [8].

The Size/Date Discrepancy: Identifying the Problem

Once the pregnancy has been dated with the most accurate data available, the EDB should not be changed. The clinical objective for the midwife shifts from assessment of gestational age to assessment of fetal growth. During the early part of pregnancy, there is a narrow range for the size of a normal fetus. However, as the pregnancy progresses, the range for normal size and growth patterns expands [4, 7, 14]. As we know, an infant may weigh 6 pounds or it may weigh 9 pounds, and still be perfectly normal. This wide range makes the assessment of adequate growth later in pregnancy more difficult. It is imperative that abnormalities in growth—either too little or too much—be identified and monitored appropriately in order to prevent or minimize complications for the fetus. It is also important that unnecessary intervention in normal pregnancy be kept to a minimum.

One of the most frequently encountered challenges in the care of the pregnant woman is the problem of the size/date discrepancy. Although the midwife is discouraged from rigidly equating weeks of gestation with the fundal height in centimeters, this is common practice in many settings and can lead to an overdiagnosis of the size/date discrepancy. Some latitude must be allowed for individual fetal variation, multiparity, and maternal build [8]. While there is no single standard uterine size at any given gestational age, there is certainly progressive uterine enlargement as gestational age advances. Progressive uterine growth is considered indirect evidence of fetal growth, and if inadequate or excessive uterine growth is noted there is reason for concern [19]. The midwife makes an assessment about whether the uterine size is consistent with gestational age at every prenatal visit, and if dates are known to be reliable there are fewer options to consider when the clinician asks which part of the inconsistent database is more likely to be misleading—the size or the dates.

When uterine size is assessed during a prenatal visit, it may be either smaller or larger than expected. The judgment that there is a discrepancy between what is expected and what is found may occur at any time during the pregnancy, and it is compounded by the lack of broad clinical agreement about appropriate uterine size at any particular gestational age. Clinical decisions will reflect the midwife's thought process in gathering further data and then exploring the options about the significance of that data. When considering the potential diagnosis of a size/date discrepancy, the midwife needs to review the initial database and then incorporate or obtain any of the following additional information as appropriate:

1. Ultrasound reports to date
2. Total weight gain
3. Current nutritional status
4. Fundal height and pattern of growth
5. Fundal height and pattern of growth with prior pregnancies
6. Evidence of gestational diabetes
7. Current polyhydramnios or oligohydramnios
8. Lifestyle conditions: stressful home or work situation, continued smoking, substance abuse

Variables such as these are associated with the infant's weight at birth, but they will vary widely from case to case and may be difficult to objectively quantify during the prenatal period. Prior obstetric history of an appropriate-for-gestational-age (AGA) infant in spite of a similar size/date discrepancy is decidedly reassuring. The midwife who has reliable dating criteria (see Table 25-1) for an uncomplicated pregnancy will ordinarily not need further information *for the purpose of establishing gestational age*. However, if an apparent discrepancy develops, more reliable information should be sought when possible in the effort to determine whether fetal growth is appropriate, or whether some other condition exists that the midwife should know about. For example, if menstrual history and bimanual exam were used as the database for initial establishment of the EDB in a pregnancy that subsequently has a discrepancy between size and dates, an ultrasound should be obtained at the first opportunity since the ultrasound is more reliable earlier in pregnancy [4]. The decision to obtain a prenatal ultrasound is influenced by the apparent gestational age at the time of the clinical encounter, and the significance assigned to ultrasound data is likewise dependent upon gestational age. For example, third trimester ultrasound data may indicate a smaller (or larger) fetus than expected, but the estimated date of delivery should not be changed in the last trimester of pregnancy.

There are many variations on combinations of subjective and objective information that can be used to date a pregnancy. The student may find it helpful to list all criteria used for establishing the EDB in the order of reliability, question the accuracy of data that do not predict an EDB that is consistent and seek more reliable data whenever possible. A primary goal for the midwife considering the size/date discrepancy is the anticipation of potential problems. An error in establishing the gestational age of a fetus can lead to errors in the interpretation of other data such as the triple screen (Chapter 23), inappropriate timing for screening (triple screen or glucose challenge test), and mismanagement based on inaccurate data (e.g., failure to appropriately manage a postdate fetus) [1].

Size Greater than Dates

Table 25-3 identifies some causes of size/date discrepancies in each trimester.

Appropriate management will be determined by the correct interpretation of data collected at each prenatal visit. Consultation or referral may be necessary as additional data are evaluated.

Management of a size/date discrepancy will be influenced by the estimate of gestational age at the time of diagnosis, as clinical implications will be quite different for each trimester (see Table 25-3). Because clinical implications for each of the possible explanations vary widely, the midwife who reaches the conclusion that the fundal height is not consistent with the estimated gestational age (i.e., discrepancy 3 centimeters or greater) has the responsibility to investigate further. When a size/date discrepancy occurs, sonographic evaluation of the fetus is the preferred method for assessing fetal growth, fetal anatomy, amniotic fluid volume, placental location, and uterine structure [12]. Ultrasonic findings permit the midwife to reliably assess the pregnancy. For example, if dating of the pregnancy is found to be in error, the adjustment is made in the chart and subsequent assessments are based on this new information. If an anomaly is identified, appropriate counseling and referral can be made. Similarly, if abnormalities such as uterine fibroids, placenta previa, multiple gestation, oligohydramnios, or polyhydramnios are found, consultation or referral must be based on clinical practice guidelines in the midwife's practice setting. (Refer to Chapter 24 for discussion of antepartal complications.)

If the ultrasound documents macrosomia, the midwife must reevaluate the woman's history for the following:

1. Diabetes screening results
2. History or family history of diabetes
3. Obesity, weight gain, nutritional status
4. Weights of previous infants
5. Previous birth routes and possible complications, especially shoulder dystocia, failure to progress, cesarean section.

Dependent on the gestational age at the time a discrepancy is noted, subsequent ultrasound scans for an estimated fetal weight may be done in 3 to 4 weeks and prior to labor. Screening for glucose intolerance and noting the pattern of weight gain, combined with knowledge of the client's family, medical, and obstetric history, will lead to identification of most women with glucose intolerance. Management of the patient with gestational diabetes or Type II diabetes should follow practice guidelines (see Chapter 24).

While dietary assessment and counseling are routine for all gravid women, additional evaluation of caloric and nutrient intake may be indicated for the pregnant woman whose uterine size is consistently larger than expected. Intensive ongoing nu-

TABLE 25-3 Causes of Apparent Size/Date Discrepancies

Trimester	Size Less Than Dates	Size Greater Than Dates
First	Inaccurate dates Missed abortion Ectopic pregnancy Maternal build	Inaccurate dates Inaccurate measurement Full bladder or bowel Multiple pregnancy Uterine fibroids Ovarian cysts Maternal build
Second	Inaccurate dates Inaccurate measurement Fetal anomaly (GU, renal agenesis) Chromosomal abnormality Placental pathology Oligohydramnios Fetal death Severe, early onset IUGR related to chronic maternal illness (i.e., diabetes, lupus, sickle cell anemia) Fetal infection (parvovirus, CMV, rubella, toxoplasmosis) Elevated MSAPF/hCG	Inaccurate dates Inaccurate measurement Multiple pregnancy Fetal anomaly (CNS, GI [tracheo-esophageal fistula]) Chromosomal abnormality Polyhydramnios Early macrosomia
Third	IUGR SGA—genetically small infant, normally grown Placental pathology (previa, abruption, infarction, circumvallate) Fetal death Oligohydramnios (may be covert ruptured membranes or maternal dehydration) Transverse or oblique lie Poor maternal weight gain	Macrosomia LGA—genetically large infant, normally grown Gestational diabetes Breech presentation Placenta previa Polyhydramnios Excessive maternal weight gain

tritional evaluation and counseling may be necessary, depending upon initial assessment and individual circumstance [13, 19, 20]. Management of the gravid woman with an established diagnosis of LGA will include consultation as well as anticipation of a macrosomic infant. Prophylactic cesarean section for the expected macrosomic infant is not recommended. If the EFW is 5000 grams or more, consideration of previous obstetric history, clinical pelvimetry, cervical Bishop score, station of the presenting part, and availability of cesarean section if needed, as well as the woman's preference, should be considered in planning for route of birth [1, 13, 20–25].

Size Smaller than Dates

There are a variety of considerations when the uterus seems to be smaller than gestational age would suggest, as shown in Table 25-3. In the first half of pregnancy, this is often attributed to inaccurate dating. However, in the second half of pregnancy, fetal growth problems are more likely to be present and may contribute to poor outcomes, especially if they are not identified [7].

As with the size greater than dates problem, continued management of the pregnancy when size lags behind dates will depend upon the correct interpretation of additional data. In most cases, an ultrasound scan will assist the midwife with appropriate anticipatory management. For example, if low station is responsible for an assessment of size behind dates, no intervention is needed. Another common situation is that of the genetically small but well-grown infant who is small for gestational age (SGA). If comparison of two sonogram studies shows the fetus to be within the normal range for size and for growth, then subsequent consistent fundal growth can be considered a reassuring indicator of appropriate fetal enlargement [8, 18–20].

If fetal size is determined to be significantly less than expected, appropriate management would include serial ultrasound scans, an attempt to deter-

mine the cause of the IUGR, and antepartal fetal testing (see Chapter 23). Although diminished fetal growth appears on a continuum of severity that becomes diagnostic of SGA at the tenth percentile, any undergrown fetus will benefit from excellent maternal nutrition as well as reduction in workload and stress. Nutritional assessment and counseling are critical, as is smoking cessation, or identification and appropriate management of other substance abuse. Excessive work hours or stress must be decreased to allow for adequate rest periods and caloric conservation. An ultrasound diagnosis of IUGR requires consultation with the physician. In most situations, collaborative midwifery management is appropriate.

Postdate Pregnancy: The Clinical Problem

Research and clinical discussions have been hampered by the lack of consistency in language. Various terms used to describe the pregnancy lasting beyond 42 weeks include prolonged pregnancy, postdate pregnancy, postterm pregnancy, and postmaturity. The postdate pregnancy, an antepartal condition, must be distinguished from postmaturity syndrome, which is a neonatal condition diagnosed after examination of the newborn. The standard definition of the postdate pregnancy is 294 days beyond the last menstrual period (LMP), or 280 days after ovulation/fertilization (refer to Table 25-1) [1, 2]. The term *postdate* will be used in this chapter, since it does not imply direct knowledge about duration of pregnancy or maturity of the fetus.

Accuracy in dating pregnancy has improved dramatically since the use of ultrasound for dating has become more common, and the reported incidence of pregnancies that carry beyond 42 weeks has fallen as a result [26–28]. The optimal range of variation for the length of human gestation is not yet known, and the selection of 2 weeks past the EDB for defining the postdate pregnancy is somewhat arbitrary. When pregnancy is carefully dated and menstrual and ultrasound assessments are consistent, the incidence of postdate pregnancy falls to 1 to 3 percent [9–12, 26–28]. In spite of the relatively low incidence of true prolonged pregnancy, several studies have shown that a large portion of inductions scheduled with the indication of postdate pregnancy were in fact less than 42 weeks by ultrasound scan dating [9–12]. In effect, these are elective inductions.

Criteria for the diagnosis of postdate pregnancy are met if labor does not occur within 2 weeks after the calculated EDB. Some authors have suggested that a pregnancy be considered prolonged at 41 weeks since some measures of neonatal morbidity and mortality increase after 40 to 41 weeks [10, 29–34]. However, approximately 18 percent of all pregnancies will continue beyond 41 weeks, and 7 to 11 percent will extend to 42 weeks, depending upon the population and the criteria used for dating [2, 6, 8–10]. Investigation of the incidence of true prolonged pregnancy—i.e., pregnancy that lasts more than 280 days beyond conception (or 294 days beyond the LMP)—remains at between 1 and 3 percent, while the remainder of pregnancies that extend at least 2 weeks beyond the calculated EDB are apparently misdated. Clearly, the more accurate the assignment of gestational age, the lower the likelihood that a pregnancy will extend beyond 42 weeks. Since it is not currently possible to accurately assign gestational age in the last trimester, the estimate of gestational age must take place as early in pregnancy as possible when an error in dating is less likely. When the EDB is established in the last trimester or based on unreliable data, the midwife should remain cautious about the reliability of the calculated due date.

Pooled data reveal that the risk of stillbirth rises with increasing gestational age after 40 weeks, a finding that has certainly contributed to the increasing popularity of induction of labor at term [10, 29–34]. The cause of the rise in incidence of stillbirth after 40 weeks' gestational age is not well understood, nor is there clinical agreement on the best management approach for prevention of these deaths [25–28, 30–32].

An area of agreement is that the risk for perinatal mortality is higher for IUGR or SGA infants than it is for AGA infants in the postdate period [29–34]. Clausson et al. determined that the odds ratios for perinatal death are not significantly different for AGA infants at term versus postterm; however, SGA infants had an odds ratio of 10.5 for stillbirth in the postterm period [35]. Therefore, accurate identification of the SGA or IUGR fetus in women who continue pregnancy beyond 42 weeks is important in minimizing risk and maximizing positive outcomes. Active management of the woman with a postdate pregnancy with an AGA fetus may in fact be counterproductive to desired outcomes, raising the rate of epidural anesthesia, cesarean delivery, and its attendant morbidity [28–38].

The increased risk associated with true postdate pregnancy is thought to be associated with uteroplacental insufficiency, which eventually leads to fetal hypoxia [38, 39]. An associated marker and risk factor for the postdate pregnancy is amniotic fluid volume, which drops significantly in the last few weeks of pregnancy [40]. The decline in amniotic fluid volume, probably related to diminishing placental function, is associated with cord compression, particularly during the intrapartum period [30, 40]. Low amniotic fluid volume is also associated with some cases of thick meconium stained fluid (i.e., less fluid to dilute meconium that is passed), and consequent problems in the neonate with meconium aspiration pneumonia [30–38]. There is an apparent loss of subcutaneous fat for some postdate fetuses, while others are more likely to have macrosomia [21–35]. Such dichotomous outcomes suggest multifactorial etiologies in the pregnancies that extend beyond 42 weeks.

Anatomy and Physiology of the Cervix

An understanding of the anatomy and physiology of the cervix will be helpful to the midwife contemplating more active management of the postdate pregnancy. The normal parturient cervix gradually softens, thins out, begins to dilate, and moves anteriorly as term approaches [41–44]. The multiparous cervix ripens more readily than the nulliparous cervix, and knowledge of parity is important in the interpretation of the cervical examination in late pregnancy [42]. Cervical ripeness is known to be associated with the probable route of delivery after labor ensues, and is therefore a valuable predictor to the midwife [41–44]. The need for an objective means to quantify cervical ripeness led to the development of what is now known as the Bishop score [43], and the original scoring system was refined to reflect the greater importance of cervical dilatation in the prediction of a vaginal delivery. The Bishop Scoring System (Table 25-4) evaluates cervical readiness for induction or need for preinduction cervical ripening. The Bishop score is the total of the scores for each factor, with a maximum score of 13 possible.

In contrast to the uterine body, which is primarily smooth muscle, the cervix is only 10–15 percent smooth muscle and the balance of the cervix is connective tissue [41]. Although the cervix is anatomically a part of the uterus, it has a highly specific function that is different from the rest of the uterus and that difference is evident histologically, anatomically, physiologically, and biochemically. In the case of childbirth, the cervix must change dramatically to allow expulsion of the fetus and placenta. While the uterine muscle is contracting and thickening during labor, the cervix is thinning and opening in response to the wedgelike effect of the presenting portion of the fetus, which is being driven toward the pelvic floor [41, 42]. Each contraction during labor shortens the uterine smooth muscle fiber, gradually reducing the volume of the uterus. If the smooth muscle fiber in the cervix responded in the same manner, the cervix would become tighter and smaller rather than looser and larger [44].

TABLE 25-4 The Bishop Scoring System

Point Value	0	1	2	3
Dilatation (cm)	0	1–2	3–4	>5
Effacement (%)	0–30	40–50	60–70	>80
Station	−3	−2	−1/0	+1/+2
Consistency	Firm	Medium	Soft	
Position	Posterior	Midposition	Anterior	

Source: Adapted from Bishop, E. H. Pelvic scoring for elective induction. *Obstet. Gynecol.* 24(2):267 (August) 1964.

Because the condition of the cervix is the best predictor of successful induction of labor, it has been hypothesized that ripening the cervix would increase the likelihood of a vaginal delivery [44]. In fact, the cervix that does not spontaneously ripen is not like the cervix that does; furthermore the palpable cervix is akin to "the tip of the iceberg" in comparison to the cervical and lower uterine tissue that is inaccessible to the examiner [62]. The timing of events leading to successful delivery is also an issue [41]. For instance, is it necessary or even better if the cervix becomes favorable prior to the onset of regular painful uterine contractions, or can outcomes be equally satisfactory if uterine contractions precede cervical change?

Circulating levels of oxytocin increase during labor and are released in a pulsatile fashion from the posterior pituitary [45]. Stimulation of the lower genital tract, cervix, and the breast also leads to oxytocin release and sensitivity of the uterine muscle to circulating levels of oxytocin increases toward term [44–49]. After the onset of labor, sensitivity of oxytocin receptors increases until the end of second stage, then decreases. This is consistent with the finding that higher doses of oxytocin are

required to induce labor than to augment labor. Thus, the effect of a specific dose of oxytocin will vary according to the sensitivity of receptors in the myometrium and decidua [44–46]. Oxytocin acts directly on uterine action through its effect on the oxytocin receptors in the uterus, and indirectly through its action in stimulating the release of prostaglandin from the decidua, which then encourages more uterine contraction—a spiraling effect that is necessary for successful vaginal delivery. The cervix has relatively few oxytocin receptors, which may explain why the unripe cervix is such an obstacle to induction of labor with standard oxytocin induction protocols [41, 44, 45]. As a consideration in the active management of postdate pregnancy, induction of labor will be addressed in the next section of this chapter.

Management Approach for the Postdate Pregnancy: Anticipatory Versus Active

The two principal schools of thought are (1) anticipatory management—anticipation of fetal well-being with increased assessment and intervention only when indicated and (2) active management—induction of labor for all women who reach 42+ weeks. Either approach may be favored by the woman or by the midwife, and clinical practice guidelines for the postdate pregnancy should be reviewed with women and their families in the effort to reach consensus and prevent any misunderstanding.

Many variations on anticipatory and active management are possible, and they include consideration of cervical readiness (Bishop score), estimated fetal weight (by Leopold's maneuvers, sonogram, or both), fetal well-being, preference of the woman, amniotic fluid volume, prior obstetric history, maternal medical status, and method of induction under consideration. A heavily weighted variable is the gestational age of the fetus, with an increasing trend toward consideration of gestational age as a continuum rather than the discrete and mutually exclusive categories of "preterm, term, and postterm" [50–53]. Active versus anticipatory management of the postdate pregnancy will also be dependent upon reliability of the criteria used for assignment of gestational age.

Clinicians have long recognized the need to effect birth when serious medical and obstetric conditions threaten either the mother or the fetus. Prior to the development of acceptable methods for inducing labor, cesarean section was the only recourse in such cases. However, there are risks associated with the induction of labor as well as risks associated with prolonged pregnancy. The decision to initiate labor, or not, must always be made as a comparison of risks to benefits with either management decision. In general, methods of induction that are most effective in leading to active labor are those associated with increased frequency of fetal heart rate changes and uterine hyperstimulation [50–56]. Further information about each of the methods for induction of labor is summarized below.

The question remains as to the appropriate role for induction of labor with the postdate pregnancy. While there is considerable consensus on the necessity of induction for selected obstetric and medical complications, the decision to induce labor in the uncomplicated postdate pregnancy carries potential for harm [50–56]. Induction of labor is associated with an increase in epidural anesthesia and cesarean delivery for the primigravid woman beyond 41 weeks whose infant's birth weight is 3800 grams or greater [52], and the primigravid with an unripe cervix (Bishop score at or below 5) who is electively induced has a cesarean delivery rate as high as 50 percent [50–56].

When reliable dating information is not available, less reliable criteria for dating pregnancy must necessarily be considered in the assignment of gestational age. However, the clinician's decision to actively intervene is difficult to justify on the basis of an unreliable database. Assessment and evaluation of fetal and maternal well-being would be a more prudent course in the event of a pregnancy dated with unreliable or missing menstrual dates (e.g., breastfeeding, spotting), last trimester ultrasound, quickening, or uterine size. Evidence of compromise to fetal well-being may encourage the decision to effect birth, but such a decision should be tempered with reasonable caution about fetal maturity.

An unripe cervix (Bishop score less than 6) is more strongly associated with cesarean section in the primigravida than the multipara [50–56]. Cost remains an unresolved issue for many, and debate continues as to whether the cost of induction exceeds the cost of additional monitoring in the pregnancy that exceeds term [57–59]. Meta-analysis of clinical trials suggests that a minimum of 500 inductions would be needed to reveal any improvement in perinatal mortality, suggesting that clinically significant outcomes for induction of

labor versus anticipatory management in the postdate pregnancy are sufficiently small as to make either choice reasonable [1, 26–28, 50–56].

Before initiation of any management plan, women and their families or support persons need to understand the risks and benefits of cautious observation of normal processes and of intervention. It is important to review dating accuracy so that they realize that the baby is most likely not actually "late," but this ambiguity is the result of not being able to determine absolute dating of the pregnancy. They also must understand that induction of labor is not as easy as it may sound or as it looks on television. That, in fact, there is no magic bullet or potion that will necessarily lead to a normal labor and subsequent vaginal birth. The fact that medical induction of labor carries with it an increased risk of fetal distress, cesarean section, infection, and hemorrhage is a great surprise to most laypersons. The midwife has the responsibility to inform women of their risks, and to document the discussion in the chart. Conversely, women should also know that truly prolonged pregnancies have an increased incidence of stillbirth, meconium-stained fluid, neonatal meconium aspiration syndrome, shoulder dystocia when the fetus is macrosomic [59–61], and fetal distress if the fetus is small for gestational age [35].

Each midwife must know the practice guidelines in the clinical setting and be able to interpret these to women in their care. It is important to know the obstetric and medical indications for induction and to explain to women that induction of labor without indication is poor practice. By 40 weeks of pregnancy, most women are tired and uncomfortable. They have difficulty sleeping and waiting becomes burdensome emotionally to the whole family. These are indicators for support, not for induction of labor. Indications for induction of labor include but are not limited to the following:

1. Nonreassuring fetal testing (low biophysical profile score; see Chapter 23)
2. Oligohydramnios
3. Worsening preeclampsia at term
4. Insulin-dependent diabetes
5. IUGR at term
6. History of a previous term stillbirth

In addition, there are some circumstances in which the convenience of induction may equate to safer care. An example would be the woman with a history of very rapid labors who presents at 40 weeks, completely effaced and 4 centimeters dilated, without labor. In order to avoid a precipitous labor away from supportive care, induction may be a reasonable choice [62]. However, scheduling induction of labor as a result of a busy office schedule or to have the baby on someone's birthday is clearly elective, and introduces unnecessary risk.

Table 25-5 offers a plan for anticipatory management of the uncomplicated pregnancy between 40 and 42 weeks; all items should be actively reviewed with the pregnant woman at each prenatal visit beginning at 40 weeks. (Refer to Chapter 23 for a review of antepartal fetal assessment methods to be initiated for care of the postdate pregnancy.)

Anticipatory management for the postdate pregnancy may appropriately begin at term since approximately one in five pregnancies at 40 weeks will continue for at least another week. An important factor for the midwife to consider is the reliability of the estimated date of birth; the less reliable the EDB is, the more cautious the midwife should be with active intervention. Midwives should also be informed concerning local laws and regulations regarding their scope of practice, consistency with their own practice guidelines, and awareness of the local community's standard of care for the postdate pregnancy. In addition, management decisions should be mutually agreeable to the woman, midwife, and physician consultant, and this should be well documented. When women are well informed about treatment options for management of postdates pregnancy and can make a well-informed

TABLE 25-5 Anticipatory Management of a Woman with a Pregnancy Between 40 and 42 Weeks

1. Review EDB with woman as the midpoint in a 4-week range (40+ weeks).
2. Review postdate management plan with woman; carefully document mutual acceptance of the plan (40+ weeks).
3. Initiate nonstress test (NST) twice weekly, starting by 41 weeks, continuing until birth.
4. Initiate amniotic fluid volume (AFV) twice weekly, starting by 41 weeks, continuing until birth.
5. Initiate full biophysical profile and consult with a physician for nonreactive NST or low AFV.
6. Consult with a physician (providing documentation) for any pregnancy reaching 42 weeks.
7. If the pregnancy continues to 42 weeks and dates are reliable (see Table 25-2, items 1–5), begin active management per protocol.

choice, and fetal well-being is assured, it is reasonable to continue anticipatory management until 42 weeks or until there is an indication for delivery. The woman's preference for management after term has been reached should be a heavily weighted and well-documented variable in management decisions, as should fetal well-being.

A note of caution concerning suggested guidelines for management of the pregnancy exceeding 42 weeks is to keep in mind the poor quality of research supporting postdate pregnancy protocols. Evidence-based practice has no clear guidelines for the management of pregnancy after term has been reached. Multi-institutional, prospective, controlled clinical trials with double-blind random assignment to treatment or control group have simply not been done, and the barriers to such research are probably insurmountable. Clinical trials are flawed by patient (and provider) self-selection to group, lack of control regarding specific measurement of each variable, and lack of clinical consensus on appropriate outcome measures. Several authors quantify the patient's self-selection bias, ranging from 20 to 34 percent, and others have addressed the impact of women's requests for the induction of labor [61–66]. Differences in regional management protocols, changes in pharmaceutical recommendations, and technology for fetal assessment have changed so rapidly that multicenter clinical trials only a few years old are not readily generalizable to current debates.

Analysis of clinical trials reveals that while there is no clear evidence that antepartum assessment (e.g., NST) reduces the incidence of morbidity and mortality in the postdate pregnancy, retrospective data analysis indicates a lower risk of morbidity for monitored women [60, 61, 67, 68]. It is not clear whether factors other than the gestational age were associated with the additional risk, but the fact remains that the NST is now firmly integrated into the care of women who are considered postdates [67–69]. Finally, the vast majority of research on induction of labor addresses comparison of one method to another rather than the underlying question of whether induction of labor at any particular gestational age improves outcomes for either mother or infant.

Active Management of the Postdate Pregnancy: Induction of Labor

In the 1970s there was a growing awareness of increased perinatal mortality with advanced gestational age. This awareness quickly led to the hypothesis that reduction of the incidence of postdate pregnancy would improve outcomes. Some have objected to induction on the basis that induction of labor is unnecessary and unnatural, and potentially harmful. The lack of credible evidence-based criteria for induction of labor in the uncomplicated postdate pregnancy has led to localized management patterns that do not necessarily minimize risk or maximize the utilization of available resources for the care of women and infants. In spite of the arguments against induction of labor and the lack of standardized criteria, the practice of induction has increased markedly over the past decade [1, 11, 26–28, 36, 37].

According to the American College of Obstetricians and Gynecologists, the desired result of induction of labor is "to achieve vaginal delivery by stimulating uterine contractions before the spontaneous onset of labor" [69]. Although the methods for induction of labor are primarily directed at initiating uterine contractions, there is increasing recognition that cervical change plays an important role that is not entirely mediated by uterine activity. Pharmacologic initiation of labor has centered on the use of oxytocin since the 1960s [70] and prostaglandin compounds since the 1970s [49, 62]. Table 25-6 presents a summary of hormonal methods for induction of labor; nonhormonal methods of inducing labor are listed separately later in this

TABLE 25-6 Hormonal Methods for Induction of Labor

1. Oxytocin (Pitocin) administered intravenously (FDA approved for induction of labor)
2. Prostaglandins
   a. Misoprostol
      (1) Brand name Cytotec: A synthetic PGE1 analogue tablet administered intravaginally (FDA approved for peptic ulcer prevention, *not induction*)
   b. Dinoprostone
      (1) Brand name Cervidil: A synthetic PGE2 preparation available as controlled release 10-mg vaginal insert (FDA approved for induction of labor in 1995)
      (2) Brand name Prepidil: A synthetic PGE2 preparation available in 0.5-mg gel form and administered intracervically (FDA approved for induction of labor in 1993)
3. Mifepristone (RU 486, a progesterone receptor antagonist) (FDA approved as a first trimester abortifacient, *not induction*) available in 200 mg tablet to be taken orally

chapter in Table 25-7. Dosing, route, and timing of administration for all methods are still being actively researched; specific recommendations are given in the text if research supports them.

In terms of effecting safe birth, successful induction of labor after cervical ripening with prostaglandin E2 (PGE2) may take place with oxytocin, and prostaglandins have proved to be more effective as a cervical ripening agent than oxytocin. Other methods of inducing labor (e.g., castor oil, breast stimulation, mechanical stretching of the cervix) have highly variable rates of success and/or little research to guide recommendations.

Oxytocin Oxytocin is the most commonly administered intrapartal medication [45]. Discovery of its pharmacologic actions in 1906 led to research that has demonstrated usefulness in reducing uterine atony after cesarean or vaginal delivery and initiating or augmenting uterine contractions [46, 70]. Appropriate use of oxytocin has significantly reduced maternal and fetal mortality. However, inappropriate use of oxytocin has resulted in grave maternal and fetal consequences, spurring the development of protocols to guide clinicians with judicious use [69].

Use of the standard oxytocin protocol with the parturient who has an unripe cervix is unsuccessful in leading to a vaginal delivery in approximately one-half of the women who are induced by this method [50, 54–56]. The most serious limitation in using oxytocin for induction of labor is in fact for the woman with an unfavorable cervix. The problems known to be associated with labor induction for these woman have led to the suggestion that a very low dose oxytocin infusion (0.5 mu/min, doubled every 40 to 60 min to a maximum of 2–4 mu/min) over 12 to 18 hours can be used for ripening the unfavorable cervix, prior to the initiation of the protocol used for induction of labor [45, 46, 51, 52, 69]. Such infusions should necessarily be done only in cases when warranted, via continuous or pulsatile intravenous infusion piggybacked to an appropriate fluid, and with appropriate monitoring of maternal and fetal status.

Oxytocin induction of labor for the woman whose cervical Bishop score is 6 or greater may begin with an initial dose of 2 mu/min, which is increased in increments of 1–2 mu/min at 30-minute intervals. Dosages, intervals for increase, and duration of administration of pitocin for the induction of labor are still actively debated, and should probably vary according to gestational age, parity and cervical score, and response to the dosage of pitocin. Individual clinical settings will have a wide range of oxytocin protocols to which they adhere. Each midwife must be familiar with these protocols if managing an induction of labor. When oxytocin is used for induction of labor after the cervix is ripe, 30-minute incremental increases are found to be associated with fewer instances of fetal distress and a lower cesarean delivery rate than a 15-minute interval, although labors are longer [71].

The fact that the cervix has relatively few oxytocin receptors may explain why the unripe cervix is such an obstacle to induction of labor with standard oxytocin induction protocols [41, 44]. Many clinicians prefer to prepare the unripe cervix with administration of prostaglandin rather than intravenous oxytocin. Studies have shown that preparation of the unripe cervix with a prostaglandin gel or suppository can safely and effectively reduce the rate of failed induction and subsequent cesarean section [71–73]. The use of oxytocin as a means of ripening the cervix follows a different protocol than oxytocin used as a labor stimulant [69].

Prostaglandins The high failure rate of oxytocin induction for women with a long closed cervix led to renewed efforts to find ways to ripen the cervix prior to induction efforts [66, 69, 71]. Intravenous administration of prostaglandins was investigated during the 1960s but sometimes severe side effects associated with systemic use led to trials with oral or local administration [71]. A meta-analysis of studies examining the use of prostaglandins for induction of labor led to the conclusion that such use reduced the incidence of failed induction, and thereby increased the likelihood of vaginal delivery [50].

Clinical trials have sought to determine the most appropriate dosages and route of administration; oral, intravenous, and intracervical and transvaginal preparations have all been evaluated [71, 72]. Oral administration is simpler and more acceptable to women, but it is much more difficult to avoid problems such as systemic side effects and hyperstimulation with oral doses [71–73, 77–80]. Many studies have compared prostaglandins to use of oxytocin or placebo for induction of labor, but if the prostaglandins are more physiologically suited to cervical ripening rather than active labor induction these comparisons may well be inappropriate.

There is some evidence to suggest that the use of prostaglandins for cervical ripening is most ad-

vantageous for the woman with an unripe cervix, and, when the cervix is already favorable, outcomes are very similar for women who are induced via PGE2 or oxytocin infusion [26–28, 54]. Outcomes such as cervical change in points (Bishop score) or time to delivery are prostaglandin-dose related, and associated with gestational age, parity, and cervical status. Mechanical stretching of the cervix such as that which takes place with "stripping the membranes" releases prostaglandin F2-alpha [47, 48].

Dose-related responses to administration of prostaglandins include cervical ripening, fetal distress, hyperstimulation, cesarean section for fetal distress, and neonatal jaundice [53–56]. Vaginal gel administration is less likely than cervical administration to be associated with an increase in cesarean deliveries, but this route of administration is associated with compromised fetal and neonatal status on several outcome measures. Tachysystole and the rate of operative vaginal birth for abnormalities in the fetal heart rate are also more likely with administration of misoprostol than dinoprostone [53–56].

Ripening or dilatation of the cervix is not always associated with any improvement in the rate of vaginal birth [24, 35, 44, 47]. The cervix is more likely to ripen with vaginal administration of PGE2 than with endocervical, yet this difference was not associated with changes in other outcome measures—e.g., use of analgesia or cesarean section [50]. Meta-analysis was not able to determine any clear differences between intracervical and vaginal administration of prostaglandin gels [50]; many studies reflect dated management protocols as well as outmoded methods of establishing gestational age.

Two prostaglandins have been the primary focus for use with labor induction; prostaglandin E1 (PGE1) and PGE2, which are both effective oxytocic agents [49]. Examples of these products are Cytotec (PGE1) and Cervidil and Prepidil (both PGE2). Misoprostol (Cytotec) is a tablet that is placed intravaginally by means of the examining hand. The tablet should be placed in the posterior fornix. It is not necessary to use a speculum for placement. Dosing should be done according to protocol in the clinical setting. ACOG recommends that a 25-mcg tablet be used for the initial dose, that doses should not be given more often than every 3 to 6 hours, and that oxytocin should not be given until at least 4 hours after the most recent misoprostol tablet [69, 73–77]. Safety of misoprostol (Cytotec) as a means of inducing labor is a concern. It is contraindicated for women with a previous uterine scar and should always be used with caution. Recently G. D. Searle, the manufacturer of misoprostol, has made public a drug warning that states that misoprostol ought not be used in pregnant women, but this has been refuted by ACOG, which states that "given the current evidence, intravaginal misoprostol tablets appear effective in inducing labor in pregnant women who have unfavorable cervices" [74].

Cervidil is a prostaglandin preparation placed in a mesh insert, which should be positioned in the posterior fornix with just a few centimeters of the attached string visible outside the vagina. The insert absorbs secretions, enlarges, and releases dinoprostone at the rate of about 0.3 mg/hr for 12 hr, at which time it is removed. The woman is asked to stay in a recumbent position for at least 2 hours after insertion so that location of the drug is maintained [75, 76]. If oxytocin is used after Cervidil is removed, the midwife should wait at least 30 minutes prior to beginning oxytocin infusion. Cervidil should be removed if active labor, fetal distress, tachycardia, or hyperstimulation occurs. An advantage to the use of Cervidil is that it can be easily inserted without the use of a speculum, and quickly and easily removed in the event of hyperstimulation or active labor, making it more convenient and safer to use on an outpatient basis [75–79].

Prepidil is a gel usually administered via a prefilled syringe into the cervical canal just inside the internal os. The syringe contains 0.5 mg dinoprostone and is brought to room temperature just prior to insertion. Speculum insertion and visualization of the cervix are necessary in order to place the gel appropriately, which is a disadvantage to this preparation. The woman is asked to remain in the dorsal position for 10 to 15 minutes to minimize leakage. The maximum recommended dosage for a 24-hour period is 1.5 mg, or 3 doses [75–79]. Prepidil gel should be swept from the vagina if active labor, fetal distress, tachycardia, or uterine hyperstimulation (tachysystole) occurs. In addition, potential side effects include uterine contractile abnormality, gastrointestinal effects (nausea and diarrhea), back pain, warm feeling in the vagina, and fever [75–79].

Mifepristone (RU 486) is not recommended for cervical ripening or induction of labor. Oral medication for induction of labor has significant drawbacks due to difficulty in reversing the effect, and there are insufficient data to establish safety of this method. Mifepristone has not been approved by the FDA for induction of labor at term [80].

Nonhormonal Methods for Induction of Labor

Several nonhormonal methods for induction of labor have been used with widely varying degrees of success. These methods are listed in Table 25-7.

Membrane Stripping The procedure known as stripping or sweeping the membranes refers to the practice of attempting to separate amniotic membranes from the reachable portion of the cervix and lower uterine segment during a vaginal examination [81, 82]. With a gloved hand, the midwife examines the woman to determine cervical effacement, dilatation, and position in the usual fashion. Care is taken to be certain that the vertex is presenting. The examiner extends the index finger as far as possible through the internal os, rotating the distal end of the finger slowly between the lower uterine segment and the membranes. Several sweeps are usually sufficient to stimulate onset of regular contractions within 72 hours [81–84]. The mechanism of action is probably the release of prostaglandins into maternal circulation. Membrane stripping is apparently safe if done appropriately, and shortens the gestational period by an average of 2 to 5 days thereby reducing the frequency of postdate pregnancy [81–84]. Stripping of the membranes should not be performed if inadvertent rupture of the membranes would be considered unsafe for the mother and infant. Membrane stripping should not be considered in cases of cervicitis, low lying or placenta previa, unknown lie, or undiagnosed vaginal bleeding.

Amniotomy Artificial rupture of the membranes (AROM) is another traditional method for induction or augmentation of labor [85]. As with membrane stripping, the midwife must do a careful vaginal examination to assess cervical effacement, dilatation, position, and the station of the presenting part. A nonvertex presentation is a contraindication to AROM, and other relative contraindications include an unengaged head, or small baby, as both conditions predispose to fetal cord prolapse. Precautions to weigh when AROM is considered include the commitment to birth (since the fetus is no longer in a sterile environment) and the increased likelihood of cord compression without hydraulic protection of the umbilical cord [85–87]. The usual method for AROM is bimanual examination with assessment for safety of the procedure, followed by insertion of an amnihook or similar instrument along the palmar surface of the examining hand. Early amniotomy (mean 2 centimeters dilatation) has been associated with more amnionitis, uterine hyperstimulation, and fetal distress than with later amniotomy (mean 5 centimeters dilatation) [85–87]. While amniotomy is used frequently to induce labor, there are no well-designed studies that prospectively randomize women to group for the purpose of evaluating this practice. It is not recommended that AROM be used alone to induce labor [69, 76, 85–87].

TABLE 25-7	Nonhormonal Methods for Induction of Labor
1. Membrane stripping or sweeping	
2. Artificial rupture of the membranes (AROM)	
3. Breast pump or nipple stimulation	
4. Ingestion of castor oil	
5. Foley bulb or balloon catheter	
6. Sexual activity	
7. Herbal preparations	

Breast Pump or Nipple Stimulation Few large studies have evaluated the safety and efficacy of breast stimulation as a method of inducing labor. However, the cumulative effect of many studies using the treatment of breast pump or manual nipple stimulation, combined with the physiologic basis for cervical change has led to an increased trend in recommendation of this relatively benign means to induce labor [88, 89]. Various treatments have included automatic electric breast pump, stimulating each breast for 15 minutes, interrupted by 15-minute rest periods; stimulation of breasts by gentle massage with a warm moist cloth for 1 hour, three times a day; breast stimulation for 45 minutes three times a day, and gentle massage of alternate breasts for a total of 3 hours a day [88, 89]. Weaknesses in the research include lack of compliance with the suggested intervention, small numbers in the groups, little control with critical variables such as gestational age, and inherent unreliability of the measure of the intervention. Not enough is known about the effect of breast or nipple stimulation to provide clear guidance regarding recommendation for use as either a means to soften the cervix or a method for induction of labor. Women who try this technique should be cautioned to limit nipple contact so that hyperstimulation of the uterus does not occur [88, 89]. (See Chapter 23 for the procedure for breast stimulation to induce a contraction stress test.)

Castor Oil The oral ingestion of 60 mg of castor oil mixed in apple or orange juice does appear to in-

crease the incidence of spontaneous onset of labor when used in term pregnancy [90, 91]. The intervention appears to have few drawbacks, but very little research is available on the topic. The best timing for ingestion of castor oil used for induction of labor is after a good night's sleep and 1 to 2 hours before the woman gets up for the day. Castor oil acts by stimulating the gut, which stimulates the vagal nerve, thereby stimulating the uterus [90, 91]. Onset of action is within 2 to 6 hours.

Foley Bulb or Balloon Catheter The Foley catheter or bulb has several advantages as a mechanical device used to stretch the cervix [92, 93]. It is readily available to the midwife, relatively safe to use, inexpensive, easy to place, and easy to remove. Additionally, fetal monitoring is not necessary while the Foley is in place, as it is to at least some extent with the use of hormonal methods of cervical ripening. Most commonly, the 16-gauge Foley catheter is inserted through the cervical canal, and then the balloon is inflated to 25 to 50 milliliters to hold it in place. Small clinical trials have shown this to be a promising technique, and many of the subjects entered labor while the Foleys were in place [92, 93]. Similar effects have been noted with the use of laminaria and synthetic osmotic dilators [94]. Clinical trials have not been sufficient to make specific recommendations.

Sexual Activity, Herbal Preparations Although there are some additional methods that have been used to ripen the cervix, initiate uterine contractions, or augment labor [95–97], there is little research to guide any specific recommendation. Nevertheless, many midwives have been routinely suggesting coitus and/or genital manipulation if the membranes are intact, nipple and breast stimulation, or herbal preparations as safe methods to hasten the onset of labor. The woman with an uncomplicated term pregnancy and intact membranes may be advised that lovemaking and breast stimulation are not contraindicated and could physiologically be associated with earlier onset of labor. Drinking herbal preparations such as evening primrose oil, black cohosh tincture, and blue cohosh tincture may be helpful, but a lack of research establishing dosage, safety, and efficacy guidelines hinders advisement. Acupuncture and homeopathy are additional venues for induction of labor that need further study [95–97].

If the midwife does conclude that active management of the postdate pregnancy is indicated, the protocol in Table 25-8 presents a guide to recommendations regarding administration, timing, dosage, and precautions. As with anticipatory management, the midwife is advised to carefully document mutual acceptance of the management plan by the woman, consulting physician, and midwife. The midwife should be familiar with the local standard of care for the postdate pregnancy, as should the woman. The woman should be informed if there is any off-label status in prescription use, and the midwife must remain current with literature related to management of postdate pregnancy. The woman's informed preference for timing of active management with postdate pregnancy should be a heavily weighted variable.

Summary

The clinical problem has been threefold: (1) reliable diagnosis of postdate pregnancy remains a challenge, (2) there is no consensus on the clinically appropriate time to suspend anticipatory management in favor of an effort to initiate birth, and (3) there are no clear evidence-based guidelines for the induction of labor in the uncomplicated postdate pregnancy.

While it is clear that there are maternal and fetal risks associated with pregnancy lasting longer than 41 weeks, it may be that some of those risks are a result of the management of that pregnancy rather than the prolongation of it. For example,

TABLE 25-8 Active Management of Postdate Pregnancy

1. Midwife follows Steps 1 through 6 in Table 25-5, as needed.
2. Woman may self-administer castor oil after 40+ weeks when the cervix is ripe, according to woman and midwife preference.
3. Midwife may sweep membranes after 41+ weeks, according to woman and midwife preference.
4. Midwife may administer prostaglandin gel (Prepidil) or insert (Cervidil) if cervix is unripe, in anticipation of induction, between 41 and 42 weeks.
5. Midwife may schedule pitocin induction of labor if 42 weeks is reached, according to woman, midwife, and consulting physician preference.
6. Midwife should not allow pregnancy to extend beyond 42 completed weeks (300 days) if dates are reliable.

Note: Prostaglandins and oxytocin are never administered simultaneously.

dysfunctional labor, fetal distress, and postpartum hemorrhage may be results of labor induction and augmentation, or they may be results of macrosomia. Knowledge of cervical readiness may be helpful for prediction of successful induction of labor, but information about fetal size apparently does not improve outcomes.

The philosophy of the American College of Nurse Midwives (ACNM) includes language that supports the normalcy of childbirth and advocates nonintervention in normal processes. When there are deviations from normal, the ACNM "supports the use of appropriate technological interventions where the benefits of such technology outweigh the risks" [98]. This belief in the normalcy of childbirth challenges the growing practice of induction of labor, particularly when risks, benefits, indications, and criteria for induction have not been clearly delineated.

CHAPTER

26

The Normal First Stage of Labor

Labor comprises those processes that result in the expulsion of the products of conception by the mother. It begins with true labor contractions, as evidenced by progressive cervical change, and ends with the delivery of the placenta. The cause of the onset of spontaneous labor is not known, although a number of interesting theories have been advanced and health care professionals know how to induce labor under certain conditions.

The first stage of labor is defined as beginning with true labor contractions as evidenced by progressive cervical change, and ending with the cervix completely dilated (10 centimeters). It is known as the stage of cervical dilatation.

Signs and Symptoms of Impending Labor

There are a number of premonitory signs and symptoms that may alert you to a woman's approaching labor. A woman may exhibit any, all, or none of these, but it is useful to keep them in mind when seeing a woman late in her pregnancy so you can provide appropriate anticipatory counseling and guidance. The signs and symptoms of impending labor are lightening, cervical changes, false labor, premature rupture of membranes, bloody show, energy spurt, and gastrointestinal upsets.

Lightening

Lightening, which occurs approximately 2 weeks before labor, is the descent of the presenting part of the baby into the true pelvis. The baby's head, if there is a cephalic presentation, usually is fixed or engaged afterwards. The woman frequently refers to lightening as "the baby has dropped." She will experience a decrease in the pregnancy discomfort of shortness of breath she has had during the third trimester because lightening will give her more room in the upper abdomen for lung expansion. However, lightening will cause other discomforts because of the pressure of the presenting part on structures in the area of the true pelvis. See parts C and D of Figure 21-2 (page 548). Specifically, she will have the following:

1. Frequency of urination, because the bladder is under pressure and has less room for expansion
2. An uncomfortable feeling of generalized pelvic pressure, which may make her feel awkward and produces the constant sensation that something needs to come out or that a bowel movement is needed
3. Leg cramps, which may be caused by the pressure of the presenting part on the nerves that course through the greater sciatic foramen and lead to the legs
4. Increased venous stasis producing dependent edema because the pressure of the presenting part in the true pelvis inhibits blood return from the lower extremities

Lightening lowers the height of the fundus to a position similar to that of the eighth month of pregnancy, and you are no longer able to ballotte the previously movable head of the baby above the symphysis pubis during abdominal palpation. Your examining fingers will now diverge rather than converge during the fourth step of Leopold's maneuvers.

Since lightening usually occurs prior to labor only in primigravidas, it is probably the result of the increasing intensity of the Braxton Hicks contrac-

tions combined with the good abdominal muscle tone more common to primigravidas.

Knowing that lightening has occurred is of value in being able to reassure the woman of the normality of the bodily changes she is experiencing and explain why they are occurring. Lightening also provides a good opportunity to review with the woman her plans for labor. Moreover it provides an indication of the adequacy of the pelvic inlet. Because the length of time between lightening and true labor varies with individuals, it is of little use in predicting the onset of labor except in a most generalized fashion of a few days to a couple of weeks. However, lightening tends to encourage the woman that the long-awaited end of pregnancy is in sight.

Cervical Changes

As labor approaches, the cervix becomes "ripe." In contrast to its closed, long, soft state during pregnancy, it becomes still softer, with the consistency of pudding, and evidences some degree of effacement and perhaps slight dilatation. Evaluation of ripeness is relative to the individual woman and her parity—for example, during pregnancy a grand multipara's cervix may normally be 2 centimeters dilated as opposed to a primigravida's normally closed cervix.

It is thought that these cervical changes are brought about by the increasing intensity of the Braxton Hicks contractions. A cervix may be ripe for a variable period of time prior to labor. Ripeness indicates a readiness of the cervix for labor. Determining ripeness allows the midwife to assure the woman that she will go into labor with the onset of labor contractions and that the time of labor is relatively close at hand. It also allows you to assess the probable success of an indicated induction of labor.

False Labor

False labor consists of painful uterine contractions that have no measurable progressive effect on the cervix. False labor contractions are in actuality an exaggeration of the usually painless Braxton Hicks contractions, which have been been occurring since about 6 weeks' gestation.

False labor may occur for days or intermittently even 3 or 4 weeks before the onset of true labor. False labor is genuinely painful, and a woman may lose sleep and energy coping with it. She has no way of knowing for sure whether she is in true labor since this can be determined only by vaginal examination. The intermittent recurrence of false labor and trips back and forth to your office or the hospital are exhausting and frustrating to the woman and her family. This situation calls for a great degree of understanding, patience, support, reassurance, and many explanations on the part of all personnel who see the woman during her trips to your office or the hospital. False labor, however, does indicate the approach of labor.

Premature Rupture of Membranes

Normally the membranes rupture by the end of the first stage of labor. Rupture before the onset of labor is called premature rupture of the membranes and occurs in about 12 percent of women. Approximately 80 percent of near-term women with premature rupture of membranes begin labor spontaneously within 24 hours (see Chapter 29).

Bloody Show

A mucus plug, created by cervical secretions from proliferation of the glands of the cervical mucosa early in pregnancy, serves as a protective barrier and closes the cervical canal throughout pregnancy (Figure 26-1). Bloody show is the expulsion of this mucus plug.

Bloody show is most often seen as a tenacious, blood-tinged mucus discharge that must be carefully differentiated from frank bleeding. Women often refer to the discharge as "seeing the sign." Occasionally the entire mucus plug is expelled en masse; if the plug is expelled during labor and can be seen extruding from the woman's vagina, inex-

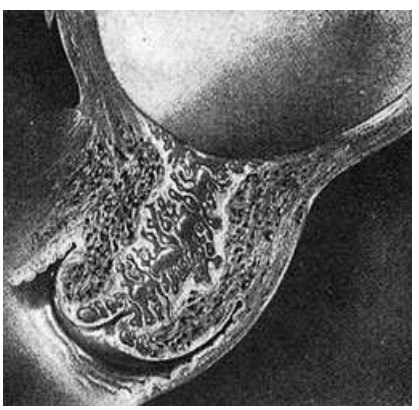

FIGURE 26-1 Cervix in pregnancy. Note the elaboration of the mucosa into a honeycomblike structure, the meshes of which are filled with a tenacious mucus (the mucus plug).

Source: From Pritchard, J. A., and MacDonald, P. C. *Williams Obstetrics*, 15th ed. New York: Appleton-Century-Croft, 1976. Reproduced by permission.

perienced obstetrical personnel may think the umbilical cord has prolapsed. More commonly it is expelled over 1 to 2 days.

Bloody show is a sign of imminent labor, which usually takes place within 24 to 48 hours. However, bloody show is of no value as a sign of labor if a vaginal examination has been done within the past 48 hours, because a blood-tinged mucus discharge during this time may be only the effect of minor trauma to or disruption of the mucus plug during the examination.

Energy Spurt

Many women experience an energy spurt approximately 24 to 48 hours before the onset of labor. After days or weeks of feeling physically tired and tired of being pregnant, they get up one day to find themselves full of energy and vigor. Typically these women feel energetic for a period of a few hours, during which they do things like clean the house, wash and iron curtains, scrub floors, cook and freeze food, and perform a variety of other household tasks that they either have not had the energy to do or now feel the need to do before the baby's arrival. Consequently they enter labor exhausted and often have long, difficult labors.

There is no known explanation for this energy spurt other than it is nature's way of giving a woman the energy she needs for the work of labor. Women should be informed of the possibility of their having this energy spurt and advised to deliberately refrain from expending it and instead to conserve it for use during labor.

Gastrointestinal Upsets

In the absence of any causative factors for the occurrence of diarrhea, indigestion, nausea, and vomiting, it is thought they might be indicative of impending labor although no explanation for this is known. Some women experience one or more of these signs.

Database for the First Stage of Labor

Components of the data base for determining the well-being of the mother and the fetus during the first stage of labor are as follows:

1. Continuing evaluation of any significant findings from the history, physical and pelvic examinations, and laboratory work done during the initial evaluation of the mother and fetus in labor
2. Evaluation of the progress of labor
3. Evaluation of the woman's behavior and her response to labor and her significant others
4. Continuing evaluation of the normality of the fetal presentation, position, and variety and fetal adaptation to the pelvis
5. Evaluation of the fetal heart tones (see Chapter 27)
6. Evaluation of maternal physiologic changes
7. Continued screening for signs and symptoms of obstetrical complications and nonreassurance of fetal well-being (see Chapters 27, 29, and 30)

In order to evaluate any of the components of the database, the midwife must know what the parameters of normal are for each of the specific pieces of information obtained for each component.

Contractions

Labor itself is an intricate interplay of physiologic and psychologic forces within the woman and the effect of these forces on the process of birth and on the baby. These forces result in the birth of the baby. The primary physiologic force during labor is that of uterine contractions. It is impossible to understand and evaluate labor progress, to understand the discomforts and pain of labor, to devise comfort measures, or to be aware of complications without a thorough comprehension of uterine contractions and their action.

The uterine contractions of labor are unique as the only painful physiologic muscular contractions in the body. Furthermore, these contractions are involuntary, as they are under intrinsic nervous control. This means that the woman has no physiologic control over the frequency and duration of these contractions, because they are not regulated by any extrauterine neural process. Every midwife, however, can recount situations in which a woman's psychological forces were such as to temporarily forestall or stop labor.

Uterine contractions are intermittent, providing for a period of uterine relaxation between contractions. These periods of relaxation between contractions serve the following essential functions:

1. Provide rest to the uterine muscle
2. Provide rest to the woman
3. Maintain the welfare of the baby, since uterine contractions constrict the placental blood vessels

The duration of a uterine contraction varies considerably, depending on where the woman is in her labor. The contractions of active labor last from

45 to 90 seconds with an average of 60 seconds. In early labor the contractions may be only 15 to 20 seconds in duration.

The frequency of contractions is determined by measuring the time from the beginning of one contraction to the beginning of the next contraction. The duration of the contraction is also noted; subtracting the duration from the frequency gives the length of the period of relaxation. For example, a woman who begins contractions at 5:05, 5:10, 5:15, 5:20, and 5:25, each lasting 60 seconds, is having contractions with a frequency of every 5 minutes and a duration of 60 seconds. The period of relaxation of 4 minutes between the end of one contraction and the beginning of the next is more than adequate for the welfare of baby, mother, and uterine muscle. An absolute critical point is reached when the contractions are more frequent than every 2 minutes and have durations longer than 90 seconds, because this does not allow for sufficient relaxation time. While more frequent contractions with longer durations beyond this critical point do not occur with normal spontaneous labor, they must be closely guarded against during pitocin induction or augmentation of labor.

In evaluating the frequency and intensity of uterine contractions, it is important to know that each contraction has three phases: increment, acme, and decrement. The increment phase is longer than the other two phases combined. With experience, you can feel an oncoming contraction with your hand before the woman can feel it. Conversely, the woman may feel the contraction for several to many seconds after you no longer feel it with your hand. What the woman is feeling may be the aftermath of the pain just experienced. When you consider, in addition, the extreme variations in individual pain thresholds, it becomes apparent that to time contractions on the basis of the woman's vocal or behavioral manifestations of pain is most inaccurate.

This holds true also for evaluating the intensity of a contraction. A frightened woman who is unknowledgeable about what is happening to her and unprepared in the relaxation and breathing techniques that can help her cope with her contractions may cry out in pain and thrash about in her bed with the mildest of contractions. Conversely, the woman who has been prepared for her childbearing experience and is supported by her significant other or a professional prepared in labor support, or the woman who is a stoic, may never evince loss of control or cry out even with the most severe contractions. Intensity, therefore, can be evaluated only by the indentability of the uterine wall by your fingers during the acme of the contraction or by the intrauterine pressure catheter of a fetal monitor. During a good, effective labor contraction, the uterine wall cannot be digitally indented and reaches a uterine pressure of more than 40 mm of mercury during the acme of the contraction.

Contractions must be evaluated not only for frequency, duration, and intensity but also for the interplay of the three factors. Generally speaking, uterine contractions start as infrequent or irregular contractions (e.g., every 20 to 30 minutes) of short duration (15 to 20 seconds) and mild intensity; become more frequent, longer, and more intense as labor progresses; and are usually every 2 to 3 minutes, lasting 60 to 90 seconds, and of severe intensity by the end of the first stage of labor. However, there are infrequent variations of this pattern that also result in birth of the baby. If a woman starts with contractions with a frequency of every 5 minutes, lasting 60 seconds, and of moderately hard intensity, don't expect them to become irregular, of short duration, and mild intensity before becoming more frequent, longer, and harder—unless she develops uterine dysfunction. Also, women have been known to deliver babies with 5- to 7- minute contractions lasting 30 to 40 seconds and of mild to moderate intensity.

Normal uterine contractions also follow another pattern, known as the normal gradient pattern. This term refers to synchronous activity of the uterine muscle that causes a contraction to be stronger and longer in the fundal portion of the uterus, decreasing in the midportion, and minimal to nonexistent toward the cervix. This pattern is essential to dilatation of the cervix. The effect of contractions on the uterus is to differentiate it into two zones (Figure 26-2): (1) the upper, contracting zone, which thickens and expels the baby during labor, and (2) the lower passive zone, composed of the isthmus of the uterus (known during labor as the lower uterine segment) and the cervix. The lower zone does not contract but thins out into an expanded muscular tube through which the baby can pass. Differentiation of the uterus into two zones is accomplished through a mechanism of contraction in which the muscle does not return to its original length in the upper zone during relaxation, but stays relatively fixed at a shorter length. The upper zone is thus kept in constant contact with the intrauterine contents, and the uterine cavity becomes progressively smaller with each successive contraction. In order for this to occur, the uterine contents must decrease in volume in the upper zone, which is

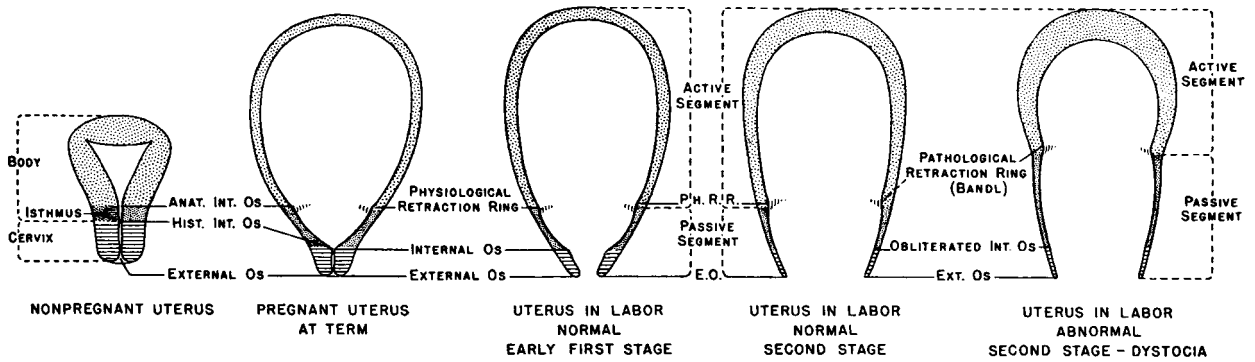

FIGURE 26-2 Sequence of development of the segments and rings in the uterus in pregnant women at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower segment of the uterine body is derived from the isthmus; the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. Anat. Int. Os = anatomical internal os; Hist. Int. Os = histological internal os; PH.R.R. = physiological retraction ring; E.O. = external os.

Source: From Cunningham, F. Gary, Gant, Norman F., Leveno, Kenneth J., Gilstrap, Larry C. III, Hauth, John C., Wenstrom, Katherine D. *Williams Obstetrics*, 21st Edition. McGraw-Hill, New York, 2001. Reproduced with permission of the McGraw-Hill Companies.

accomplished by expansion of the musculature of the lower zone so that more of the intrauterine contents can distend its walls. The muscle fibers of the lower zone lengthen under the influence of upper-zone contractions and do not return to their shorter length during relaxation but remain relatively fixed at a longer length. The changes in the two zones complement each other: The upper zone thickens only to the extent that the lower zone expands and thins. If the uterus were to contract equally all over rather than in its normal gradient pattern, nothing would be accomplished. If the lower zone were to contract more than the upper zone, labor would be dysfunctional and cervical dilatation would not occur.

Contractions have the additional effect of elongating the uterine ovoid by an estimated 5 to 10 centimeters with a corresponding decrease in the horizontal plane. This has the effect of straightening the fetal vertebral column, thereby bringing the upper pole of the fetus in solid direct contact with the contracting uterine fundus while the lower pole is directed downward and pushed into the pelvis. Known as fetal axis pressure, this also results in the exertion of pressure against the cervix and lower uterine segment, thereby additionally affecting cervical effacement and dilatation.

Effacement and Dilatation

Effacement and dilatation are the direct result of the contractions as described above.

Effacement is the shortening of the cervical canal from its usual length of 2 to 3 centimeters to the point where the cervical canal is obliterated, leaving only the external os as a circular orifice with thin edges. This shortening results from the lengthening of the muscular fibers around the internal os as they are taken up into the lower uterine segment. Effacement is facilitated by the cleftlike arrangement of the endocervix, which in effect unfolds like an accordion as it is stretched and taken up to become part of the lower uterine segment. The process of effacement is also facilitated by and is the cause of expulsion of the mucus plug. Effacement is clinically evaluated in terms of percentages, with no effacement being 0 percent and complete effacement being 100 percent.

Dilatation is the enlargement of the external cervical os from an orifice of a few millimeters in diameter to an opening large enough for the baby to pass through. In addition to the primary action of the contractions, dilatation is facilitated by the hydrostatic action of the amniotic fluid under the influence of the contractions, which causes the membranes to serve as a dilating wedge in the area of least resistance in the uterus. Although intact membranes enable this hydrostatic action of the amniotic fluid and provide the most effective dilating wedge, if the membranes have ruptured, the pressure of the presenting part on the cervix and the lower uterine segment can also have a dilating effect depending on the presenting part and its position in relation to the cervix.

Dilatation is clinically evaluated by measuring the diameter of the cervical opening in centimeters, with 0 centimeters being a closed external cervical

os and 10 centimeters being complete dilatation. The magic number of 10 centimeters is based on the fact that the suboccipital-bregmatic diameter of the fetal head, which is the widest diameter of the flexed head in the normal mechanisms of labor, is approximately 9.5 centimeters at term.

Initial effacement and dilatation vary between a primigravida and a multigravida entering labor. A primigravida's cervix is frequently 50 to 60 percent effaced and a fingertip to 1 centimeter dilated prior to labor as the result of the Braxton Hicks contractions before labor begins. Such early effacement and dilatation are part of the cervical changes that contribute to the "ripeness" of the cervix as a premonitory sign of labor. Progressive cervical change in a primigravida in labor is generally sequential, then simultaneous, with 50 to 100 percent effacement occurring first, followed by a combination of any remaining effacement and dilatation. A primigravida with a paper-thin cervix is on the verge of active labor. The cervix of a multigravida entering labor is frequently 1 to 2 centimeters dilated (or more, depending on parity) with little to no effacement.

You can develop clinical judgment in your fingers for assessing centimeters of dilatation not only by practicing on cervical effacement and dilatation models but also by running your fingers around the edge of and across any circular object with which you come into contact (e.g., drinking glasses, telephone receivers, cups, vases, flat circular knobs on machines), estimating its diameter in centimeters, and then checking its actual measurement with a centimeter measuring tape or ruler.

Because it is difficult at times to distinguish between true and false labor contractions, the only indicator that enables one to diagnose labor accurately is progressive cervical change—that is, cervical effacement *and* dilatation. All information concerning the contractions, location of pain, and the premonitory signs of labor is useful in differentiating between early labor and false labor but is diagnostically adjunctive to assessment of the cervix.

Station

Station is the relationship of the lowermost part of the presenting part to an imaginary line drawn between the ischial spines of the woman's pelvis. The lowermost part of the presenting part at the level of the ischial spines is called 0 station. Station is measured in terms of centimeters above or below the level of the ischial spines, with *above* being designated as –1, –2, –3, –4, and –5 station and *below* being designated as +1, +2, +3, +4, and +5 station. A –5 station is equivalent to a floating head and a +5 station is equivalent to a head at the vaginal orifice (see Figure 26-3).

Frequently, a description of 0 station is given inaccurately as a definition of engagement. The reason

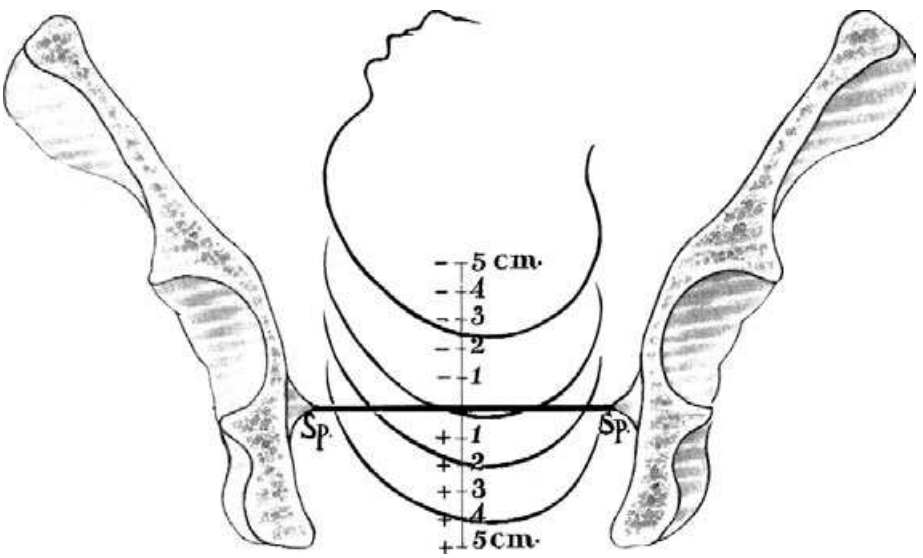

FIGURE 26-3 Station, or level of descent, of the head of the fetus through the pelvis. The location of the forward leading edge (lowest part of the head) is designated in centimeters above or below the plane of the interspinous line.

Source: From Greenhill, J. P., and Friedman, E. A. *Biological Principles and Modern Practice of Obstetrics*. Philadelphia, PA: Saunders, 1974. Reproduced by permission.

for this error is that, generally speaking, when the head is engaged the lowermost part of the presenting part is at the level of the ischial spines, because the distance from the pelvic inlet to the ischial spines is usually 5 centimeters and the distance from the biparietal diameter of the full-term fetal head to the occiput is $4^1/_2$ centimeters. This is not always true, however, inasmuch as pelvic structure varies with the individual woman and the size of the fetal head may alter this finding. For example, a preterm infant of 34 weeks' gestation may well have its head engaged and be at a –1 station. Remember that *engagement* is defined as the point when the widest diameter of the presenting part (which, in a cephalic occipital presentation, is the biparietal diameter) has passed through the pelvic inlet.

Station is at times difficult to ascertain if there has been considerable molding of the fetal skull and development of caput succedaneum. In a cephalic presentation, the actual lowermost part of the presenting part, which is the skull bones, may be a centimeter or so higher than the caput, which is what your fingers are feeling. This is important to remember if you are concerned about the adequacy of the midpelvis and are using station as an indication that the fetal head has maneuvered this portion of the pelvis.

Status of Membranes

Determination of whether the membranes have ruptured is essential and at times difficult. (See also Chapter 29.) This diagnosis is made difficult by a hazy history, false-positive results on the nitrazine paper test, and the fact that the membranes may have a high leak that has sealed over as a result of the pressure of the presenting part against the cervix and lower uterine segment.

When a woman gives a history suggestive of ruptured membranes and she is not in active labor, a sterile speculum examination is indicated to observe the cervix for escaping amniotic fluid. Some clinicians believe a nitrazine test is also indicated. The nitrazine paper test is based on the fact that the usually dark yellow paper turns blue-green to deep blue when moistened with a substance with an alkaline pH. The pH of amniotic fluid is an alkaline 7.0 to 7.5. Unfortunately, blood, cervical mucus, and secretions produced by certain vaginal infections (bacterial vaginosis; trichomoniasis) are also alkaline and, if present, these may invalidate the test for rupture of the membranes.

A nitrazine test is properly performed during the sterile speculum examination but *not* by holding a strip of nitrazine paper between gloved fingers and inserting them in the vagina or by clamping a strip of nitrazine paper with a ring forceps and placing it at the cervical os. Remember that the nitrazine paper is not sterile. The chance of an invalid nitrazine test is reduced, and sterility is maintained, by obtaining a specimen during the sterile speculum examination with a sterile cotton-tipped applicator in a pool of fluid in the posterior vaginal fornix, avoiding all structures while withdrawing the specimen, and then touching it to the nitrazine paper. (The emphasis on sterility is to reduce the chance of infection in the event the membranes are ruptured, especially if there is no labor.) However, the specimen is obtained from the same area where extrusion of the mucus plug occurs, and some minute bleeding accompanies its disruption. Also, it is possible for the collecting device to rub against the membranes, which would render the resulting positive nitrazine test invalid. An alternative method is to press a strip of nitrazine paper against the inside of the lower blade of the speculum after withdrawing the speculum from the vagina. Although the nitrazine test can be a helpful adjunct, it should not be relied on for making a definitive diagnosis of ruptured membranes.

A specimen from the vaginal pool, if present, can be used for doing a fern test for detecting amniotic fluid in the secretions. This test is based on a fernlike crystallization of the sodium chloride in amniotic fluid, which can be observed microscopically when the specimen is dried (see Figure 29-1 on page 864). However, a moderate amount of bloody show or vaginal or cervical secretions caused by an infection can interfere with this test, rendering it invalid.

Digital examination for rupture of the membranes is most helpful, especially if speculum findings are inconclusive and you are not concerned with premature rupture of the membranes and the development of chorioamnionitis. If you cannot easily feel the membranes bulging over the presenting part, it is helpful either to have the woman bear down or to apply fundal pressure, which may cause the membranes to bulge if they are there. Membranes in close contact with a head feel smooth and slick to the touch in contrast with the slightly irregular and comparatively more coarse feel of hair. A digital examination is *not* necessary for diagnosing ruptured membranes if findings during the speculum examination are definitive.

Diagnosis is definitive for ruptured membranes (1) when you see amniotic fluid escaping from the cervical os and pooled in the vaginal vault during

speculum examination or (2) when you cannot feel the membranes over the presenting part at the cervical orifice. When you feel the membranes bulging against your examining fingers during vaginal examination of the cervix, other possibilities must be considered, including (1) unruptured membranes, (2) a high leak that is occluded by pressure from the presenting part, or (3) escape of fluid trapped between the membranes with rupture of the chorion only, and not the amnion.

Progress of Labor

The first stage of labor is divided into two sequential phases: latent and active. Midwives have long described a transitional phase of labor late in the active phase from approximately 8 to 10 centimeters of dilatation [1]. In 1955, Friedman [2] depicted the progress of labor as a sigmoid curve and subdivided the active phase into three sequential phases: acceleration, maximum slope, and deceleration. In 1970 Philpott and Castle [3] developed the partogram that described the active phases of labor as progressing in a straight line. Likewise, the work of Kilpatrick and Laros in 1989 [4] and of Albers, Schiff, and Gorwoda in 1996 [5] does not delineate subdivided phases within the active phase of labor when discussing the length of labor. This chapter provides the average length of time for the first stage of labor or cervical dilatation rate ascertained by these different authors and cites both the most recent data published by Albers in 1999 [6] and the long established limits dictated by the Friedman graph, which is widely used in obstetrics in the United States.

The later data support the concept that normal labor may last longer than is generally acknowledged based on the Friedman curve. It is critically essential that the midwife not consider deviation from the Friedman curve as abnormal but as a signal that this woman needs to be carefully and comprehensively evaluated to assess whether she and her fetus indeed are still within the realm of normal and will remain so over time. The operative word is *progress*. If there is not progress in one area (e.g., dilatation), is there progress in another area (e.g., descent, working through any psychologic obstacle)? Is the progress sufficient for continuing maternal and fetal well-being?

Each phase of labor is characterized by measurable physical changes and by psychological changes. The physical changes are used to evaluate progress in labor; the psychological changes are used to estimate where a woman is within a phase of labor without resorting to a vaginal examination and to guide the midwife in devising appropriate support and comfort measures.

Latent Phase The latent phase covers the period of time from the beginning of labor to the point when dilatation begins to progress actively. This generally is from the onset of regular contractions to 3 to 4 centimeters dilatation or to the beginning of the active phase. Little to no descent of the presenting part occurs during the latent phase.

Contractions become established during the latent phase as they increase in frequency, duration, and intensity—from occurring every 10 to 20 minutes, lasting 15 to 20 seconds and being of mild intensity to contractions of moderate intensity (averaging 40 mm Hg at their acme from a baseline uterine tonus of 10 mm Hg) occurring approximately every 5 to 7 minutes and lasting 30 to 40 seconds.

Accurate measurement of the length of the latent phase of the first stage of labor is impossible for a number of reasons: (1) the difficulty of differential diagnosis between latent phase and false labor, (2) not being able to objectively quantify the start of the latent phase and thereby having to rely on a report by the woman or whoever is with her as to when she became aware of her contractions and when they became "regular," and (3) variations between women on cervical ripeness at the onset of labor. Vaginal examination during this period of time documents cervical changes, expecially effacement in primigravidas, and beginning dilatation.

Usually during the latent phase of labor the woman experiences a mixture of emotions: she is excited, happy, and relieved that the end of pregnancy has come and the long period of waiting has ended, but she feels a sense of anticipation and some apprehension about what is yet to come. Generally, she is not too uncomfortable and copes well with her situation. However, for a woman who has had no preparation regarding what to expect, the latent phase of labor may be a time when she cries out as much in fear as with pain with the mildest contractions and does not seem able to cope until with increased frequency and intensity of the contractions it becomes obvious to her that she really is in labor. Often this coincides with entry into the active phase of labor and admission to the labor and birth unit, which she may perceive as a source of security and help—all of which will enable her to be less frightened and better able to cope. For a women who has been suffering from the general miseries of the end of pregnancy and false labor, the emotional response

to the latent phase of labor is at times dramatic: relief, relaxation, and increased coping ability regardless of the planned locale of birth. Even though tired, she knows she is at last actually in labor and what she is now experiencing is productive.

Active Phase The active phase covers the period of time from the start of active progression of dilatation to the completion of dilatation and includes the transitional phase. This is generally from 3 to 4 centimeters (or the end of the latent phase) to 10 centimeters dilatation (or the end of the first stage of labor). Progressive descent of the presenting part occurs during the latter part of the active phase and during second stage.

Contractions during the active phase become increasingly frequent, of longer duration, and of greater intensity. Effective contractions are those that have a normal triple gradient pattern, reach a uterine pressure of 40 to 50 millimeters of mercury during the acme of the contraction, and return to a resting uterine tonus of 10 millimeters of mercury. By the end of the active phase, contractions are usually coming every 2 to 3 minutes, lasting around 60 seconds, and reaching firm intensity (more than 40 mm Hg) with an average of about 55 millimeters of mercury.

According to Freidman [7], the *acceleration phase* starts the active phase of labor and leads into the phase of maximum slope. The *phase of maximum slope* is the time when cervical dilatation is occurring most rapidly and increasing from 3 to 4 centimeters to about 8 centimeters. Normally the rate of dilatation is constant, averaging 3 centimeters per hour, with a minimum rate of not less than 1.2 centimeters per hour in nulliparas. In multiparas, the average rate of dilatation during the phase of maximum slope is 5.7 centimeters per hour, with a minimum rate of 1.5 centimeters per hour. The *deceleration phase* is the end of the active phase, during which the rate of dilatation slows and the cervix reaches a dilatation of from 8 to 10 centimeters while descent reaches its maximum rate. The average maximum rate of descent in nulliparas is 1.6 centimeters per hour and normally at least 1.0 centimeters per hour. In multiparas, the rate of descent averages 5.4 centimeters per hour, with a minimum rate of 2.1 centimeters per hour.

Philpott and Castle [3] developed a single straight Alert Line based on a rate of 1 cm per hour for primigravidas, which they considered an acceptable limit in defining progress. They then established an Action Line that parallels the Alert Line, only it is 4 hours later. This arbitrarily chosen time was selected as sufficient time, once a woman crossed the Alert Line, for her to transfer from rural areas in Rhodesia, Africa, to a central unit where interventions could be made. In their study of 624 consecutive primigravid patients published in 1972, 438 (70 percent) delivered inside the Alert Line and half of the remaining group delivered normally (without oxytocic stimulation or cesarean section) within the 4 hours between the Alert Line and the Action Line. Kilpatrick and Laros [4] determined a statistically significant difference in the length of the first stage of labor dependent on whether conduction anesthesia was used (see Table 28-1). The first stage of labor for nulliparas averaged 8.1 hours without conduction anesthesia and 10.2 hours with conduction anesthesia; multiparas averaged 5.7 hours without conduction anesthesia and 7.4 hours with conduction anesthesia. Perl and Hunter [8] found that of 505 consecutive singleton labors without a protocol in place for "slow" cervical dilatation, 105 progressed at an overall cervical dilatation rate of less than 1 centimeter per hour but that only those progressing at less than 0.5 centimeter per hour had a significant increase in cesarean sections.

A study published in 1996 by Albers, Schiff, and Gorwoda [5] of 1473 low-risk women without either oxytocin or conduction anesthesia determined an average length of first stage labor as 7.7 hours for nulliparas and 5.7 hours for multiparas. A later study published by Albers in 1999 [6] of 2511 women without either oxytocin or conduction anesthesia found a mean length of first stage labor of 7.7 hours for nulliparas and 5.6 hours for multiparas. Concurring with others who raise the question of reassessing the length and definition of normal labor, Albers recommends that 0.5 centimeter per hour in the absence of other problems or symptoms be considered within the normal limits of progress for the first stage of labor.

Tables 26-1 and 26-2 show the average and upper limit of normal active labor for nulliparas and multiparas, respectively, in four comparable studies [2, 4–6, 9, 10].

As labor progresses through the active phase, the woman may become increasingly apprehensive. As the contractions become harder, last longer, and occur more often, it becomes apparent to her that she cannot control them. With this realization she becomes more serious. She wants someone with her, as she is frightened of being left alone and of being unable to cope with the contractions. She experiences a number of ill-defined doubts and fears. She can tell you she is scared but is unable to tell you what she is scared of.

TABLE 26-1 Average and Upper Limit Length of Normal Active Labor for Nulliparas

Author	Mean (hours)	Upper Limit[a] (hours)
Friedman (1956; 1967) (Measured from 3–4 cm to 10 cm)	4.9	11.7
Kilpatrick and Laros (1989) (Measured from regular, painful contractions q 3–5 min by history to 10 cm)		
No conduction anesthesia	8.1	16.6
With conduction anesthesia[b]	10.2	19.0
Albers, Schiff, and Gorwoda (1996) (Measured from 4 cm to 10 cm)	7.7	19.4
Albers (1999) (Measured from 4 cm to 10 cm)	7.7	17.5

[a] Mean plus two standard deviations (95th percentile)

[b] Conduction anesthesia: 95% epidurals; 5% saddle blocks

TABLE 26-2 Average and Upper Limit Length of Normal Active Labor for Multiparas

Author	Mean (hours)	Upper Limit[a] (hours)
Friedman (1956; 1967) (Measured from 3–4 cm to 10 cm)	2.2	5.2
Kilpatrick and Laros (1989) (Measured from regular, painful contractions q 3–5 min by history to 10 cm)		
No conduction anesthesia	5.7	12.5
With conduction anesthesia[b]	7.4	14.9
Albers, Schiff, and Gorwoda (1996) (Measured from 4 cm to 10 cm)	5.7	13.7
Albers (1999) (Measured from 4 cm to 10 cm)	5.6	13.8

[a] Mean plus two standard deviations (95th percentile)

[b] Conduction anesthesia: 95% epidurals; 5% saddle blocks

There are other observations you can make that indicate the woman's progress in labor. These are based on the fact that descent of the fetus in the pelvis changes the location of findings elaborated from the fetus. The low back pain a woman experiences is caused by the pressure of the fetal head against her spine. This is not a generalized pain but rather pain that the woman can precisely pinpoint for you. As the baby descends, the location of this back pain correspondingly moves down her lower spine. Also, the location of the fetal heart tones moves lower in her abdomen as descent occurs.

Transitional Phase During the transitional phase, the woman is ending the first stage of labor as she nears and prepares for the second stage of labor. A large number of signs and symptoms, including behavior changes, have been identified as indicative of this transition. The signs and symptoms are listed below; those occurring late in the transitional phase are known as the signs of impending second stage and are marked with an asterisk (*).

Beads of perspiration on the upper lip or brow
Shaking legs
Chattering teeth
Cramps in the buttocks, thighs, or calves
Hiccupping
Belching and burping
Thirst
Anorexia
Nausea and possibly vomiting
Inability to breathe abdominally
Irritable abdomen—increased tenderness to touch over the abdomen and back
Marked restlessness
Natural amnesia between contractions—appears exhausted and is difficult to rouse
Difficulty in readily comprehending directions
Contractions every $1^1/_2$ to 2 minutes, lasting 60 to 90 seconds, of severe intensity; seem almost continuous and are quite painful
Toes curl with contractions
Generalized discomfort
Doesn't want to be touched
Bewildered, frustrated, and exasperated by the severity of the contractions
Severe low backache
Marked decrease in the sense of modesty
Unable to cope with the contractions if left alone
Irritable behavior
Pulling or stretching sensation deep in the pelvis
Rejection of those about her
Quite apprehensive
*Increase in bloody show
*Rectal pressure, feeling of having to have a bowel movement, repeated requests for a bedpan or to go to the bathroom
*Uncontrollable desire to bear down
*Membranes rupture

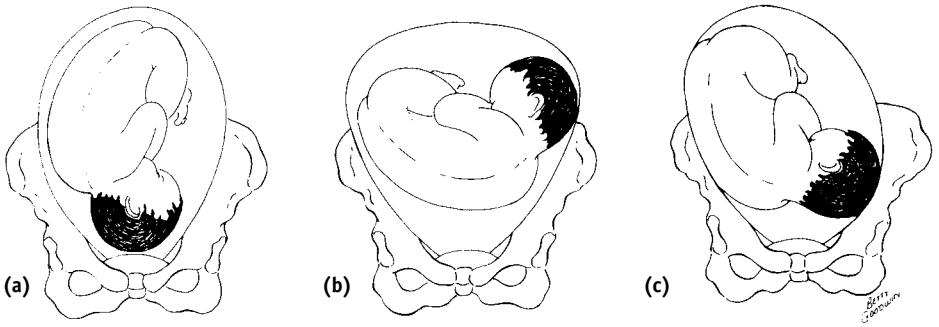

FIGURE 26-4 Lies: (a) longitudinal; (b) transverse; (c) oblique.

*Rectal and perineal bulging and flattening
*Expulsive grunt upon exhalation

Usually a woman exhibits a combination of several of these signs and symptoms during transition. It is not uncommon for a woman to exhibit all or nearly all of these signs and symptoms, particularly if she is a primigravida who has not had the benefits of preparation from childbearing classes.

Fetal Components

Lie, Presentation, Position, and Variety Determination of the lie, presentation, position, and variety of the fetus is essential database information. These determinations require an understanding of the words used and of the anatomical landmarks of the fetal skull in relation to the maternal pelvis.

Lie is the relationship of the long axis of the fetus to the long axis of the mother. There are three possible lies: longitudinal, transverse, and oblique (Figure 26-4).

Presentation is determined by the presenting part, which is the first portion of the fetus to enter the pelvic inlet. There are three possible presentations: cephalic, breech, and shoulder. Cephalic and breech presentations are further subdivided. A cephalic presentation can be either vertex, sincipital, brow, or face. A breech presentation can be either frank, full/complete, or footling (single or double).

The *attitude* of the fetus is its characteristic posture. This is determined by the relationship of the fetal parts to each other and the effect this has on the fetal vertebral column. The attitude of the fetus varies according to its presentation. For example, a fetus in a vertex presentation has a well-flexed head, flexion of the extremities over the thorax and abdomen, and a convex curved back; the ramrod straight attitude of a fetus with a sinciput presentation has given it the name of a military attitude; and a fetus with a face presentation has a head that is acutely extended, flexion of the extremities on the thorax and abdomen, and a vertebral column that is arched to some degree (Figure 26-5).

Position is the arbitrarily chosen point on the fetus for each presentation in relation to the left or right side of the mother's pelvis. These are shown in Table 26-3.

Position is commonly used to refer to the designations of left occipital anterior (LOA), right sacral transverse (RST), and so forth, and one of these is

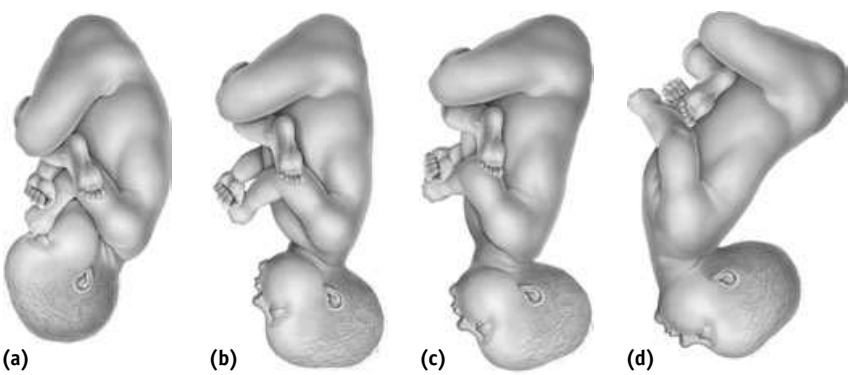

FIGURE 26-5 Attitude of the fetus in (a) vertex, (b) sinciput, (c) brow, and (d) face presentations.

TABLE 26-3 Possible Fetal Relationships to the Maternal Pelvis for Each Lie and Presentation

Lie	Presentation	Arbitrarily Chosen Point on the Fetus	Designation for Position (left or right side) and Variety (anterior, transverse, or posterior portion of the mother's pelvis)	
Longitudinal	Cephalic			
	Vertex	Occiput	ROA	LOA
			ROT	LOT
			ROP	LOP
	Sinciput	Sinciput (bregma, anterior fontanel)	Sinciput and brow presentations usually convert to either a vertex or a face presentation.	
	Brow	Brow		
	Face	Mentum (chin)	RMA	LMA
			RMT	LMT
			RMP	LMP
	Breech			
	Frank	Sacrum	RSA	LSA
			RST	LST
			RSP	LSP
	Full/Complete	Sacrum	Same as frank presentation	
	Footling	Sacrum	Same as frank presentation	
Transverse	Shoulder	Acromion	RAA	LAA
			RAP	LAP
			A transverse variety is not possible.	
Oblique	With an oblique lie, the midwife will feel nothing at the inlet. There is no presentation, position, or variety associated with an oblique lie, which is usually a transitory condition.			

the expected answer to the question "What is the position?" Technically such designations are not accurate, but they serve as shorthand, since such a designation gives not only the position and variety but also the lie and presentation. For example, the designation LOA tells you that the lie is longitudinal, the presentation is vertex, the position is the occiput in the left side of the mother's pelvis, and the variety is the occiput in the anterior portion of the pelvis.

Variety is the same arbitrarily chosen point on the fetus used in defining position in relation to the anterior, transverse, or posterior portion of the pelvis. Table 26-3 summarizes the possibilities.

Transverse and oblique lies in labor are abnormal conditions. They require collaboration with your consulting physician and will most likely necessitate cesarean section. Approximately 0.5 percent of women enter labor with a shoulder presentation.

Of the presentations associated with a longitudinal lie, the most common is the vertex cephalic presentation. It has an incidence of approximately 95 percent. Of these, approximately two-thirds will be positioned with the occiput in the left side of the mother's pelvis (LOA, LOT, LOP) and one-third with the occiput in the right side of the mother's pelvis (ROA, ROT, ROP). Because the head usually enters the inlet with the occiput directed to the transverse portion of the mother's pelvis, the most common position at the onset of labor is left occiput transverse (LOT). Figures 26-6 and 26-7 show left occipital positions.

FIGURE 26-6 Left occiput transverse (LOT).

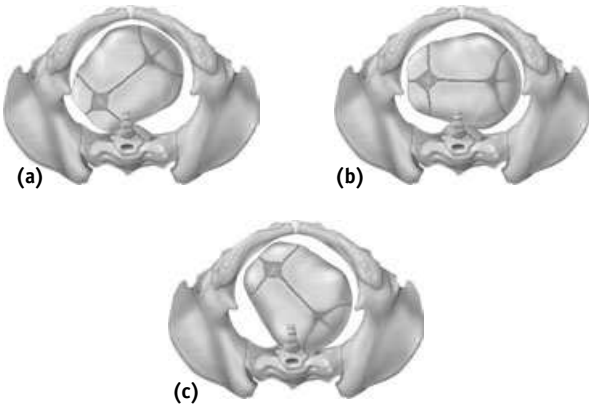

FIGURE 26-7 Varieties of the cephalic left occipital position, view from below. (a) left occipital anterior (LOA); (b) left occipital transverse (LOT); (c) left occipital posterior (LOP).

Approximately 3.0 to 3.5 percent of women enter labor with a breech presentation and 0.5 percent with a face presentation. The midwife collaborates with a physician in the management of women with a breech or face presentation. (See Chapter 30.)

It is thought that the reason the vast majority of presentations are cephalic at term is the interrelationship between the decreased amount of amniotic fluid and the piriform shape of the uterus, with the roomier portion being in the fundus. Although the breech of the fetus (podalic pole) is smaller than the fetal head (cephalic pole), the combination of the breech and the flexed lower extremities is bulkier, because the flexed upper extremities are not as close to the head as the lower extremities are to the breech. Prior to the thirty-second week of pregnancy, the bulkiness of the poles of the fetus is not a factor in fetal presentation because the amniotic cavity is large in relation to the total fetal mass. The incidence of breech presentation at this time may be as high as 50 percent. After the thirty-second week, the combination of fetal growth and the decrease in amniotic fluid causes the fetus to be constrained by the uterine walls. The fetus thus accommodates itself to the shape of the uterus so that the majority of the earlier breech presentations spontaneously convert to vertex presentations by term. Those that do not convert spontaneously may be responding to abnormal uterine shape, extension of the fetal vertebral column, placenta previa, hydrocephaly, or unknown influences. Hydrocephaly must be ruled out, because this condition makes the cephalic pole bulkier than the podalic pole. Accommodation by the hydrocephalic fetus puts the larger cephalic pole in the fundus and accounts for the high incidence of breech presentation when the fetus is hydrocephalic.

Vaginal examination during labor after the cervix has begun to dilate is invaluable for confirming abdominal findings as well as enabling more definitive diagnoses regarding the fetal presentation, position, and variety. This is because you will be able to feel the fetal suture lines and fontanels, or portions of the fetal face, or portions of the fetal breech or external genitalia, or the fetal extremities (hands or feet). Since the cephalic vertex presentations are by far the most common, it is vital to be well versed in the essential landmarks of the fetal skull as indicated in Table 26-4 and Figure 26-8.

Position and variety of the vertex presentation, therefore, are determined vaginally by feeling the anterior or posterior fontanel (its shape and the sutures leading off the fontanel) and identifying which fontanel is in which side and portion of the maternal pelvis. In order to identify which part of the fetal skull you are feeling, it helps to remember that the sagittal suture is the only suture that has the anterior fontanel at one end and the posterior fontanel at the other end.

Adaptation to the Pelvis Vaginal examination during labor also provides other information regarding the adaptation of the fetus to the pelvis, specifically, the synclitism or asynclitism of the fetal head and the extent of any molding and caput succedaneum.

Synclitism/Asynclitism. Synclitism and asynclitism are terms to describe the relationship of the sagittal suture of the fetal head to the symphysis pubis and the sacrum of the mother's pelvis. This relationship is determined when the anteroposterior diameter of the fetal head is in alignment with the transverse diameter of the pelvic inlet, which is the usual case for entry into the pelvic inlet and engagement. This places the sagittal suture line of the fetal skull in the same line as the transverse diameter of the pelvic inlet and the occiput of the fetal head in the transverse portion of the mother's pelvis. *Synclitism* is the term used when the sagittal suture is midway between the symphysis pubis and the sacral promontory. *Asynclitism* indicates that the sagittal suture is directed either toward the symphysis pubis or toward the sacral promontory (Figure 26-9). Determination of whether this is anterior asynclitism or posterior asynclitism is based *not* on which maternal pelvic structure the sagittal suture

TABLE 26-4 Essential Landmarks of the Fetal Skull

Anatomical Part	Description
Bones	
Frontal	There are 2 frontal bones.
Parietal	There are 2 parietal bones.
Occipital	There is 1 occipital bone.
Sutures	
Frontal	The frontal suture is between the 2 frontal bones.
Sagittal	The sagittal suture is between the 2 parietal bones.
Coronal	There are 2 coronal sutures, 1 each between the frontal and parietal bones on either side of the head.
Lambdoid	There are 2 lambdoid sutures, 1 each between the parietal bones and the upper margin of the occipital bone on either side of the head.
Fontanels	
Anterior	Formed by the meeting of the frontal, sagittal, and 2 coronal sutures. The anterior fontanel is roughly the shape of a diamond (◊), and 4 sutures can be felt leading off the anterior fontanel in 4 directions as indicated by the points on the diamond.
Posterior	Formed by the meeting of the sagittal and the 2 lambdoid sutures. The posterior fontanel is roughly the shape of a triangle (∇), and 3 sutures can be felt leading off the posterior fontanel in 3 directions as indicated by the points of the triangle. The occipital bone, which serves as the base of the triangle, can also be felt.

is closer to but instead on which parietal bone is dominant. Therefore, anterior asynclitism occurs when the anterior parietal bone (the one closest to the symphysis pubis) becomes the lowermost part of the presenting part, due to deflection of the head toward the sacral promontory, causing the sagittal suture to lie closer to the sacral promontory. Posterior asynclitism occurs when the posterior parietal bone (the one closest to the sacral promontory) becomes the lowermost part of the presenting part as a result of deflection of the head toward the symphysis pubis, causing the sagittal suture to lie closer to the symphysis pubis. In normal labor, the head usually enters the pelvic inlet with a moderate degree of posterior asynclitism and then changes to anterior asynclitism as it descends further into the pelvis before the mechanism of internal rotation takes place. This sequential change from posterior to anterior asynclitism facilitates the mechanism of descent; it is an accommodation by the fetus to take

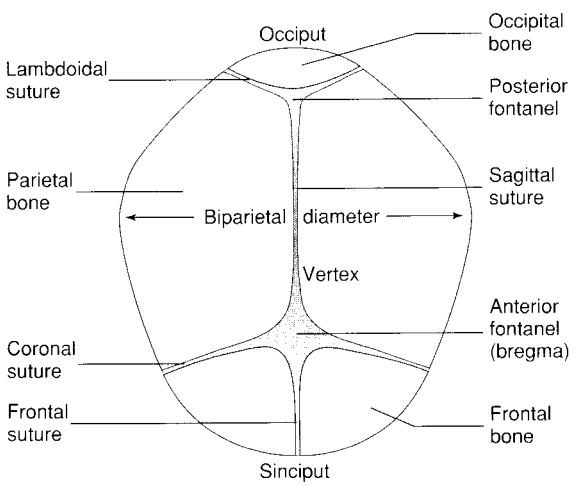

FIGURE 26-8 Fetal skull: Landmarks, bones, fontanels, sutures, and biparietal diameter.

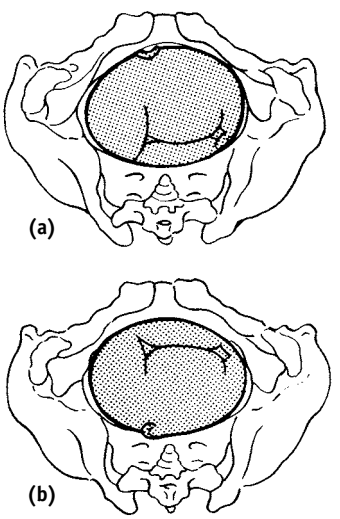

FIGURE 26-9 Asynclitism: (a) anterior; (b) posterior.

advantage of the roomiest portions of the true pelvis.

Molding and Caput Succedaneum. Both molding and caput succedaneum result from pressure exerted on the fetal head by the maternal structures of the birth canal.

Molding is the change in the shape of the head as a result of the soft skull bones' overriding, or overlapping, each other because they are not yet firmly united and movement is possible at the sutures. The shape the head becomes depends on the presentation, because this determines which parts of the skull are subjected to pressure. Because of the prevalence of occipital cephalic presentations, molding usually occurs as the overriding of the parietal bones over the occipital bone, which, in effect, obliterates the posterior fontanel and leaves a ridge. When the parietal bones overlap at the sagittal suture, which is not uncommon, the parietal bone that was anterior in the pelvis overlaps the "posterior" parietal bone, which was depressed because of pressure from the sacral promontory. Therefore, in an ROT position that rotates to ROA, the left parietal bone overrides the right parietal bone, and vice versa for an LOT position that rotates to LOA. In thinking about the overriding of the parietal bones, do not confuse the location of the left and right parietal bones (either anterior or posterior) with anterior and posterior asynclitism. Whether the left or right parietal bone is anterior is based solely on whether the occiput is to the left or right of the pelvis, which then determines which one lies closest to the symphysis pubis and which one lies closest to the sacrum.

Molding involves the entire skull, with overlapping in one area being counterbalanced with movement elsewhere. This creates harmony between the base and the vertex of the skull in order to prevent destructive tension and possible rupture of the cranial membrane, the dura mater.

Caput succedaneum is the formation of an edematous swelling over the most dependent portion of the presenting fetal head. Pressure around the presenting part by the cervical opening produces congestion and edema of the portion of the fetal head over the cervical opening. If the fetal membranes are ruptured and the fetal head (rather than the membranes) is functioning as the dilating wedge against the cervical opening, a greater amount of caput succedaneum will be formed. Caput succedaneum can be differentiated from *cephalhematoma* by the fact that caput succedaneum crosses suture lines as a generalized swelling, whereas a cephalhematoma, which is bleeding beneath the periosteum, may occur over more than one cranial bone but is limited to each individual bone and does not cross any sutures.

The formation of a few millimeters of caput succedaneum is not unusual or abnormal. A small caput succedaneum may be indicative of a somewhat prolonged labor resulting from uterine inertia with weak contractions. Formation of extensive caput succedaneum, which makes the identification of fetal sutures and fontanels impossible, combined with severe amounts of molding is usually seen only when the pressure has been great and labor prolonged; cephalopelvic disproportion must be suspected. A sizable caput may also be seen from positional pressure when the fetal position was occipitoposterior.

Maternal Physiological Changes

A number of normal maternal physiological changes take place during labor. It is important to know those that may be ascertained clinically in order to accurately interpret certain signs, symptoms, and physical and laboratory findings as normal or abnormal during the first stage of labor. These are detailed in Table 26-5, along with their significance in the management of care of the woman during labor.

Maternal Psychological and Behavioral Changes

The maternal psychological and behavioral changes that occur during the latent, active, and transitional phases of the first stage of labor were discussed earlier in this chapter. Unlike the physiological changes that are more general to the first stage of labor, but like the physical changes such as contractions and cervical changes, these psychological and behavioral changes are quite specific as labor goes on. They comprise a means of evaluation of a woman's progress in labor and how she is coping with the demands being placed upon her by labor and the environment within which she is laboring.

In addition to the specific changes, the overall psychology of a woman in labor will vary widely depending on the preparation and anticipatory guidance she has had prior to labor; the support she is receiving from her partner, significant others, family, and caretakers; the environment she is in; and whether this baby is a wanted baby. Many babies are not planned for but the majority of babies are wanted by the end of pregnancy. However, if the

TABLE 26-5 Significance of Maternal Physiological Changes Occurring During Labor

Physiological Change	Significance
Blood Pressure	
Rises during contractions with the systolic rising an average of 15 (10–20) mm Hg and the diastolic rising an average of 5–10 mm Hg	To ascertain the true blood pressure, be sure to check it well between contractions, preferably with the woman in a side-lying position.
Between contractions, the blood pressure returns to its prelabor levels.	
A shift of the woman from a supine to a lateral position eliminates the change in blood pressure during a contraction.	
Pain, fear, and apprehension may further raise the blood pressure.	If a woman is extremely fearful or apprehensive, consider the possibility that her fear (rather than preeclampsia) is causing an elevated blood pressure. Check other parameters to rule out preeclampsia. Give supportive care and medications that will relax the woman before making a final diagnosis if preeclampsia is not readily evident.
Metabolism	
During labor, both aerobic and anaerobic carbohydrate metabolism steadily rises. These increases are due largely to anxiety and to skeletal muscle activity.	
The increased metabolic activity is reflected by an increase in body temperature, pulse, respirations, cardiac output, and fluid loss.	The increase in body temperature, pulse, and respirations is discussed below. The increase in cardiac output and fluid loss affects renal function and necessitates concern for and action to prevent the development of dehydration.
Temperature	
Slightly elevated throughout labor; highest during and immediately after delivery To be considered normal, this elevation should not exceed 1 to 2°F (0.5 to 1°C). It reflects the increase in metabolism that occurs during labor.	A slightly elevated temperature may be normal. If labor is prolonged, however, an elevated temperature may be indicative of dehydration, and other parameters should be checked. Also, if the membranes ruptured prematurely, an elevated temperature may be indicative of infection and cannot be considered normal in these circumstances.
Pulse (Cardiac Rate)	
Marked change during contractions with an increase during the increment, a decrease during the acme to a rate lower than that between contractions, and an increase during the decrement to the rate usual for the woman between contractions.	
The marked decrease during the acme of the uterine contraction does not occur if the woman is in a lateral rather than a supine position.	
The pulse rate between contractions is slightly higher than during the immediate prelabor period. This reflects the increase in metabolism that occurs during labor.	A slightly elevated pulse may be normal. Check other parameters to rule out an infectious process.
Respirations	
A slight increase in respiratory rate is normal during labor and reflects the increase in metabolism that is occurring.	It is difficult to obtain accurate findings regarding respirations as their rate and rhythm are affected by excitement, pain, apprehension, and the utilization of breathing techniques.
Prolonged hyperventilation is abnormal and may result in alkalosis.	Observe the woman's breathing and aid her in controlling it to avoid prolonged hyperventilation, which is evidenced by her feeling tingling in her extremities and feeling dizzy.

TABLE 26-5 Significance of Maternal Physiological Changes Occurring During Labor (*continued*)

Physiological Change	Significance
Renal Changes	
Polyuria is frequent during labor. It may be the result of a further increased cardiac output during labor and probable increase in glomerular filtration rate and renal plasma flow. Polyuria is less pronounced in the supine position, which has the effect of decreasing urine flow during pregnancy.	The bladder must be frequently evaluated (every 2 hr) for distention and emptied to prevent (1) obstruction of labor by a full bladder that prevents descent of the presenting part and (2) trauma to the bladder from prolonged pressure, which will cause hypotonia of the bladder and urinary retention during the immediate postpartal period.
Slight proteinuria (trace, 1+) is common in a third to half of women in labor.	More frequent in women who are primiparas, or have anemia, or are in prolonged labor
Proteinuria 2+ and above is abnormal	Indicative of preeclampsia
Gastrointestinal Changes	
Gastric motility and absorption of solid food are severely reduced. This, combined with a further decrease in the secretion of gastric juice during labor, brings digestion to a virtual standstill and yields a significantly prolonged gastric emptying time. Liquids are not affected and leave the stomach in the usual amount of time. Food ingested during the immediate prelabor period or the prodromal or latent phase of labor will most likely remain in the stomach throughout labor.	A full stomach may cause discomfort and general misery during transition. Women should therefore be instructed not to eat a big meal or drink excessive fluids but to drink and eat at will to maintain energy and hydration.
Nausea and vomiting are not uncommon during the transition phase marking the end of the first stage of labor.	Oral medications are rendered ineffective during labor. Gastrointestinal changes are probably a response to one or a combination of the following factors: uterine contractions, pain, fear and apprehension, medications, or complications.
Hematologic Changes	
Hemoglobin increases an average of 1.2 gm/100 mL during labor, returning to prelabor levels the first postpartum day in the absence of abnormal blood loss.	Don't be falsely reassured that a woman is not anemic if the results of blood tests are borderline and thus be lulled into ignoring the increased risks of the anemic woman during the intrapartal period.
Blood coagulation time decreases and there is a further increase in plasma fibrinogen during labor.	These changes decrease the risk of postpartum hemorrhage in the normal woman.
The white blood cell count progressively increases throughout the first stage of labor by about 5000 to an average total WBC count of 15,000 at the time of complete dilatation. There is no further increase after this.	Increased white cell count is not necessarily indicative of an infectious process when at this level. If much above this level, check other parameters for an infectious process.
Blood sugar decreases during labor, dropping markedly in prolonged and difficult labors, most likely as a result of the increase in activity of the uterine and skeletal muscles.	Use of laboratory tests to screen a woman for diabetes during the intrapartum period would yield most inaccurate and unreliable results.

baby is not wanted, the psychology of the mother may affect the course of labor.

Preparation and anticipatory guidance vary widely depending on the philosophy and experience of the childbirth educator. There is childbirth education that is institution-based and may reflect the attitudes and practices of the institution; there is childbirth education that reflects a plan to birth in a birth center or at home; there is childbirth education that gives knowledge of the process but still leaves the woman subordinate to the institution or the practitioner; there is childbirth education that gives knowledge of the process but uses it to empower the woman to own her body and birth; there is childbirth education that has a set curriculum outline; there is childbirth education that begins with what the participants want to know, discuss, or explore; there is childbirth education that

"teaches from the 'outside,' in other words, how it is perceived and managed by professionals" and there is childbirth education that "prepares a mother for birthing from within . . . what labor and birth will be like from her perspective" [11]. Each type of childbirth education deeply influences a woman's psyche: her self-image, expectations, and self-confidence.

The support that a woman does or does not receive in her birthing environment, including from those who are with her, profoundly affects her psychologically at a time when she may easily feel vulnerable as each contraction and its pain continues to come again and again. The freedom to be herself and to be able to "let go and go with the flow" is critical to her feeling of acceptance and sense of well-being. The support and comfort measures discussed later in this chapter communicate caring, compassion, and a sustaining human presence to a woman.

Management of Care During the First Stage of Labor

Management of care during the first stage of labor includes responsibility for the following:

1. Differential diagnosis of labor
2. Management of false labor and of early labor
3. Initial evaluation of the mother and fetus in labor
4. The 12 basic management of care decisions
5. Continuing evaluation of maternal and fetal well-being
6. Continuing evaluation and facilitation of the progress of labor
7. Bodily and supportive care of the mother and her significant other/family/friends

Many of the activities involved with each of these responsibilities may be going on simultaneously.

Differential Diagnosis of Labor

In making a diagnosis of labor, you must differentiate not only between true and false labor but also between labor and any discomforts or complications that masquerade or can be misinterpreted as labor. These most commonly include urinary tract infections and what may be called "the general miseries of the end of pregnancy," which some women have to a rather severe degree. Abruptio placentae with a posterior placenta should also be considered (see Chapter 24).

A woman with false labor may be experiencing considerable discomfort and exhaustion from days of false labor contractions. Such contractions are differentiated from true labor contractions in that false labor contractions do not increase in frequency, duration, and intensity; they are irregular and of short duration; they are rarely intensified and may actually be relieved by walking; and they are usually felt in the lower abdomen and groin. True labor contractions may start as irregular and of short duration but then become regular with increased frequency, duration, and intensity; they are intensified by walking, and they are usually felt as radiating across the uterus and the lower back. At times, though, it is not easy to differentiate between false and true labor contractions. The actual diagnosis of false labor is based on the definition of labor as progressive cervical change. The fact that false labor contractions do not result in cervical effacement and dilatation leads to the diagnosis being made on the basis of a lack of cervical change.

The suprapubic, flank, and back pain that may be associated with a urinary tract infection are frequently mistaken by both woman and examiner as symptomatic of labor. Added to this is the possibility of misinterpreting the frequency and urgency of urination associated with urinary tract infection as merely that experienced by the woman from pressure of the enlarged uterus on the bladder, especially if lightening has occurred. A urinary tract infection should be suspected in this situation in the absence of uterine contractions and cervical effacement and dilatation. This picture may be complicated in the presence of false labor contractions, and a diagnosis of urinary tract infection can be missed in the diagnosis of false labor.

When you suspect a urinary tract infection, you should take a careful history of any previous urinary tract infections, fever, chills, nausea and vomiting, frequency, urgency, dysuria, suprapubic pain, flank pain, lower back pain, and hematuria; you should conduct a physical examination for temperature, suprapubic pain, and CVA tenderness; and you should collect a urine specimen for routine analysis, culture, and sensitivity. These steps provide the necessary database from which to confirm or rule out the infection. In the meantime, true labor is ruled out in the absence of cervical change and false labor is ruled out in the absence of irregular uterine contractions that are relieved by walking.

The general miseries of the end of pregnancy are frequently seen in, but not limited to, women who have been having periodic episodes of false

labor. These women are terribly uncomfortable; have muscular aches and pains, particularly in the back, abdomen, and legs; walk and move with great lassitude and difficulty; haven't been eating well; are somewhat emotionally depressed because they are tired of being pregnant; are physically tired; are not sleeping well; and generally "just don't feel good." Labor is absent, as is any causative disease process for these symptoms.

Management of False Labor and of Early Labor

The management of care of the woman with false labor and of the woman with the general miseries of the end of pregnancy is the same. Both require a large dose of patience, understanding, explanations, and tender, loving care. These requirements also extend into the home, and family members need to offer support and patience.

Once fetal well-being is assured and labor is ruled out, send the woman home with some suggested comfort measures. Instruct her to soak in a tub of warm water, filled enough to cover her abdomen; then, after getting out of the tub, to drink a hot drink of her preference (tea, coffee, milk, chocolate) with sugar, or a glass of wine; and then to go to bed to sleep. (If a family member can give her a backrub before she sleeps, it will also help her feel more comfortable.) The tub bath relaxes and soothes her aching muscles by dilating the blood vessels, thus increasing blood flow and oxygenation to the area, and the motion of the water is psychologically soothing. She will need help from family members to get in and out of the tub. The hot drink, made for her by a family member, is the time-honored method for facilitating sleep. The addition of sugar to the drink provides needed calories and energy to the body's cells. A glass of wine or sherry also is often used to promote relaxation. The back rub given by a family member again gives relief to aching muscles and bespeaks tender loving care. If a woman is unable to sleep with nonmedicinal methods, 25 to 50 mg of diphenhydramine (Benadryl), available over-the-counter, may be used to promote sleep.

It is frequently difficult to differentiate between false labor and the early latent phase of labor. The management of care of such a woman, in the absence of any complications, will vary according to the setting in which she will labor and deliver. If she plans to deliver in a hospital, the plan will vary according to hospital policies and facilities, distance the woman lives from the hospital, availability of transportation, her and her family's coping abilities, and the woman's preference. If, for example, the hospital has a unit for labor observation or early labor, admission to this unit is appropriate. If, however, the hospital does not have such a unit and has a policy that patients are not to be admitted to the labor and delivery suite until in active labor, unless the membranes are ruptured, or except with complications, then you must decide whether to keep the woman in the hospital emergency room or area where you examined her or to send her home until labor is more definitively established. In such a situation, a compromise is generally struck between realities and the philosophy that a woman will probably feel and cope better in the more pleasant, familiar surroundings of her home.

Since walking may stimulate true labor or relieve false labor, the woman is usually asked to walk outside or in designated areas of the hospital and return to be rechecked in 1 to 2 hours. If no change in the cervix is noted during this repeat examination and if the woman lives nearby, has no transportation problems, and wants to go home, she is managed for false labor and sent home. If, however, the woman lives a great distance away and you are still unable to make a diagnosis of false labor or early latent phase labor, the woman may be asked to walk for another couple of hours and again be rechecked before a final decision is made to send her home. A woman who lives many miles from the hospital may prefer to walk for hours in the hospital until she is convinced that this is false labor rather than have the worry that she might not return in time and might deliver either at home or en route. A combination of lack of cervical progress and exhaustion will often make the woman decide to go home; she should be encouraged to follow the regimen for false labor so that she can get some much-needed rest.

Management of the woman in the early latent phase of labor again varies according to the setting in which she will labor and give birth. If she plans to deliver in a hospital, the management of care varies according to hospital policies, hospital facilities, distance the woman lives from the hospital, availability of transportation, the coping abilities of the woman and her family, and the woman's preference. If the hospital has an early labor unit, admission to it is appropriate. This enables the woman to undergo routine admission procedures and spend her early labor in a more homelike atmosphere. Comfortable chairs for her and her significant other; materials and personnel to explain the progress of labor and helpful breathing and re-

laxation techniques; diversions to help pass the time, such as playing cards, books, television, and magazines; and freedom to walk and move around are basics in such a unit. If the hospital does not have such a unit, a woman who lives nearby and has ready access to transportation may prefer to go home and return to the hospital when her labor is more active. A woman who lives some distance from the hospital may have friends or relatives with whom she would prefer to spend this period of early labor. Even if a hospital does not have a 4-centimeter dilatation admission requirement, some women who live too far away to return home for early labor prefer to walk outside or in designated areas of the hospital; the midwife may recommend that she visit the cafeteria or snack shop for tea or coffee with sugar or fruit juice before being admitted to the labor and delivery suite. Any time a woman in early labor who plans to deliver in the hospital enters the active phase of the first stage of labor, ruptures her membranes, or develops signs and symptoms of a complication, she is admitted to the labor and delivery suite.

Admission When a woman is admitted to the labor and birth suite she undergoes an admission procedure. This procedure varies from hospital to hospital but generally includes the following:

1. Having the woman change from street clothing to a hospital gown
2. Tagging and marking of the woman's personal belongings
3. Putting an identification band on the woman
4. Filling out of chart forms and signing of necessary permission forms
5. Admission orders
6. Initial evaluation of the woman and fetus in labor—history, physical and pelvic examinations, and laboratory tests

The admission orders include not only the routine laboratory tests but also your initial management decisions.

In an out-of-hospital setting the woman wears her own clothing and institutional procedures are unnecessary. In the home setting the word "admission" takes on a different meaning, as the woman and whomever she wants with her admit *you* into *her* environment.

Initial Evaluation of the Mother and Fetus in Labor

When a woman presents herself for examination thinking that she is in labor, you need to evaluate her possible labor status, assess her well-being and that of the baby, screen for immediate complications, and, on the basis of these findings and other factors, make a decision as to whether the woman is in labor or needs any medical help or intervention.

Labor status refers to just that information needed to determine where a woman is in the progress of her labor and to anticipate her continued progress. It has nothing to do with the well-being of either the mother or the baby. The items in Table 26-6 that pertain to evaluation of labor status are indicated with an asterisk (*).

If you determine that the woman is in labor—whether at home, in a freestanding out-of-hospital birth center, an in-hospital birth center, or the labor and delivery suite of a hospital—a complete evaluation of her condition and the condition of her baby, including a history, physical and pelvic examinations, and laboratory tests, is conducted. This evaluation is more comprehensive when done in a hospital, where the midwife may not have seen the woman before or the woman may not have had any prenatal care. A woman in a home birth practice or an out-of-hospital birth center is more apt to have been closely followed antepartally by the midwife who is with her in labor. This woman would be well known to the midwife and would not require such an extensive history and examination, but the midwife should completely review the same information and evaluate her and her baby's current condition and status of labor.

History The history is similar to the history outlined in Chapter 2, with the additions outlined for history in Chapter 22 and in Table 26-6.

If the woman's prenatal record is available, it is often used as the source of information for the history, with the exception of the labor history. Specifically, identifying information, present pregnancy history, past obstetric history, past medical and primary health care history, and family history can be reviewed from the woman's prenatal record. This spares the woman from having to reiterate history she has given before, from being disturbed at a time when she is coping with the demands and stresses placed upon her by her labor condition and situation, and from being disrupted while concentrating on her breathing during contractions. However, a few critical items of history should be double-checked, specifically, the existence of any of the following: drug allergies, blood transfusions and reactions, and major obstetrical or medical complications.

TABLE 26-6 Database for Diagnosis of Labor and Initial Evaluation of the Mother and Fetus in Labor

Item	Significance
History	
*Age	An age of under 16 or over 35 predisposes the woman to a number of complications. Under 16 increases the incidence of preeclampsia. Over 35 increases the incidence of chronic hypertension (which underlies an increased incidence of preeclampsia and abruptio placentae); Type II diabetes (which underlies an increased incidence of gestational diabetes as well as diagnosed Type II diabetes); prolonged nulliparous labor; cesarean section; preterm delivery; IUGR; chromosomal anomalies; and fetal death.
*Gravida and para	Need explanation of gravida and para numbers for this woman to identify potential problems with this birth and postpartum. Parity has an effect both on the duration of labor and on the incidence of complications. A cervix that has been completely dilated in a previous labor offers less resistance to being dilated again, thereby shortening the length of labor. In addition, multiparas have more pronounced fundal dominance with their contractions and more relaxed pelvic floors, which offer less resistance to the passage of the baby and decrease the length of labor. However, the duration of labor in grand multiparas may progressively increase with greater numbers of babies, presumably as a result of changes in the uterine musculature—a condition that is often referred to as "exhaustion of the uterine muscle." It is not uncommon to see a woman having a longer labor with her eighth full-term baby than she had with her first baby. Increased parity increases the incidence of abruptio placentae, placenta previa, uterine hemorrhage, maternal mortality, and perinatal mortality. Double ovum twinning increases in Gravida 5 and above.
*Time of onset of contractions and the frequency and duration of the contractions from onset to present	This information is necessary in order to establish the start of labor, usually timed from when the contractions became regular, and to differentiate between true and false labor contractions. False labor contractions do not increase in frequency, duration, and intensity; are irregular; and are of short duration. True labor contractions may start as irregular and of short duration but then become regular with increased frequency, duration, and intensity.
*Intensity of the contractions when lying down contrasted to when walking around	This information helps to differentiate between true and false labor contractions. True labor contractions are intensified by walking, whereas false labor contractions are rarely intensified by walking and may actually be relieved.
*Descriptions of the location of discomfort or pain felt with contractions	This information also helps to differentiate between true and false labor contractions. False labor contractions are usually felt in the lower abdomen and groin. True labor contractions are usually felt as radiating across the uterus from the fundus to the back.
Fetal movement	To assess fetal well-being.
*Length of previous labor	The length of a previous labor is a good indication of the potential length of this labor, allowing for the differences between a primigravid and secundigravid labor and the labor of increasing great parity.
AP, IP, PP complications during previous childbearing experiences	To identify potential problems with this birth and postpartum.
Delivery method of previous deliveries	To identify previous cesarean section or operative vaginal deliveries.
Size of largest and smallest previous babies	The size of the largest baby delivered vaginally ensures the adequacy of the woman's pelvis for up to that size baby. It also provides baseline information for anticipating possible complications when compared with the estimated fetal weight of this baby and is important for decision-making concerning the route of delivery in breech presentations. A woman who has a history of small babies by the same father will tend to have a small baby this time. This may, however, be affected by nutrition, hypertension, or diabetes.
EDB and present weeks of gestation	These are baseline data for evaluating gestational size, whether labor is at term or premature, and possible complications for the weeks of gestation.
*Absence, presence, or increase in bloody show	Bloody show is a premonitory sign of labor. An increase in bloody show is indicative of impending second stage of labor.

Starred items pertain to evaluation of labor status.

TABLE 26-6 Database for Diagnosis of Labor and Initial Evaluation of the Mother and Fetus in Labor (*continued*)

Item	Significance
Absence or presence of vaginal bleeding	Bleeding is abnormal. Since vaginal examination is almost always contraindicated in the presence of bleeding, the midwife must ask the woman if she has had any vaginal bleeding prior to doing a vaginal examination. Frank bleeding requires physician consultation and collaboration or referral.
*Status of membranes	Ruptured membranes are a premonitory sign of labor. Because ruptured membranes predispose both mother and baby to increased risk of intrauterine infection, a history of ruptured membranes demands determining by examination whether they have indeed ruptured. Women are not always clear as to whether their membranes have ruptured because a slow leak can easily be confused with incontinence of urine. A report of a sudden gush of water that ran down her legs and filled her shoes and subsequently necessitated her wearing a sanitary pad, or of wetting of clothes, is a good indication that the membranes have ruptured.
Any prenatal problems	It is essential to screen the woman quickly for antepartal complications that may affect the intrapartal period (e.g., preeclampsia, anemia) or masquerade as signs of labor (e.g., urinary tract infection).
When she last ate	Information will be wanted by anesthesiologist in the event of surgery. Also useful for assessing energy reserve and fluid status.
Physical Examination	
Vital signs: BP, T, P, R	An elevated or lowered blood pressure is indicative of the hypertensive disorders of pregnancy or shock, respectively. An elevated systolic but normal diastolic blood pressure may indicate anxiety or pain. An elevated temperature is indicative of an infectious process or dehydration. An elevated pulse may indicate infection, shock, anxiety, or dehydration. An elevated respiratory rate may indicate shock or anxiety.
Weight	Weight is taken to obtain the total weight gain for pregnancy.
FHT	To assess the status of the baby. A fetal heart rate below 120 or above 160 may be indicative of fetal distress and warrants immediate evaluation.
Fetal movement	To assess fetal well-being.
*Contraction pattern	The frequency, duration, and intensity of the contractions must be accurately assessed to determine labor status.
*Engagement	Determined by abdominal palpation. An unengaged or unfixed head on a primigravida in labor is indicative of possible cephalopelvic disproportion. Such a finding requires repeating clinical pelvimetry during the vaginal examination and evaluation in relation to the estimated fetal weight.
*Estimated fetal weight and fundal height, and abdominal girth when indicated	In relation to the weeks of gestation. A smaller than expected estimated fetal weight (EFW) and fundal height indicate either that the woman's dates are in error, a small-for-dates baby, or oligohydramnios. A larger than expected EFW and fundal height indicate that the woman's dates are in error, a large baby (indicative of diabetes), multiple gestation, or polyhydramnios. A large baby also forewarns you of (1) the possibility of postpartum uterine atony producing hemorrhage or (2) possible shoulder dystocia. An EFW 1 or more pounds larger than the woman's preceding babies, even though not excessive in size, also alerts you to the possibility of difficulty with delivery of the shoulders. Abdominal girth is indicated if you suspect multiple gestation or polyhydramnios.
*Lie, presentation, position, and variety	To ascertain an abnormal lie (i.e., transverse), presentation (i.e., breech), or position (i.e., mentum, brow, sinciput). Also to determine variety, as a posterior variety may lengthen or increase the discomfort of the first stage of labor. A woman in even very early labor must be admitted to the hospital if she has a transverse lie. A primigravida with a breech presentation is at risk and should also be admitted.
Abdominal scars	Obtain explanation to ascertain integrity of her uterus.
Edema of the extremities	This is one of the classic signs of preeclampsia. The midwife should check for and evaluate any ankle, pretibial, finger, or facial edema. Edema of the feet and ankles alone may simply be dependent edema resulting from the decrease in venous blood flow caused by pressure from the enlarged uterus.

TABLE 26-6 Database for Diagnosis of Labor and Initial Evaluation of the Mother and Fetus in Labor (*continued*)

Item	Significance
Reflexes and clonus	Hyperreflexia (3+, 4+) is one of the signs of severe preeclampsia. Clonus is usually seen with impending or actual eclampsia.
Pelvic Examination	
*Effacement and dilatation	To determine whether progressive cervical change has occurred and diagnose labor. Also to determine what stage and phase of labor the woman is in, if in labor.
*Position of the cervix	The cervix is usually far back and directed posterior prior to labor. Movement of the cervix so it is directed forward in a midline position indicates readiness for, or entry into, labor.
*Bloody show	Increased bloody show is a sign of impending second stage.
*Station	To determine descent of the fetal head. Descent of the fetal head is one of the mechanisms of labor and is indicative of progress and pelvic adequacy.
Molding and caput succedaneum	To ascertain fetal adaptation to the mother's pelvis.
*Lie, presentation, position, and variety	To confirm abdominal findings. Sometimes it is easier to obtain these findings on vaginal examination because the presenting part—suture lines, fontanels, skull bones (if a cephalic presentation), a hand, or a foot—can be felt directly.
Synclitism/Asynclitism	To ascertain fetal adaptation to the mother's pelvis.
*Status of membranes	To confirm or rule out a history of ruptured membranes or detect a rupture of membranes not reported for reasons stated under *History*.
Vaginal orifice and perineal body	To evaluate thickness, length, and stretchability to ascertain possible need for an episiotomy.
Clinical pelvimetry	To assess pelvic adequacy.

If the woman is being admitted for a reason other than labor—such as premature rupture of the membranes, vaginal bleeding, or a medical complication—or if any finding during the examination is indicative of a complication, then the appropriate related history needs to be taken (see the section on Chief Complaint and History of Present Illness in Chapter 2).

Physical and Pelvic Examination A screening physical examination is done on all women admitted to the hospital. This not only provides up-to-date baseline data but also screens for any infectious disease and for major medical problems that might affect a safe intrapartum period for the women.

If the woman's prenatal record is available, the physical examination that was done during her initial antepartal visit is reviewed for any medical abnormalities or disease (see Chapters 2 and 22). If the woman has been closely followed throughout her antepartal course by a consistent care provider, a repeat of the total gross screening physical examination is not necessary. If the woman entered the labor and birth suite in late active labor without prenatal care, an abbreviated gross screening examination is done and a more comprehensive review of systems and physical examination can be performed postpartally.

A finding indicative of a complication requires further physical examination pertaining to that complication. For example, an elevated blood pressure, with or without the presence of edema, is an indication for eliciting and evaluating deep tendon reflexes as well as taking a history for symptoms of preeclampsia.

In addition to the screening physical examination, thorough abdominal and pelvic examinations are essential for evaluation of labor status and the well-being of the fetus. These are detailed in Table 26-6. Other vaginal findings may be ascertained while following a woman's progress during labor. If, however, there is any reason to question the adequacy of a woman's pelvis at this time—because of a larger baby than she previously had, or a large baby in a primigravida, or a small body frame, or an unengaged head in a primigrvida—now is the time to do clinical pelvimetry. It is easier to perform clinical pelvimetry with the woman on an examining table than in a bed.

Laboratory Tests The laboratory tests ordered on a woman's admission to a hospital may vary by pol-

icy from setting to setting, but generally include the following:

Hematocrit—ordered or done *stat* by the midwife
VDRL
Urinalysis—minimum of dipstick test for protein, glucose, and acetone; in some settings a urine specimen is collected and sent to the laboratory for routine microscopic examination or done *stat* by the midwife.

In addition, a type and antibody screen may be drawn, even, by hospital policy, as a repeat of prenatal determination, or if the woman had no prenatal care. A blood sample for cross-match may also be drawn and held for use if the woman's clinical situation requires a blood transfusion.

The blood for the laboratory tests may be drawn by the midwife (see Chapter 47). If the woman will be having an intravenous infusion, the blood specimens are obtained at the same time the IV is started (see Chapter 48).

The woman's prenatal record is reviewed for the results of the following laboratory tests and adjunctive studies done during pregnancy. Results are recorded in the admission note.

Blood group (ABO)
Rh factor
Antibody screen
Serology
GC and chlamydia culture
Hepatitis screen (HBsAg)
HIV screen
Pap smear
Group B Streptococcus (GBS) status
Last hemoglobin and hematocrit
Last urinalysis
Glucose screen
Rubella titer
Varicella antibody screen
Sickle cell screen
Tuberculin screen
Any special tests

The Twelve Basic Management of Care Decisions

The 12 basic management decisions are the decisions that routinely may be made about each woman in labor and individualized for that woman. Some of these decisions are relevant only to a hospital setting and are not an issue if the woman is giving birth at home or in a freestanding out-of-hospital birth center. Some of these decisions may be predetermined by existing policies in the particular hospital setting where labor and birth is taking place. Other management decisions besides these may need to be made, depending on the woman, her condition, her situation, and the setting. The following 12 decisions are the most common management decisions made in a hospital after a woman is admitted to the labor and delivery unit. Their applicability (if any) to the home or birth center settings is included in the discussion of each.

1. Whether the woman may have food or fluids by mouth and, if so, precisely what is allowed
2. Whether the woman is to have IV access
3. Whether the woman has any position or ambulation limitations and, if so, what these are
4. Whether to give the woman oral/IM/IV medication and, if so, what, how much, and when
5. Whether the woman is to have epidural analgesia/anesthesia
6. The frequency with which the woman's vital signs (blood pressure, pulse, and temperature) are to be checked
7. The frequency with which the fetal heart tones are to be checked and how this will be done
8. The frequency with which vaginal examinations are done
9. Identification of the woman's significant others and their roles
10. Whether to artificially rupture the membranes and, if so, when
11. Determination of whether there is a need for physician consultation or collaboration
12. When to prepare for birth

Many of these decisions are made over again several times during the course of labor as the woman's condition changes and labor progresses. Each must be considered in relation to the individual woman at a given time. However, there are specific factors to consider in making each decision. The management decisions are made in the course of carrying out the various management responsibilities identified at the beginning of this section and depend on evaluation of the information in the database described at the beginning of this chapter. The first five decisions are discussed separately. Decisions 1 through 3 and 6 through 8 are usually included in the admission orders. Decisions 6 through 12 are discussed within the context of the management responsibilities for continuing evaluation of maternal and fetal well-being, continuing evaluation and facilitation of the progress of labor,

and bodily and supportive care of the mother and her significant other/family/friends.

Foods and Fluids by Mouth The provision of foods and fluids by mouth during labor is a subject of long-standing controversy. The general standard for the past 40 or 50 years has been for the woman to have no food or fluids by mouth (NPO), the rationale being that having an empty stomach reduces the risk of aspiration pneumonia in the event of need for general anesthesia. There are several flaws in this thinking, however; the research it is based on is also flawed [12].

There has been some loosening of the NPO standard. The thinking promulgated by those brave enough to challenge the standard was that solid food was the real problem, as it would remain in the stomach throughout labor because of decreased gastric motility, gastric absorption, and secretion of gastric juice during labor, but that liquids were not affected and left the stomach in the usual amount of time. Liquids, therefore, were acceptable intake for women during labor in the hospital and the woman could have sips of water, tea with sugar (for energy), or athletic drinks. The liquids would supplement what few calories the woman could get from her carefully packed bag of hard candies (or lollipops to avoid aspiration). Eating and drinking have always been self-determined by women who labor and give birth at home and birth centers have always been less restrictive than hospitals.

The facts are that fasting increases the concentration of hydrochloric acid, which is the dangerous substance in aspirate; women have more energy and are better hydrated when they have eaten; women who are in a situation in which they can eat as they wish, often eat early in labor but generally don't want much other than liquids during active labor; the volume of stomach contents and gastric juice varies widely regardless of the interval since the last intake; when there is pulmonary aspiration there is likely to have been difficult or failed intubation; and the few statistics for anesthesia-related maternal morbidity and mortality are often not specific as to the cause [12–14].

Women having their babies at home eat at will. Freestanding out-of-hospital birth centers have kitchens for the woman and her family to use (see Figure 26-10). Providing sustenance during labor in the hospital is reasonable. A standard of eating and drinking at will for women in normal labor is warranted. Women need to be warned that excessive fluids may produce nausea and discomfort. Large quantities of chilled, sweetened fruit juices can produce gas and possibly cause nausea and vomiting.

FIGURE 26-10 Kitchen in the Family Childbirth Center, New Haven, Connecticut.

Intravenous Access The purposes of intravenous access are twofold: (1) as a lifeline for medications, fluid, or blood in the event of an obstetric disaster and (2) as a means of maintaining maternal hydration. Intravenous access is mandatory if any of the following conditions are present; some of which require continuing infusion:

1. Gravida 5 or greater
2. An overdistended uterus for any reason, including
   a. multiple gestation
   b. polyhydramnios
   c. an excessively large baby (estimated at 9 pounds or more)
3. A pitocin induction or augmentation
4. History of previous postpartum hemorrhage
5. History or presence of any other condition that predisposes the woman to immediate postpartal hemorrhage
6. Maternal dehydration or exhaustion
7. Positive maternal Group B Streptococcus status requiring IV antibiotics in labor

8. Maternal temperature greater than 100.4° F in labor
9. Any obstetric or medical condition that is life threatening, such as abruptio placentae, placenta previa, ruptured uterus, preeclampsia, or eclampsia
10. Epidural analgesia/anesthesia

The decision of whether to start an intravenous infusion on a woman other than one for whom it is mandatory becomes, in practice, largely a matter of what the individual clinician believes and is comfortable with in consultation with the woman. Some clinicians believe "it is better to be safe than sorry" and want all of their clients to have an IV. Most midwives believe it is unnecessary to subject all women to the pain, bother, and restrictions of an IV and want none of their clients to have an IV unless there is an indication for it. These midwives, however, reserve the right to start an IV in the event the woman's condition changes such that either maternal hydration cannot be maintained with oral fluids (e.g., too much nausea and vomiting for retention of oral fluids) or complications are now an anticipated possibility.

A compromise used by some midwives is to insert a "heparin lock" (a capped intravenous catheter). This may be used to draw the admission lab work and then left in the vein without attaching IV fluids and tubing. Thus, only a single needle stick needs to be done, minimizing discomfort for the woman. If there is no indication for IV hydration in labor, it does not interfere with the mother's ability to move about. If IV antibiotics are needed, they can be administered over a brief period of time, after which the tubing is disconnected. If IV access becomes necessary, administration of fluids or blood can be done quickly with minimal discomfort to the woman and maximal efficiency for the midwife or nursing staff.

The usual intravenous solution for a woman in labor consists of 1000 cc D_5W or D_5RL given at 125 cc per hour. This may vary if the woman is mildly dehydrated, in which case approximately 300 cc may be run in and then the IV slowed to 125 cc per hour. IVs for women in labor should always be started with an intravenous catheter (see Chapter 48). In contrast to a butterfly needle or a straight needle, an intravenous catheter permits the woman to more freely move her arm without trauma to the involved blood vessel and has the best chance of staying in the vein should she become physically active during labor. It also allows easier administration of large amounts of fluids or a blood transfusion.

Position and Ambulation A woman in labor should assume a position that is comfortable for her, provided that there are no contraindications to it. Positions may include supine (with the head of the bed at any angle of inclination, or flat), lateral recumbent, knee-chest, all-fours (hands-knees), sitting, standing, walking, and squatting.

The position a woman assumes may aid the rotation of the fetus from a posterior position to an anterior position. Any position that directs the uterus forward (anterior) helps gravity bring the heavier back side of the fetus forward toward the lower side of the woman's abdomen. Such positions include leaning forward over a birthing ball or, if in bed, over an overhead table; leaning forward against a support person while standing; the hands-knees position; and the knee-chest position. If a woman is in bed, lying in a left lateral recumbent/Sims'/semiprone position will help her fetus rotate anteriorly from a right occipital posterior position; lying in a right lateral recumbent/Sim's/semiprone position will help her fetus rotate anteriorly from a left occipital posterior position.

A woman in labor should be able to ambulate when and for as long as she desires, provided there are no contraindications. Walking in early labor may stimulate labor. Many women experience relief and cope with their labor better when they can walk. Being free to walk, sit in a chair, use the toilet, and so forth is certainly more conducive to a comfortable and progressive labor oriented to normal processes than is the sickness orientation of being confined to bed.

There are, however, times when the woman should not be out of bed or ambulating, among them the following:

1. When the membranes are ruptured and the fetus is either small (under 2000 grams) and unengaged or in a footling or ill-fitting breech presentation, or in a transverse lie. In such events there is a risk of cord prolapse, which is increased if the woman is upright. Even a supine position with the head of the bed, including pillows, elevated higher than 20 to 30 degrees further increases the risk of prolapsed cord. The lateral recumbent position and the knee-chest position are good alternatives to the supine position in this situation.
2. When the woman has been medicated with any drug that might make her lightheaded, dizzy, or unsteady on her feet.
3. During rapidly progressive labor, late first stage labor in multiparas, or second stage labor in primigravidas, unless the woman and you have

planned for her to give birth squatting or standing.

4. When a woman has any obstetric or medical complications requiring that the woman remain in bed, (e.g., abruptio placentae, placenta previa, severe preeclampsia).

The lateral recumbent position (Figure 26-11) has several beneficial effects:

1. Better coordination and greater efficiency of uterine contractions because they are stronger and less frequent than when the woman is in a supine position
2. Facilitation of kidney function (urine flow is decreased in the supine position)
3. Facilitation of fetal rotation in posterior positions
4. Relief of uterine pressure on, and compression of, the major maternal blood vessels (the inferior vena cava and the aorta), which may result when the woman is supine

FIGURE 26-11 Father/husband supporting woman in active labor. The woman is in the left lateral recumbent position.

These beneficial effects can be used to good advantage and the woman should assume the lateral recumbent position in the following situations:

1. Maternal supine hypotensive syndrome
2. Fetal distress (to reduce uterine activity, relieve pressure on the umbilical cord, or eliminate hypoxia resulting from maternal supine hypotensive syndrome)
3. ROP or LOP fetal positions if long arc rotation is slow; if the fetal position is ROP the woman should be on her right side, if the fetal position is LOP the woman should be on her left side
4. Severe preeclampsia (for best urine flow)
5. Mild uterine hypertonicity or ineffectual uterine contractions

Medication (Oral, IM, IV) *Commonly Used Drugs and Practices.* Medication may be used during labor for one or all of the following purposes: pain relief, decrease of anxiety and apprehension, sedation, and control of vomiting. The drugs most commonly used by midwives and the purposes they serve are listed in Table 26-7.

The midwife must make several decisions regarding medication during labor:

1. Whether to give a medication
2. Which medication to give
3. Dosage of the medication to be given
4. Route to use in giving the medication, if there is a choice
5. When to give how much of what medication by what route

This final decision summarizes the other decisions and emphasizes the importance of the timing in giving the medication in relation to the status and progress of labor.

The midwife is not limited to a single dose of a single medication. She or he may mix drugs (adding them together), divide doses, and repeat doses in accord with the midwife's prescriptive authority or

TABLE 26-7 Medications Commonly Given During Labor

Trade Name (Generic Name)	Classification	Pain Relief	Decrease Anxiety and Apprehension	Sedation	Antiemetic
Demerol (meperidine)	Narcotic analgesic	X		X (mild)	
Nubain (nalbuphine)	Narcotic analgesic	X		X (mild)	
Phenergan (promethazine)	Ataractic		X	X (moderate)	X (moderate)
Stadol (butorphanol)	Narcotic analgesic	X		X (moderate)	
Vistaril (hydroxyzine)	Ataractic		X	X (moderate)	
Seconal (secobarbital)	Barbiturate sedative		X (mild)	X	X (mild)

practice guidelines without consulting a physician. Remember that the ataractics (tranquilizers) potentiate the action of the narcotic analgesics. The most common medication practices of midwives are summarized in Table 26-8.

Factors Affecting Medication Decisions. What the midwife decides to do regarding medications will be based on consideration of the following factors.

Woman's Desire for Medication. Some women want as much medication as they can get. Usually such women do not understand why you cannot give them enough to take the pain away, even after you explain several times. Generally such women are having a difficult time coping with their labor, are quite frightened, and have had little to no education or preparation regarding childbirth.

In contrast are the women who have read extensively, attended preparation for childbirth classes, practiced breathing and muscle techniques for labor, and want to experience as much of the labor as they can without medication. Some of them are adamantly opposed to any medication. However, "prepared childbirth" means the woman's knowledgeable, active participation in the natural, normal processes of childbearing—it does *not* mean childbirth without medication. Women who are natural childbirth devotees who have lost sight of the meaning of prepared childbirth and have distorted it to mean childbirth without medication may suffer tremendous and damaging feelings of failure and guilt if they "succumb" and express a need for medication during labor. Such women need help in revising their definitions and expectations of themselves and in accepting their own behavior. Medication that takes the edge off the pain but leaves the woman fully aware and still able to participate actively in her experience not only can contribute to a successful birth experience but also is desirable for a woman who needs it, because it may be just what enables her to stay in control of herself and to continue coping with the demands of her condition and situation.

TABLE 26-8 Common Practices in Medication Administration During Labor

Drug	Single Dose and Route	General Timing
Demerol	50 mg IM	Active labor
	12.5–25 mg IV	Active labor
Nubain	10–20 mg SQ or IM or IV	Active labor
Morphine	10–15 mg IM or IV	Prodromal labor or prolonged latent phase Hypertonic uterine dysfunction
Phenergan	25–50 mg IM or IV	Early or active labor, or both
Stadol	1–2 mg IM or IV	Active labor
Vistaril	50 mg IM	Early or active labor, or both
Seconal/ Nembutal	100 mg po	False labor
	100 mg IM	Early labor

The art of medication during labor comprises achieving a balance between the woman's desire and need for medication and your own need, as her midwife, to facilitate her coping abilities within the parameters of safety. In order to do this you must know the woman's viewpoints and preferences regarding medication during labor. Ideally the two of you have discussed this prior to labor as part of providing continuity of care; however, this is not always the situation. You must be careful not to assume or impose your own values and beliefs regarding medication. Ask the woman what she wants and then strive to practice the art of medication within the limits of safety and her desire.

Labor Status. When the medication is given is vitally important. The midwife should observe the following principles:

1. Evaluate the progress of labor carefully and time the medication so it will *not* be at its peak action at the time the baby is born. Otherwise the baby might be sleepy and have some respiratory depression. This principle does not apply to very small doses of medication (e.g., 25 mg of Demerol) as long as this dose is not the last of a series of doses but is rather a single and only dose for the total of labor, as might occur if the woman arrives in the labor and delivery suite far advanced in labor.
2. Do not give a narcotic analgesic until the woman is in active labor. If given before the contractions are well established, as in the latent phase of labor, the drug will most likely render the contractions ineffectual by diminishing their frequency, duration, and intensity. In effect, although you have made the woman extremely comfortable, you have lengthened the total labor by several hours (for which she would probably not thank you if she knew). If the membranes are ruptured, lengthening labor could be dangerous. After the woman is in well-

established active labor, a narcotic analgesic will not affect the contraction pattern.

3. The ataractics do not affect uterine contractions and will not slow down or delay the progress of labor. In fact, because ataractics have a calming effect, progress of labor is often facilitated as the woman relaxes and begins to work with rather than against her labor.
4. Sedatives should be used in specific circumstances:
   a. when the woman is in false labor
   b. when the woman is in early labor and is exhausted and needs a rest
   c. as part of the treatment for hypertonic uterine dysfunction, to stop the present labor with its abnormal gradient contraction pattern

Fetal Size. Because of developmental immaturity and a high risk of respiratory distress in a preterm (premature) or small-for-gestational-age fetus, all medications may be withheld during labor from a woman carrying a preterm or small baby, in order not to depress the baby. Unlike full-term babies, small or premature babies may not be able to tolerate depressing drugs crossing the placental barrier.

Fetal Condition. If there is any evidence of fetal distress, regardless of fetal age or size, all medications are withheld from the woman in order not to further stress the fetus. Epidural analgesia/anesthesia may be the best maternal pain management option for a woman with a high-risk fetus. Continuous electronic fetal monitoring is always indicated for the high-risk fetus.

For any fetus at risk—such as those of diabetic mothers, severely preeclamptic mothers, or those who are postterm—judicious, very small dosages might be tried and the fetus carefully monitored for the drug's effect. Further medication is based on this trial and on the status of the condition that is placing the fetus at risk. In such cases internal fetal monitors will probably be used, permitting comprehensive monitoring of the fetal response.

Maternal Size. The amount of medication is limited by the fact that the fetus cannot tolerate the levels it would take to totally alleviate the woman's pain. Thus, if the woman is large, you cannot give additional medication in accord with her increased body size. On the other hand, you still need to consider the body size of the small, petite woman in determining the amount of medication within the limits imposed by the fetus.

Woman's Response to Support in Labor. Support for women in labor is discussed in detail later in this chapter. It has been said that effective supportive care in labor is worth 100 to 200 mg of Demerol. If the woman is responding well to support, there is a corresponding decrease in the amount of medication she needs. This is typical of women who have undergone preparation for childbearing. It can also be true for unprepared women, depending on a number of variables, such as the woman's pain threshold, how early in labor you establish contact with her, how much education and breathing preparation you can give her during early labor, the presence and help of her significant other, her previous experience and what she has heard from others regarding labor, and the amount of continuing constant supportive care that can be given her. There are circumstances, however, in which the woman is unable to cooperate with and respond well to the support; these women will need more medication, within the limits of safety.

Need for Medication. The woman's need for medication encompasses her desire or preference regarding medication, her labor status, and her response to support in labor. In addition to and underlying these factors is the amount of real pain she is feeling. This varies for each woman, depending on her pain threshold and on the amount of anxiety and tension she has and their effect on intensifying the amount of pain.

It is not uncommon to see women in early normal labor complaining of great pain as evidenced by thrashing about, doubling up, and much vocal expression—yet you palpate only mild, brief contractions. You can bring about a dramatic change in behavior by paying attention to what the woman is feeling physically and experiencing psychologically. Most likely she is frightened. Supportive care alone or in conjunction with a little ataractic often changes her into a smiling, coping woman rapidly progressing into active labor who has no need for a narcotic analgesic at this time.

On the other hand, in medicating a woman, you should always anticipate when she is really going to need it most—which is during transition—and plan accordingly. A woman's pain in labor, as she is experiencing it, should never be scoffed at regardless of your findings—she is feeling it and her experience must be respected. Again, the art of medicating involves a total plan of supportive care, including medication, throughout labor, designed for each woman within the limits of safety.

Epidural Analgesia/Anesthesia Over the past three decades, the use of epidural analgesia/anesthesia for control of pain in labor, spontaneous vaginal births and operative births, has dramatically increased due to improvement in the techniques and access to the procedure. In addition, women are increasingly demanding use of epidurals to diminish the pain of childbirth. In the 1960s women demanded greater participation in the birth of their babies by avoiding mind altering drugs and interventive medical technology. A societal shift has occurred in which women seem more willing to relinquish control of their bodies in favor of decreasing pain. Technology is revered, and epidurals are perceived by many to be very safe. Midwives have long been the advocates of non-interventive means of labor and birth, and have worked hard to keep the use of technology, including epidurals to a minimum.

Some midwives may still have limited use of epidurals in their practice. However, for those midwives who are serving women who will give birth in hospitals and who have midwifery care either for the supportive nature of midwifery or because they are the designated providers, epidurals may be commonplace. Midwives working in out-of-hospital birth sites and those who have a population of women who are seeking low tech, normal birth also must have an understanding of the use of epidurals as women in their care who develop complications may require more medicalized care and use of an epidural.

It is important to remember that the goal of midwifery care is a safe, satisfying birth experience for each woman, based on her own perceptions of birth. As Burst stated in an editorial on "real" midwifery:

> If we believe that every woman has the right to receive care from a midwife [sic], then the practice of midwifery [sic] must encompass all women regardless of their normalcy or risk status, the setting in which they receive their care, or the practices within that setting. We must recognize that, as individuals, each of us differs in what we choose to do and that it is acceptable to differ. . . . *Real* midwifery is "with woman," wherever she may be, in whatever circumstances she may be in, in whatever condition her pregnancy, in whatever health care system. [15]

Using an epidural should not be considered an impediment to quality midwifery care. It should not keep women from midwifery care, nor should midwives shun women because of their preference for a medicalized birth.

Indications and Contraindications. Relief of pain in labor is the obvious indication for use of an epidural. Women come to the decision to rely on epidural when other means of coping with labor have been ineffective or because they are fearful of pain associated with childbirth. Some have experienced birth previously with or without medication and are basing decisions on their own experience, while many hear tales of birthing that lead them to decide that the pain is not manageable without the epidural. There are also women who do not wish to use analgesic methods for the birth of their baby, but due to medical complications, require anesthesia for abnormally painful labor or for operative births.

Overall, epidurals provide the most complete relief of pain in labor and childbirth of any other method. Research has found that women using epidurals had lower pain scores and were more satisfied with their analgesia than women using parenteral opioids when simply evaluating the experience of pain [16, 17]. They are, however, the most invasive pain relief method. Nor can the positive sense of empowerment attained by women who labor and give birth without medical intervention be overestimated.

In July 2002, the American College of Obstetricians and Gynecologists (ACOG) released a Practice Bulletin in which the following statement was made:

> Labor results in severe pain for many women. There is no other circumstance where it is considered acceptable for a person to experience untreated severe pain, amenable to safe intervention, while under a physician's care. In the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief during labor. [18]

Indications for the use of epidural anesthesia include the following:

1. Relief of pain in active labor and for spontaneous or operative vaginal birth
2. Cesarean section
3. Decreases need for general anesthesia for operative deliveries
4. Need to diminish maternal expulsive efforts (e.g., maternal cardiac or ophthalmologic disease)

5. Decreases fear of pain and birth for some women
6. Provides opportunity for rest in the midst of a protracted, exhaustive labor

In some cases when an emergent cesarean birth may be required, an epidural may be recommended in order to avoid any loss of time if the emergency in fact occurs. This would be the situation when a "double set-up" is done for rupture of membranes with a floating head, for a vaginal breech birth or for a twin birth. It may also be the case when a forceps birth is to be attempted with strong anticipation of the need for a cesarean section. If a woman requires a forceps delivery and does not have an epidural, it may be initiated prior to the forceps delivery if there is time and the fetus is stable, in order to assist her in relaxation and to spare her the intense pain that can accompany forceps application and extraction.

A less common but important consideration is for women with a history of sexual trauma. For some, labor brings great anxiety about painful stimuli in the vaginal/rectal area, flashbacks of the abusive events, and uncertainty about letting their baby pass through the vagina, which may have very negative connotations for them. Assurance of analgesia may be very helpful to abused women planning for their births.

Many medical disorders can impact the choice of medications for pain relief and management of labor and birth. Evaluation of the woman for any medical risk factors that would be contraindications to an epidural or where special circumstances may be encountered is critical. Absolute contraindication to epidural or spinal anesthesia include the following:

1. Patient refusal or inability to cooperate
2. Skin or soft tissue infection at the site of needle placement
3. Frank coagulopathy
4. Uncorrected maternal hypovolemia (e.g., hemorrhage)
5. Inadequate training or experience in the technique

Under the following circumstances, women may be best served by a consultation with an anesthesiologist prior to labor:

1. Scoliosis, spina bifida, or other spinal column abnormalities
2. Previous back surgery
3. Preexisting arthritides
4. Preexisting tracheostomy
5. Preexisting neurologic or neuromuscular disease (e.g., multiple sclerosis or muscular dystrophy)
6. Preexisting cardiac disease
7. Preexisting pulmonary disease other than mild asthma
8. Low platelet counts (<100,000), or use of heparin in pregnancy
9. Preexisting coagulopathies
10. Any history of complications with an epidural or other anesthetic
11. Family history of major anesthesia complications
12. Allergy to anesthetics
13. Morbid obesity; BMI >30
14. Suspected difficult airway
15. Severe anxiety regarding regional analgesia

Anatomy/Physiology. During the first stage of labor, pain is experienced from cervical dilatation and uterine contractions. The pain sensations travel via sympathetic nerves that enter the spinal cord through the posterior segments of thoracic spinal nerves 10, 11, and 12 [19]. During the second stage, pain primarily comes from distention of the pelvic floor, vagina, and perineum stimulating sensory fibers of the sacral nerves 2, 3, and 4 (pudendal nerve) [19].

Local anesthetics, deposited in the epidural space, interrupt sensations of pain, touch, movement, and temperature in the nerves as they enter and leave the spinal cord. The degree to which these sensations are blocked is related to the dose of medication.

Epidural or intrathecal (spinal) opioids have a different mechanism of action than the local anesthetics. They do not "block" transmission of all sensation by the nerves. Instead, they work specifically to mediate pain and therefore do not cause muscle weakness. The combination of a local anesthetic and opioid injected into the epidural space is found to offer excellent pain relief with less of a motor block, and a smaller overall dose of medication.

The duration of pain relief from a single dose of local anesthetic is one to two hours. If the epidural is being used for an operative procedure only—e.g., cesarean section or forceps delivery—one dose is all that may be needed. More commonly, the method is used for longer duration of pain relief. Additional medication can then be given through the epidural

catheter in intermittent boluses or "top-offs," in a continuous small dose by pump, or it can be done by patient-controlled epidural analgesia (PCEA).

Description of Lumbar Epidural Procedure. A lumbar epidural is placed by either a nurse anesthetist or an anesthesiologist. A 16- to 18-gauge needle is used to identify the epidural space (see Figure 26-12). Then, a catheter is threaded through the needle and left in the epidural space when the needle is removed. The external portion of the catheter is then stabilized by taping it to the mother's back. Once the insertion and stabilization of the catheter are complete, a local anesthetic is injected through the catheter. A test dose of anesthetic is given to ensure that the catheter was not inadvertently placed in the spinal canal or in a blood vessel. With the catheter in place, additional anesthetic may be added by anesthesia personnel throughout the course of labor and birth.

A segmental lumbar epidural, placed via the L2-3, L3-4, or L4-5 interspace, will allow the use of a dilute anesthetic solution that will block the sympathetic nerves that carry painful impulses in the first stage of labor. During this time, sensation and motor function of the perineum and lower extremities remain mostly intact [19]. With minimal doses of anesthetic, some centers will allow women to be ambulatory during this phase of the epidural. When the fetal head causes more pressure and stimuli in the perineal region, a larger and more concentrated dose of anesthetic may be given to provide perineal anesthesia for the birth and/or repair if necessary. This increased dose of medication will cause more of a motor block, and women will no longer be able to ambulate safely.

A newer technique for management of labor pain is the use of intrathecal (spinal) opioids. This is usually done as a combined spinal/epidural procedure. Once the larger (16–18 gauge) epidural needle is placed, a small spinal needle (25–27 gauge) is introduced through the epidural needle, through the dura, and into the subarachnoid space. Very small doses of opioid (usually fentanyl or sufentanil) are needed and produce almost immediate relief of pain. The spinal needle is then removed, and the epidural catheter is threaded through the epidural needle. The epidural needle is then withdrawn and the catheter secured to the woman's back. If the woman wishes to be ambulatory, this method can be used prior to injecting local anesthetic into the epidural space. The spinal analgesia has little or no interference with motor function [19], and it does not have the side effect of hypotension [20]. The duration of the single spinal injection is limited to 1 to 2 hours. At that time, if the woman requires continued pain relief, the epidural route is available through the previously placed catheter. More commonly, the combined, spinal-epidural is used to provide rapid relief of labor pain while awaiting onset of the epidural block.

Intrathecal opioids enhance the local anesthetic in addition to providing immediate pain relief and the ability to ambulate. With very small doses of opioids, the overall dose of local anesthetics can be decreased. The results with intrathecal opioids give bilateral relief and the chance of systemic drug toxicity is reduced, and the method is reversible with a narcotic antagonist [21].

Epidural/Spinal Associated Risks. There are potential side effects related to each procedure and medication used. Most of the common side effects are not serious. Others are rare, but potentially severe or life threatening. Side effects related to local anesthetics include hypotension, bladder distension, and leg numbness and weakness, all caused by relaxation of muscle tone. Side effects related to performance of the procedure are postdural puncture headaches, back pain, and, very rarely, spinal cord injury.

Hypotension (systolic blood pressure <100) is noted in up to 50 percent of women following administration of epidural analgesics [22]. The effect of local anesthetics on the large spinal nerves is to decrease the tone of muscles, including those in the walls of blood vessels. Blood then pools in the lower extremities and there is a decrease in the return of the blood to the right side of the heart [19]. Cardiac output decreases and hypotension results. This transient side effect is treated with changing maternal positioning to avert aortal/vena caval hypotensive syndrome, and increased intravenous hydration. Significant complications are uncommon, but blood flow to the uterus diminishes, which can affect the fetus, and blood flow to the maternal cerebrum can also be diminished. If hypotension is prolonged, it can be treated with a vasopressor, most commonly ephedrine, by anesthesia personnel.

Bladder distension occurs when there is loss of the sensation to void, relaxation of overall bladder tone, and loss of control of the urinary sphincter. As always, attention must be paid to the bladder to prevent interference with fetal descent and overdistension, which could contribute to postpartum

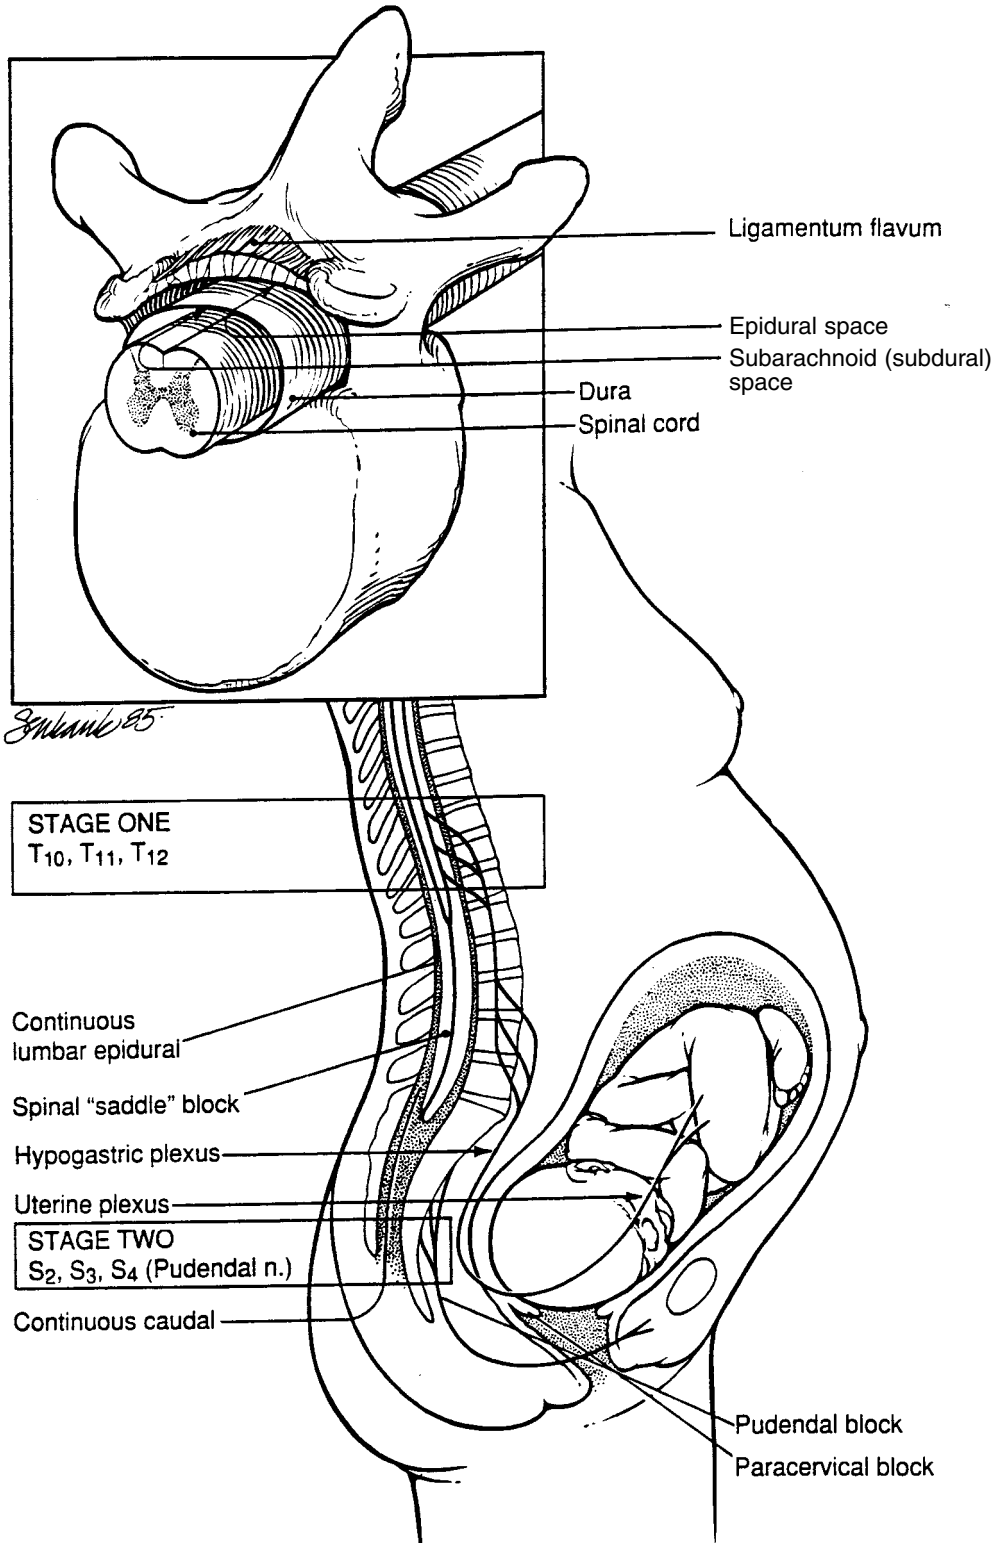

FIGURE 26-12 Pain pathways of labor and delivery and nerves blocked by various anesthetic techniques.

Source: Gabbe, S. G., Niebyl, J. R., and Simpson, J. L. *Obstetrics: Normal and Problem Pregnancies*, 4th ed. New York: Churchill Livingstone, 2002, p. 432. Reproduced by permission.

hemorrhage and voiding difficulties. Women are encouraged to attempt spontaneous voiding after an epidural, but often are unable to electively control the urinary sphincter. If the bladder is empty when the epidural is begun, and the woman gives birth within a short period of time, catheterization may not be required. However, large volumes of intravenous fluids are used to maintain blood pressure and the bladder may fill quickly. Straight catheterization during labor and/or at the time of birth is common. If many hours will elapse between initiation of an epidural and birth, and the woman is unable to void on her own, then an indwelling catheter should be considered to keep the bladder empty and decrease the risk of urinary tract infection. The catheter should be discontinued by the time the fetal head is nearing the perineum. Urinary incontinence related to epidurals has been demonstrated in the immediate postpartum period only.

Postdural puncture headaches occur in about 1 percent of women with an epidural or combined spinal epidural (CSE) [20]. If the epidural needle is inadvertently pushed a little too far and pierces the dura, cerebrospinal fluid may be allowed to leak out of the spinal space, into the epidural space. This causes low pressure in the spinal canal. The spinal needle used for the CSE is very small gauge and has not been shown to increase the likelihood of postdural headache over epidural alone [23]. When the woman is in an upright position, the brain can "sag," pulling on sensitive structures. If the woman remains supine, these symptoms will resolve. However, this is not a good remedy for most women who are recovering from birth and caring for a newborn. Resolution of the headache will occur when the CSF stops leaking and is replenished. In most cases this will happen spontaneously within 4 to 5 days with rest, increased oral hydration, caffeine, and simple analgesics such as acetaminophen (Tylenol) or ibuprofen (Motrin, Advil). If the headache is severe and/or prolonged, it can be treated with a "blood patch." This is done by an epidural injection of the mother's blood which then seals the leaking membrane and results in nearly immediate relief in 80 percent of cases [20].

Back pain is a common side effect of labor and birth, with or without an epidural. When lower back pain occurs following regional analgesia, the epidural is often felt to be the causative factor. General tenderness at the site of the epidural injection may be present for several days; however, long-term back pain is present in similar numbers of women regardless of anesthesia method [16, 20, 22, 24–26].

Permanent injury to the spinal cord is extraordinarily rare, occurring in 1/500,000 to 1/1,000,000 women postepidural [20]. These rare cases are related to either epidural hemorrhage resulting from a coagulation disorder or from development of an infected spinal abscess. Evaluation of maternal medical history and current platelet counts prior to placing an epidural and use of sterile technique should decrease this risk [19].

In 0.01 percent of cases [19], systemic local anesthetic toxicity may occur from IV injection of the anesthetic. This may result in seizures, cardiac arrest, or death of the mother and/or fetus.

Total spinal anesthesia occurs in 0.03 percent of cases when the level of the anesthesia rises dangerously high, resulting in paralysis of the respiratory muscles including the diaphragm [19]. This is due to an unintentional spinal injection after an epidural placement or an excessive dose of medication for a spinal block. When this occurs, the woman will suffer anxiety, numbness of the hands and fingers, and dyspnea. Treatment is accomplished with assisted respiration until the block resolves.

Side effects of the spinal analgesia, apart from the epidural, are most commonly itching, nausea, and vomiting. Pruritis (skin itching) is the most common, occurring in varying degrees in 50 percent to 90 percent of patients. Diphenhydramine (Benadryl; 25 mg IV) can be of value, or in severe cases, naloxone (Narcan) can be administered [21]. Less common is urinary retention and respiratory depression.

An increase in the incidence of maternal fever (>100.4° F) has been demonstrated in women with epidurals [16, 22, 24, 27]. This has not, however, been associated with an increased incidence of infectious processes. Most likely, the cause of epidural-related fever is from thermoregulatory alterations [24, 28]. Unfortunately, during the course of labor it is not possible to distinguish fever of benign versus infectious origin. Therefore, an increased number of women receive intravenous antibiotics and more women have cesarean or instrumented vaginal deliveries with the potential risk of chorioamnionitis as an indication [24]. Infants of mothers with fever are more likely to be subjected to sepsis workups in the nursey.

Neonatal outcomes of fetal heart rate abnormalities, intrapartum meconium, poor 5-minute Apgar scores, and low umbilical artery pH have not been shown to be significantly different between women using epidurals and those using IV opioids

or no medications [16, 24]. A meta-analysis comparing intrathecal opioids with traditional epidurals identified an increase in fetal bradycardia within one hour of dosing. This effect was transient, and it was not associated with an increase in cesarean, or operative vaginal birth, or poor neonatal outcomes [21, 29]. Maternal fever was increased with epidurals as was the incidence of infant sepsis workups; however, the incidence of neonatal sepsis was not increased in the infants of mothers with epidurals [16, 22, 24, 28, 30]. Neurological studies of epidural-exposed infants, opioid-exposed infants, and nonmedicated infants did not find large differences in performance between any of these groups [24]. Breastfeeding initiation and continuation through 6 weeks postpartum were shown not to be influenced by the method of analgesia [16].

Outcomes of Labor. Throughout the years that epidurals have been in use, there has been concern as well as disagreement regarding the adverse effects of epidurals on the course and outcomes of labor and birth for both mother and fetus. Leighton and Halpern published a meta-analysis of epidural effects on labor, and maternal and neonatal outcomes that evaluated four studies including a total of 4324 women [16]. Lieberman and O'Donoghue reviewed the literature regarding use of epidurals with low-risk pregnant women and the unintended effects for the mother, fetus, and neonate [24]. Epidural analgesia side effects and co-interventions were reviewed by Mayberry et al. [22]. The findings of all of these studies demonstrate inconsistencies in the literature and difficulties encountered in attempting to identify specific outcomes of research with differing definitions of practice.

Length of labor and the effects of epidural anesthesia are very difficult to determine due to many confounding variables. In general, it is felt that epidurals can slow the rate of cervical dilatation in the first stage of labor [24, 31], especially if it is given during the latent phase of labor [31]. Some studies have shown no difference in the length of first stage of labor, [16, 22]. This may have been affected by the increased use of oxytocin after initiation of analgesia in the women with epidurals.

Conversely, some women have an accelerated course of labor following epidural analgesia [31]. This may be due to increased fundal dominance after epidural anesthesia [31]. In addition, it is not uncommon to see women relax with the relief of pain, to demonstrate a decreased sense of fear, and to progress rapidly to second stage and birth. All of these factors must be taken into consideration when counseling women regarding the use of epidurals. "Prolonged duration of labor is often quoted as an adverse maternal event; however, duration alone is of little significance if labor pain is adequately controlled and fetal/neonatal well-being is preserved" [25].

Use of epidurals early in labor relaxes the pelvic floor and may contribute to malpositions before the fetal head is flexed into a normal position for descent and rotation. Subsequently, the rates of oxytocin use and instrumented vaginal deliveries is increased [32]. The second stage has been shown to be significantly lengthened in epidural study groups [4, 16, 20, 22, 24, 27, 31]. The incidence of operative vaginal deliveries is consistently higher with epidurals [16, 22, 33, 34]. This is very important as both forceps and vacuum-assisted births are associated with major perineal lacerations and neonatal birth injury [24].

When epidural blocks are very dense in the pelvic floor region, the normal mechanisms of labor may be interfered with. When the fetal head descends and hits the pelvic floor, there is normally strong muscle tone that guides the fetal head into the path for birth. However, when the pelvic floor is very relaxed, the head may remain in a posterior presentation or may be compacted into the posterior pelvis, resulting in asynclitism. At the least, the length of second stage is extended while the mother is unaware of the normal stimulus to push and the fetus may not rotate and extend its head in the usual fashion.

Some practitioners have advocated cessation of epidural analgesia for the second stage to enable the woman to experience the urge to push and to be able to actively participate in expulsive efforts. For a few mothers, this is a successful approach, but for many, severe pain and anxiety ensue making this a traumatic event and often decreasing the woman's ability to cooperate in pushing. According to Chestnut, the length of the second stage as well as the incidence of malpresentation and of instrumented deliveries can be reduced with the use of a more dilute solution of local anesthetic in the second stage [31]. "Maintenance of total anesthesia likely prolongs the second stage of labor, and it may increase the incidence of instrumental vaginal delivery" [31, p. 423].

Whether epidurals influence the cesarean birth rate is controversial. Cesarean delivery rates were not different between the study groups with epidural use and those with parenteral opioids or

no medication [16, 24, 27, 31]. Most studies found no increase in the rate of cesarean births for an indication of nonreassuring fetal status [22]. Some authors feel that there is a clinically significant, if not statistical, increase in the incidence of cesarean deliveries for women with epidurals [22, 24, 27, 31]. This may be due to a predisposition to abnormal presentation and asynclitism, or it may be related to the fact that women with dysfunctional labors have increased length of labor and increased intensity of pain, therefore increasing their likelihood of electing regional analgesia.

Another factor that seems to contribute to increased cesarean rates is the arbitrary termination of the second stage. For women with regional analgesia, a 3-hour second stage can be considered normal if there is progressive descent of the presenting part [35]. If the fetal heart rate status is reassuring, and progress is continuing, there should be no arbitrary time to abandon vaginal birth for women with or without epidurals. Delaying the onset of pushing until the fetal head spontaneously descends has been suggested as a means of decreasing the cesarean rates with epidurals [36].

Medical risks are not the only consideration with epidural anesthesia [37]. Less measurable and often overlooked psychosocial side effects also must be considered. When a woman has an epidural, she is usually confined to bed. The aura of normalcy of the labor and birth process, strength and health of the woman, and the sense of a woman being in control of her body and its functioning are shifted to a "sick role" requiring specific medical attention. For the woman who is highly invested in an unmedicated birth but requires an epidural for pain management, there may be a strong sense of failure. Preparation prior to labor should help women to have realistic attitudes toward prepared childbirth, but this disappointment may occur in any event.

Having an epidural does indeed relieve a woman of a great deal of the discomfort of labor and birth. However, many women are unprepared for the lack of control they feel physically. Some women are disconcerted by the extreme lack of sensation and inability to move their lower extremities, the lack of bladder control, and need for attachment to multiple machines and electrical and IV leads.

Preparation of the Woman. All women requiring epidural analgesia/anesthesia will have intravenous fluids in order to ensure maternal hydration, manage hypotension, and administer medications such as ephedrine. Assessment of maternal vital signs will allow for determination of baseline blood pressure and pulse prior to initiating medications that can alter these. Fetal assessment with continuous electronic fetal monitoring allows reassurance of fetal well-being or identification of a fetus who may not tolerate an episode of maternal hypotension. Asking the woman to empty her bladder prior to the start of an epidural ensures at least an initial period when the maternal bladder will not overdistend or require catheterization.

The epidural catheter can be placed with the mother in either a side-lying position or sitting at the side of the bed. This will be determined by the anesthetist at the time of the procedure. In any case, the woman should be assisted with getting into the required position, and assisted with staying as still as possible in this position throughout the procedure. This is usually done by the L&D nurse but could also be done by the midwife. The woman should be informed about each step of the procedure as it is about to happen. Usually the nurse anesthetist or anesthesiologist will keep the woman informed, but this may become a nursing role.

Her back will be cleansed with an antibacterial solution and covered with a sterile drape, and a local anesthetic will be injected at the site of the lumbar vertebrae to be used. Once local anesthesia is in effect, the epidural needle will be guided slowly through the vertebrae and into the epidural space. After ensuring the correct needle placement, the anesthetist will thread the epidural catheter into place, remove the needle, and secure the catheter to the mother's back. At that time, the mother will be assisted to lie in a semi-Fowler's position with the uterus laterally displaced with a towel roll or pillow under one hip. A test dose will be given followed by the full dosage of local anesthesia. Performance of frequent blood pressures is critical at this time and for the duration of the use of the epidural. Initially, blood pressures are taken every 5 minutes, then every 15 minutes until the epidural is discontinued.

Particular attention should also be paid to the fetal response to the epidural immediately and over the 30 minutes following a dose of medication. Local anesthetics cause a relaxation of maternal musculature, including the vascular walls. This will result in lowering maternal blood pressure. Even when the maternal blood pressure remains within normal range, blood flow to the uterus and therefore placenta and fetus will be diminished at least transiently. This commonly results in a drop of the fetal heart rate 10 to 20 minutes after the local anesthetic is given. The usual fetal heart rate pat-

tern is variable deceleration (can be to the 80 bpm rate) for 1 to 3 minutes. Most of the time this is quickly resolved with an increase in maternal IV fluids, and turning the mother to her side. In rare cases, ephedrine is required to elevate maternal blood pressure and restore blood flow to the fetus.

Informed Consent. Pain relief during labor is ideally discussed during prenatal care [30, 38, 39]. True informed consent is difficult to obtain by a woman in the throes of active labor or transition, or under the influence of intravenous narcotics. Women should be informed of the range of risks as well as benefits associated with epidural administration [39]. All midwives, regardless of their site of births, should have a firm knowledge of this frequently requested technology. Information can be shared verbally during pregnancy, and, ideally, a woman would be given written information regarding risks and benefits of all methods of pain relief including epidurals. A survey of women who used epidural analgesia in labor revealed very poor recall of the risks of epidural [38]. Participation in prenatal classes demonstrated an improvement of recall of risks, supporting the concept that the prenatal period is the most advantageous time to give women information regarding risks and benefits of pain relief methods. Documentation of this discussion is advised [38].

During the course of prenatal care, the midwife will explore with each woman what her anticipated choices for pain relief will be in labor. As in all other areas of childbirth, women should understand the full implications of their choices. This includes that having an epidural requires the use of other medical technology: IV fluids, frequent vital sign monitoring, usually with a blood pressure cuff and pulse oximeter attached for the duration of labor and birth, and continuous electronic fetal heart rate monitoring.

It is important for women and midwives to understand that there will be a time delay between request for epidural analgesia and actual relief of pain. At least 30 minutes must be allowed to pass for the nurse anesthetist or anesthesiologist to come to the labor and delivery unit, to review the medical record and assess the woman, and to prepare equipment, scrub, position the woman, prepare a sterile field, and place the needle and catheter, and then another 10 minutes must be allowed for the local anesthetic to work effectively. The woman should also be aware that if she has a rapid or precipitous labor, an epidural may not be indicated or possible.

Midwifery Management. When midwives use epidurals as a part of their management of labor and birth, there are a variety of logistical issues to consider. These include the availability of anesthesia personnel with the expertise to perform epidurals. In some hospitals, the consulting obstetrician is required to be "in house." Clinical practice guidelines that are agreed upon by the midwife and the consulting physician should address use of epidurals, indications for their use, and what special circumstances require additional assistance, if any.

When to initiate epidural analgesia is a common dilemma for the midwife. It has long been felt that epidurals given during the latent phase of labor were more highly associated with prolonged labor, need for oxytocin administration, and higher rates of operative births. Therefore, withholding epidurals until active labor is well established—at least 4 centimeters dilated and progressing—has become a more common practice. Use of relaxation, breathing and distraction techniques, water, and a birthing ball during this period is the most accepted approach for most women. Narcotic pain relief may also provide the relaxation needed to decrease the pain and fear cycle the mother is experiencing. The most important consideration is individualization of care. For some, latent phase labor is very painful, stressful, and exhausting. In this case, early epidural followed by rest may be the best approach. For those women who have decided prenatally to have an epidural but who are coping well through progressive labor, supportive methods and encouragement may be the best approach.

Supportive care during labor is a hallmark of midwifery care. For women who give birth without epidural anesthesia, the supportive techniques and attitude of midwifery care cannot be too highly valued. But for those women who elect epidural anesthesia for their labor and birth experience, midwifery management has the same strong role. Attention to the personal needs of a woman and her family and focus on the woman and the birth remains the central point of care. Too often, technology is allowed to take center stage. Women are strapped into stirrups, draped as if they were having major surgery, and attached to automatic blood pressure monitors, pulse oximeters, continuous electronic fetal monitors, IV fluids, and sometimes pitocin pumps and even cardiac monitors. How easy it is to lose sight of the birth of a child and a family. The midwife's role in de-emphasizing the technology and centering the focus of the birth environment on the mother cannot be understated.

Klein et al. found that practitioners who use fewer epidurals for their patients also are more likely to spend more time with women in labor and to use intermittent fetal monitoring than those practitioners who used epidurals for a higher percentage of women they cared for in labor. When using epidurals, the practitioners with the lowest use started epidurals at a more advanced cervical dilatation, had shorter labors, fewer forceps and cesarean births, and fewer admissions to newborn special care units [32].

While the mechanics of technology may be required when epidurals are used, it is not necessary to routinely use stirrups for birth. A semi-Fowler's position with the mother grasping her knees or supported by her partner works very well. Draping is only necessary under the buttocks for the purpose of maintaining a clean field for the birth. A quiet, low-light environment can easily be created where the woman and the newborn are the focal point with the technology in the shadows.

The midwife must set this tone with the nursing staff, anesthesia personnel, and other medical providers as well as with the woman and her family. Speaking in a low voice, dimming bright lights, and turning off the blaring television can all assist in setting the mood for birth. When the women you are serving have not sought out midwifery care and have not participated in shaping their own birth environment, the midwife has a special opportunity to make each birth experience one that shows respect for human birth, even in the midst of a highly medicalized system.

Continuing Evaluation of Maternal and Fetal Well-Being

Continuing evaluation of maternal and fetal well-being includes monitoring the following:

Maternal

1. Vital signs
   a. blood pressure
   b. temperature
   c. pulse
   d. respirations
2. Bladder distention
3. Urine
   a. protein
   b. ketones
4. Hydration
   a. fluids
   b. nausea/vomiting
5. General condition
   a. fatigue and physical depletion
   b. behavior and response to labor
   c. pain and coping ability

Fetal

1. Normality of the fetal lie, presentation, attitude, position, and variety
2. Fetal adaptation to the pelvis
3. The fetal heart rate and pattern

An inherent part of this continuing evaluation is determination of your need to consult a physician in the event your evaluation reveals deviation from normal. The need for consultation with a physician is determined by the midwife while evaluating the normality of the woman, fetus, and progress of labor; screening for medical and obstetrical abnormality; and anticipating possible potential problems. The parameters of normal were covered earlier in this chapter. Screening for and disposition of complications, including when to consult with the physician, are covered in Chapters 29 and 30.

Maternal Well-Being *Vital Signs.* The parameters of normal and their significance for all the maternal vital signs were detailed earlier in this chapter in the discussion of the database for the first stage of labor (Table 26-6). All of the vital signs are checked every time the woman is seen for diagnosis of labor and again during the initial evaluation when she is in labor. Thereafter, the frequency with which vital signs are checked may vary with the setting. Hospitals and birth centers usually have a policy regarding the frequency with which vital signs should be checked to ensure adherence to a minimum standard. Any desired or indicated frequency greater or lesser than that stated by policy requires a specific order in the hospital. The following schedule for checking vital signs reflects generally accepted norms of frequency for a normal woman during the active phase of the first stage of labor, regardless of setting:

1. Blood pressure: every hour
2. Temperature, pulse, and respirations:
   a. every 2 hours (or every 4 hours) when the temperature is normal and the membranes are intact
   b. every hour (or every 2 hours) after the membranes have ruptured

Bladder. The woman's bladder should be evaluated for distention at least every 2 hours during the ac-

tive phase of the first stage of labor. The bladder needs this attention because it is a pelvic organ. With the descent of the fetal presenting part into the true pelvis, the bladder is compressed so that distention occurs with only approximately 100 cc of urine in the bladder. If the bladder is not carefully attended to and emptied, but instead allowed to become more distended, the following may result:

1. Obstructed labor: An overdistended bladder can impede the progress of labor by preventing fetal descent.
2. Discomfort: A distended bladder increases the discomfort or pain in the lower abdomen that women frequently experience during labor.
3. Difficulty in management of shoulder dystocia: An overdistended bladder interferes with descent of the shoulders and decreases the amount of room in the true pelvis.
4. Difficulty in management of an immediate postpartal hemorrhage resulting from uterine atony: An overdistended bladder displaces the postpartal uterus, thereby inhibiting its ability to contract and effect uterine hemostasis.
5. Bladder hypotonicity, urine stasis, and infection during the postpartal period: This can result from trauma from pressure exerted on the distended bladder during labor

Routine assessment of the bladder is done every 2 hours to be sure distention does not go undetected. However, every time the woman's abdomen is bared for abdominal examination or to take the fetal heart tones, the contour of her abdomen should be noted for bladder distention. A distended bladder appears as a bulge above the symphysis pubis and, in severe cases, may extend as high as the umbilicus. When the fetus is in a posterior position the contour of the woman's abdomen may look as though she has a full bladder; distention must then be ruled out.

In the event of bladder distention all measures must be taken to facilitate the woman's efforts to urinate. The best method is for her to walk to the toilet if there are no contraindications to her ambulating. If she is unable to be out of bed and if the usual methods (having her listen to the sound of running water; running warm water over her perineum; applying light suprapubic pressure; and having her practice perineal relaxation) do not cause her to urinate, then the midwife must decide for or against catheterization. This decision is based on weighing the risk of infection from catheterization against the risk of postpartal infection plus the other possible problems and sequelae if the woman is not catheterized. This latter risk is evaluated on the basis of the severity of the distention, the woman's labor status, and her progress in labor.

Urine. In addition to the initial specimen collected at the time of admission for routine microscopic examination, the urine should be examined by dipstick for protein and ketones when a woman urinates during labor.

The results of examination of the urine for protein should be evaluated in relation to the type of urine specimen it was and the contaminants it might have in it. This is important because the urine is examined for protein as a routine screening for one of the signs of preeclampsia. If there is protein in the specimen, it is vital to know whether the woman is evidencing proteinuria. If the specimen was a voided specimen and the woman has a copious amount of bloody show, the specimen will be contaminated with blood. The results are thereby rendered worthless because the positive protein results may be due to the contamination by blood protein. If, however, the specimen was obtained during catheterization, the results may be considered valid. The results from carefully collected clean-catch specimens under favorable conditions (i.e., without contamination from vaginal discharges) may also be considered valid.

The urine is examined for ketones to screen the woman for maternal exhaustion and distress inclusive of dehydration, electrolyte imbalance, and nutritional deficiency during labor. Since most of the other signs and symptoms of maternal exhaustion and distress are difficult to differentiate from normal physiological changes and physical manifestations during labor, the presence or absence of ketonuria is essential for establishing a differential diagnosis and instituting corrective treatment (see Chapter 29). It is most important to use dipstick testing of the urine for ketones to evaluate the laboring woman for the adequacy of her oral intake of liquids for maintenance of hydration. Good oral fluid intake is not usually possible in prolonged labor or when there has been uterine inertia. Ketonuria would indicate the need for an IV.

Hydration (see also pp. 761–762). The maintenance of hydration throughout labor is essential for the woman's well-being. The time span of labor does not lend itself to evaluation of hydration on the basis of such signs as skin turgor. On the other hand, signs of dehydration such as dry or cracked lips, a dry mouth, or a parched throat may not be

due to dehydration at all in a woman in labor but may instead be due to the type of breathing she is doing with her contractions. Evaluation thus is based on screening for ketonuria and on a knowledge of the woman's fluid intake (by whatever route) and loss. Concentration of the urine should also be noted.

Not only the woman's fluid intake but also any loss of fluids affects the maintenance of hydration. Excessive nausea or vomiting in a woman without an IV will decrease her desire for fluids and her ability to take fluids by mouth. Excessive vomiting in a woman with an IV must be counterbalanced by an increase in her IV fluids. Although you need not keep a strict intake and output record on a normal laboring woman, her labor record should reflect her fluid intake, urinary output, and the amount of any emesis.

General Condition. Evaluation of the well-being of the woman necessarily includes evaluation of several areas that interrelate and overlap: her state of fatigue and physical depletion, her behavior and responses to labor, and her perception of pain and ability to cope with labor.

Her state of fatigue and physical depletion is affected by her state of fatigue on entering labor, maintenance of hydration during labor, length of labor, and her ability to cope with the demands placed upon her by her condition and situation. These may be part of a vicious cycle: a lack of ability to cope may increase fatigue and fatigue may decrease her ability to cope; or the longer the labor, the greater the fatigue, but fatigue may also cause labor to be longer. Occasionally a woman enters labor truly exhausted and dehydrated from days of the general miseries of the end of pregnancy or from false labor. A management plan for such a woman should include helping her rest during early labor with 100 mg of secobarbital (Seconal) intramuscularly while hydrating her with intravenous fluids.

A woman's behavior normally changes throughout labor, as described earlier in this chapter. These changes can be used in evaluating her response to labor. Her behavior is also affected by her degree of self-confidence, her anxiety and fear, and the amount of pain she is experiencing. In another cycle of interplay, these in turn affect her coping ability, and her ability to cope affects her self-confidence, anxieties, and fears. Intervention during labor is most effective with women who have been prepared for childbearing during pregnancy. With or without this preparation, evaluation of behavior during labor will aid in determining a number of the support and comfort measures needed, including the need for medication.

Fetal Well-Being Evaluation of the fetal lie, presentation, attitude, position, and variety is done first by abdominal palpation (see "Abdominal Palpation and Leopold's Maneuvers" in Chapter 53) and confirmed by vaginal examination as discussed in detail earlier in this chapter. The first part of this chapter also discussed the information needed to evaluate fetal adaptation to the pelvis: synclitism/asynclitism, molding of the fetal skull, the formation of caput succedaneum, and the parameters of normal for each.

All the information on fetal well-being is obtained whenever the woman is evaluated for diagnosis of labor, during the initial evaluation when she is in labor, and any other time a vaginal examination is done during labor, whether for purposes of updating this information or to evaluate the progress of labor by cervical change and fetal descent.

One of the management decisions a midwife makes is to determine the frequency with which the fetal heart tones are to be checked and how this will be done. The frequency is standard regardless of setting; the how will vary by setting, as no homes and very few birth centers have electronic fetal monitors. In the hospital the possible methods include intermittent auscultation of the fetal heart; intermittent external fetal monitoring; continuous external fetal monitoring; and continuous internal fetal monitoring. This management decision should be based on indicated need. If the woman is healthy and has had an uncomplicated pregnancy, there is no need for electronic fetal monitoring.

The fetal heart rate and pattern should be evaluated using auscultation with a fetoscope or an ultrasonic method (e.g., Doptone) every 30 minutes during active labor. In addition, the fetal heart is checked at other times during the course of a normal labor:

1. When the membranes rupture
2. After expulsion of an enema
3. Whenever there is any sudden change in the contraction or labor pattern
4. After giving the woman medication and again at its peak action time
5. Whenever there is any indication that an obstetric or medical complication is developing

The methods of assessing the fetal heart rate and pattern, and the parameters of normal for the baseline fetal heart rate, irregularity, and periodic fetal heart rate changes are discussed in Chapter 27. See also "Location of Fetal Heart Tones" in Chapter 53.

Continuing Evaluation and Facilitation of the Progress of Labor

Information on the following items is used in the continuing evaluation of the progress of labor:

1. Effacement
2. Dilatation
3. Station
4. Contraction pattern
   a. frequency
   b. duration
   c. intensity
5. Maternal behavior changes
6. Signs and symptoms of transition and impending second stage
7. Position of low back pain
8. Position of location of maximum intensity of fetal heart tones

All eight of the above items were discussed and their parameters of normal for the phases of the first stage of labor were given earlier in this chapter. The findings obtained from examination and/or observation of these eight items are evaluated in relation to information obtained from the woman when she was initially evaluated for labor:

Age
Gravida and para
Time of onset of true labor
Length of previous labor
Number of years since last baby
Size of largest previous baby
EDB and present week of gestation

and in relation to the following information obtained in continuing evaluation of the fetus:

Estimated fetal weight
Presentation, position, and variety
Synclitism/asynclitism
Molding
Caput succedaneum

and in relation to the following information obtained in continuing evaluation of the woman:

Bladder status
General condition including her state of hydration, fatigue, and physical depletion

and, finally, in relation to whether the woman has had any medication, and if so, what, how much, by what route, and when.

Management decisions relating to the continuing evaluation of progress in the first stage of labor include the following:

1. The frequency of vaginal examinations
2. Whether to artificially rupture the membranes
3. Management of an anterior cervical lip
4. When to prepare for birth
5. Whether the need to consult with the physician is inherent in your evaluation and interpretation of findings

Frequency of Vaginal Examinations The frequency with which vaginal examinations are done depends on the woman's condition and on the midwife's ability to use other parameters for evaluating progress in labor. It is not always necessary to do a vaginal examination in order to evaluate the progress of labor. The practice of vaginal examinations every 1 to 2 hours only subjects the woman to unnecessary discomfort, intrusion, and increased risk of infection. Astute observation of the woman (possible only if the observer stays in the room)—her behavior, contraction pattern, the signs and symptoms of transition, and changing location of back pain and fetal heart tones—should give the midwife a good idea of whether the woman's labor is progressive. This does not negate performance of a vaginal examination either if there is a question of progress or if you are not sure of your observations and interpretation of them.

For the normal intrapartal woman there are five times when a vaginal examination is indicated:

1. On admission, to establish an informational baseline
2. Before deciding on the kind, amount, and route of any medication
3. To verify complete dilatation in order to either encourage or discourage maternal pushing effort
4. After spontaneous rupture of the membranes if a prolapsed cord is suspected or is a possibility
5. To check for a prolapsed cord when fetal heart rate decelerations are not improved with the usual maneuvers

Other than these five times, vaginal examinations serve no function in normally progressive labor other than to reassure the insecure clinician.

If the membranes have ruptured prematurely, no vaginal examinations should be done except by permission of the person responsible for the obstetric management of the woman. This person may be you—and it is up to you to both restrict vaginal examinations and determine when one may be done. The restriction on vaginal examinations is imposed because of the increased risk of introducing contaminants and the development of intrauterine infection without the protective barrier of the membranes (see Chapter 29). If you determine that a vaginal examination is to be done for carefully considered, unavoidable, and urgent reasons (e.g., to check for a prolapsed cord), then it should be a sterile vaginal examination. A sterile vaginal examination involves cleaning the perineum (quickly) and using sterile examination gloves.

Artificial Rupture of the Membranes (see also Chapter 25, page 728) Whether to artificially rupture the membranes (perform an amniotomy) depends on the indications for amniotomy as weighed against possible undesirable effects and potential hazards of the procedure if conditions do not meet certain criteria. Indications for artificial rupture of the membranes include the following:

1. To attach an internal fetal monitor electrode
2. Baby about to be born with the membranes intact at the time of birth
3. Need to stimulate labor—for example, in hypotonic uterine dysfunction
4. To facilitate fetal descent and reduce the possibility that the force of the pushing contractions will lead to sudden and vigorous rupture of the membranes that will cause the cord to prolapse

Possible undesirable effects of artificial rupture of the membranes include the following:

1. Cord compression
2. Uneven head compression with more extensive molding and caput succedaneum may increase the risk of intravascular hemorrhage, especially if membranes are ruptured early in labor

Potential hazards include the following:

1. Potential prolapse of the umbilical cord if membranes are ruptured with the fetal head unengaged or with a compound presentation, an ill-fitting breech presentation, or a small baby (less than 2000 grams)
2. Potential intrauterine infection if the membranes are ruptured before labor is established and rupture of the membranes is prolonged

Because of the potential hazards of amniotomy, midwives artificially rupture the membranes only if the following criteria are met:

1. The woman is in active labor with a well-established contraction pattern and cervix dilated 4 to 5 centimeters.
2. The baby has a cephalic vertex presentation with the head engaged.

Consultation with the physician is indicated if the midwife decides that the membranes need to be needled to facilitate descent of a floating fetal head. Artificial rupture of the membranes (AROM) in this situation is done either by the physician or by a highly experienced and skilled midwife who has extended her or his boundary of safety to include this. AROM in these circumstances is done between contractions to avoid a sudden rupture with a gush of fluid that might result if the membranes were torn by the force of a contraction. Such a sudden rupture may bring a prolapsed cord with the gush of fluid.

In the past it was not uncommon management of a normal labor to rupture the membranes at 4 to 5 centimeters of dilatation, in order to "speed up labor" for no reason other than to shorten the whole process for the mother and the attendants. Now that possible undesirable effects on the fetus from early rupture of the membranes have been identified, most midwives will not perform an amniotomy on a normal woman until late in labor, and then only if there is an indication (even if criteria are met much earlier in labor).

In performing an amniotomy the midwife should observe the following principles:

1. Do the amniotomy between contractions so that
   a. the force behind the rupture is reduced
   b. the membranes are not stretched tightly against the fetal head (which leaves too little room in which to safely grasp the membranes in order to tear them)
2. Use an instrument that will be effective quickly and easily, such as an Allis clamp or various hooks manufactured for this purpose. An instrument that simply glides and slips along the membranes frustrates the clinician and prolongs the discomfort of a vaginal examination for the woman.
3. After rupturing the membranes, leave your fingers in the vagina through the next contraction in order to

   a. evaluate the effect of the amniotomy on the cervix (dilatation) and on the fetus (descent and rotation)
   b. assure that there was no prolapse of the umbilical cord
4. Have the fetal heart tones evaluated during and after artificial rupture of the membranes to assess the immediate effect of the amniotomy on the well-being of the fetus.

Management of an Anterior Cervical Lip Sometimes progress at the end of the first stage of labor is impeded by the development of an anterior lip of cervix. In other words, the cervix may be completely dilated with the exception of this anterior lip, which may become increasingly edematous. Occasionally, an anterior lip of cervix starts developing earlier in the first stage of labor and may be felt when cervical dilatation is only 6 centimeters. If the cervical lip becomes extremely edematous it is a matter of concern not only because it impedes the progress of labor but also because there is greater potential for damage to the cervix as it is caught between the fetal head and the symphysis pubis. In extreme cases the cervical lip can become separated from the cervix, if the condition is ignored.

An edematous anterior cervical lip rarely develops early in labor. Watchful waiting and noninterference are usually sufficient until dilatation reaches the point where the anterior lip is all that remains and it can be managed as described below. If the anterior cervical lip becomes so edematous before the end of dilatation that the condition is of serious concern and further waiting is questionable practice, the edema can be reduced by positioning the woman for a speculum examination, visualizing the cervix, and puncturing the edematous lip of the cervix multiple times and places with a needle [40].

Management of an anterior lip when dilatation is otherwise complete or nearly complete is as follows:

1. Do a vaginal examination and place your fingers on the anterior lip where it touches the fetal head.
2. During a contraction, run your fingers back and forth the distance of the junction of the anterior cervical lip with the fetal head and push the cervical lip backwards until it slips over the fetal head and above the inferior border of the symphysis pubis.
3. Hold the cervical lip in this position while waiting for the next contraction.
4. Continue to hold it in position and ask the woman to push down during the next contraction.
5. Allow your fingers, but not the cervix, to be pushed downwards and out as the fetal head fills the space and presses against the inferior border of the symphysis pubis.
6. Do not remove your fingers from the vagina until you are sure that the cervical lip will remain in its new position both during and between contractions.

The second stage of labor has now begun. You will need to examine the cervix for lacerations after delivery of the placenta.

Preparation for Birth Preparation for birth varies considerably from setting to setting. In the home the woman may have prepared a special place where she wants to give birth. At home or in a birth center, women may give birth in a regular bed in a variety of possible positions or on a birthing stool, or squatting, or standing. Many hospitals have instituted birth rooms, in-hospital alternative birth centers, or combination labor/delivery/recovery (LDR) or labor/delivery/recovery/postpartum (LDRP) rooms. One outcome of this development is that women do not have to move from bed to table at the critical moment of giving birth. Since there often is now an option, the midwife in the hospital must make a management decision as to whether to move the woman to the delivery room. This decision, however, may be predetermined by a hospital policy that specifies who can give birth in a birth room and who must be delivered in the delivery room. These criteria are generally designed to take into account any developing or potential complications (e.g., meconium stained fluid, anticipated shoulder dystocia) or procedures that may need to be done (e.g., forceps delivery, newborn resuscitation). Some in-hospital birth rooms are designed so some procedures can take place in the birth room.

Regardless of where birth takes place, a number of preparations for the birth must be properly timed or the midwife will not be ready. In all settings this involves getting out whatever instruments and supplies the midwife uses and making sure they are ready and accessible. (At a minimum a midwife uses sterile gloves, a bulb syringe, two clamps, a pair of scissors, a cord clamp or tie, something to catch the placenta in, a type of chux, 4×4 gauze squares, a receiving blanket, and a head cover for the baby.) Experience in refining observations and a

sixth sense are required in order to achieve proper timing. However, there are a few cardinal generalities that are valid enough of the time to be useful in timing preparation for birth in any setting.

1. Primigravidas: Preparations for birth should begin after complete dilatation, and, depending on the amount of descent, after some time of pushing or until the time-honored maxim of fifty cents—the size of a half-dollar—indicates the amount of fetal head visible at the vaginal introitus *between* contractions.
2. Multiparas: Preparations for birth should begin before complete dilatation, at approximately 8 centimeters during transition. If you wait longer you are inviting an uncontrolled delivery of the baby before you have finished preparations for the birth.
3. Progress of labor must be taken into account in making the decision of when to begin preparations. A rapidly progressive labor or a more desultory type of labor invalidates the above two statements and the timing of preparing for birth should be adjusted accordingly. The rapidity of second stage labor is also affected by the degree of relaxation, stretch, and give in the woman's vagina and perineum as well as by her parity.

Preparations for birth get more complex in the hospital, especially if the woman has to be moved to the delivery room. There are hospitals that still require that women be moved to the delivery room for birth. Deciding exactly when is the best time to do so is a refined art.

Ideally the woman should be moved in an unrushed fashion. She should have time to move from her bed to the delivery room table between contractions. Preparations (getting legs into stirrups or being positioned for dorsal delivery, perineal cleansing, draping) should be done at a steady, quiet, nonfrantic pace; there should be time for procedures that have been selected as part of the management plan (e.g., pudendal block). Birth should immediately follow completion of all preparations, thereby keeping at a minimum the amount of time the woman's legs are in stirrups. Again, ideally all this should be accomplished without having to tell the woman to pant in order to prevent her from pushing and having the baby before all is ready. What you want to avoid is a wild scene of a mad dash to the delivery room with personnel rushing around and yelling at the woman not to push while they don gloves and frantically pour some solution over her perineum so the delivery can be called "sterile."

Whatever the setting, if you find that you have mistimed your preparations, it is far better to stop everything, put on gloves, and calmly assist the mother in the birth of her baby. Equipment and supplies can be obtained by others as needed. It is up to the midwife to direct everyone else in the situation in what to do to be helpful to the mother, to you, and to the baby when born.

Bodily and Supportive Care of the Mother and Her Significant Other/Family/Friends

Purpose of Supportive Care One of the hallmarks of a midwife is the constant care she or he gives the woman throughout labor. This does not mean remote control management of the woman but, rather, being an active and participating presence in the room both to manage the care of the woman obstetrically and to provide or facilitate the provision of indicated supportive care. Women's horror stories of being left alone in fear and in pain without knowing what was going on, with only an hourly check of the blood pressure and fetal heart tone and a "mashing" of her abdomen for comfort and company, are anathema to the midwife. This sort of trauma experienced by a woman in labor may have a negative psychological effect on her for the rest of her life and on her relationship with the child, whom she may see as the cause of her trauma.

In order to provide supportive care one must know how to do so. Otherwise the caretaker becomes frustrated by not knowing how to help the woman and uncomfortable with the woman's suffering and ultimately removes herself or himself from the situation by leaving the room. From this scenario come the horror stories and the trauma experienced by women. Supportive care during labor miraculously changes this entire scenario. The dramatic effects relate not only to the woman's psyche but also to the physiological effects on the fetus, who benefits from less medication and a naturally shorter labor. As mentioned earlier, effective supportive care is worth 100 to 200 milligrams of Demerol—it can shorten labor by 2 to 3 hours and provides uncountable psychological benefits.

Lesser and Keane [41] identified five needs of a woman in labor:

1. Bodily or physical care
2. Sustaining human presence
3. Relief from pain
4. Acceptance of attitudes and behavior
5. Information and reassurance of a safe outcome for herself and her baby

The following discussion of support and comfort measures includes specific actions for meeting these five needs. By implementing these you become at least one sustaining human presence for the woman. The basis for deciding which support and comfort measures to implement, and when and where, is your observations of the woman, the agreement between you as to what might be helpful, and her description of the location of her discomfort or pain. Inherent throughout is the acceptance of the woman's attitudes and behavior and the belief that whatever she is doing is the best she is capable of at that moment. Supportive care requires patience and understanding on your part and perseverance in your efforts to help her. She desperately needs positive input—not negative reactions—in order to continue coping with her condition and situation and to have a sense of satisfaction afterward.

The support and comfort measures that emphasize explanations and teaching—meeting the woman's need for information—are means of breaking the fear-tension-pain syndrome described by Dick-Read [42]. This vicious cycle occurs when fear causes both mental and muscular tension, which in turn causes pain, which in turn increases fear, and so forth. Dick-Read advocated breaking this cycle with education to reduce fear, combined with exercises geared toward further facilitating muscular relaxation. Subsequent natural psychoprophylactic methods of childbearing vary in the emphasis they place on preparatory muscular and breathing exercises, but all educate the woman about the processes occurring within her body and means of coping with them, thereby reducing fear.

The support and comfort measures described in detail in the next section are the "what-to-dos." Of equal importance is determining *how* to do the what-to-dos in terms of purpose, approach, implementation, and expectations of results. Five "how-to-do" considerations are important:

1. The support and comfort measures that are listed constitute an armamentarium from which to choose. Not all women need all of these measures. Some women will not respond to any of them. Some women will find some measures helpful and others irritating—and which are considered helpful and which irritating will vary from woman to woman. You can but try each that may be indicated and seek validation from the woman as to its helpfulness. Ask—do not go strictly on the woman's behavior, especially if she is nonresponsive, as you can misinterpret her behavior. Ask her if a certain measure is helping or not and if she wants you to continue it. Use your knowledge of labor processes, combine this with the woman's need-for-help, learn from each experience with a laboring woman, and think up support and comfort measures other than those listed here. Do not be limited by books and articles; use your intelligence, ingenuity, and compassion.
2. Define your purpose—that is, what you are trying to accomplish with your support and comfort measures and care of a woman. One such statement of purpose would be to facilitate the efforts of the woman to cope effectively with, and function capably in response to, the demands being placed on her by her condition and situation.
3. How you talk with a woman in labor may determine your effectiveness. It does no good to give her instructions or coach her with her breathing if she can't hear you. The advent of a contraction causes the woman to direct her total mental concentration toward her response to that contraction. For the unprepared woman in particular the response may be fear and bodily tension and pain. You will need to break through this mind set. To do so requires your speaking with a degree of authority and firmness with enough vocal timbre and projection to be heard. Whispering, unless it is directly into her ear (which most women find irritating), is useless. Soft-spoken instructions from a distance (i.e., across the room, from the foot of the bed) are also a waste of breath. This does not mean, however, that you should shout or yell at the woman. This is equally useless—it only heightens the woman's sense of aloneness and pain and is not helpful. Shouting at a woman in labor is intolerable.
4. The key to success in supportive care is your own involvement. Involvement means facilitating others in their support as well as doing things yourself. There will be times when you are as exhausted, or more so, than the woman after the birth because you will have breathed, rubbed, and pushed with her throughout her labor in addition to carrying out all your other responsibilities. Supportive care demands your presence if you are the one giving it. You cannot simply make an hourly visit and then conduct supportive care from afar with a string of orders. This does not mean, however, that you are the only one capable of giving supportive care. Far from it. Use others—nursing staff and significant others (Figure 26-13). Involve them so that each feels the importance of his or her contribution to the care of the woman through childbirth.

5. Be realistic in your expectations of what you can accomplish with your support and comfort measures. It is unrealistic to think you can take away all the woman's discomfort and pain and make her fully capable and blissfully happy throughout her labor. Although it is true that some women, especially prepared women, cope effectively with their labor, are well in control of themselves and measures that relieve their discomfort, and respond with relief and gratitude to everything you do, there are other women, usually unprepared, who scream, thrash, and writhe their way painfully and miserably through labor and seem to get no relief from anything you do. Don't feel you have failed. If you talk with such a woman about her experience the next day she probably will tell you that your perseverance and your sustaining human presence meant everything to her.

Allow for individual attitudes and behavior. In some cultures women are supposed to scream during labor in order to atone for their sins. The more screaming there is, and the louder and longer the screaming, the more sins are atoned for. Other women try to be stoics when what they really need is to be encouraged to yell at the peak of hard contractions. Each woman comes into labor with her own expectations, fears, preparation, pain threshold, personality and behavioral makeup, and way of experiencing what is happening to her. You must adapt to her—not expect her to adapt to you—and quickly learn her individuality in order to facilitate her coping efforts as you manage her care for a safe outcome for herself and her baby.

Support and Comfort Measures *Positioning.* A woman should assume whatever position brings her some comfort. This position may change, sometimes frequently, and may be in bed or out-of-bed, standing, walking, sitting, on or over a birthing ball, rocking, squatting, kneeling, hands and knees, knee-chest, or in the supine or lateral (left or right) positions (see pages xxx–xxx). Positioning in bed involves placing pillows, rolled blankets or towels, or a combination of these in strategic spots to promote relaxation, reduce muscle tension, and eliminate pressure points. This can be done in any position the woman assumes.

At a minimum a laboring woman needs a pillow under her head. If there are no pillows, make one by stuffing two full sheets or two blankets into a pillow case. This pillow is more comfortable if the sheets or blankets are shaken out first rather than placed folded inside the pillow case. It takes only a few more seconds to do and the results are worth it.

To promote generalized relaxation, encourage the woman to assume a side or elevated supine position if in bed. Figures 22-3 and 26-14 illustrate the position of the pillows and rolled blankets and towels for those two positions.

Relaxation Exercises. There are three relaxation exercises that may help the woman in labor.

FIGURE 26-14 Midwife supporting woman in labor in elevated supine position.

1. *Progressive relaxation:* This type of relaxation should be practiced during the antepartal period so that a woman can quickly will herself to relax her muscles and, if needed, to catch catnaps between contractions. The exercise involves deliberately tightening a single muscle group (e.g., hand, arm, leg, face) as tight as possible and then letting it go as limp as possible. Muscles are tightened sequentially and progressively from one end of the body to the other. The exercise promotes total body relaxation and rest or sleep.
2. *Controlled relaxation:* This type of relaxation also should be practiced during the antepartal period so that the woman can make effective use of it during labor. The exercise involves having one muscle group contracted while keeping other muscle groups relaxed. This is akin to labor, in which the uterus is tightly contracted and it is desirable *not* to tense other muscle groups in response. The woman practices the exercise by tightening one muscle group while relaxing its counterpart. For example, in order of increasing difficulty:
   - Right arm tightened, left arm relaxed (and vice versa)
   - Left leg tightened, right leg relaxed (and vice versa)
   - Right arm and right leg tightened, left arm and left leg relaxed (and vice versa)
   - Left arm and right leg tightened, right arm and left leg relaxed (and vice versa)
3. *Deep breath and sigh after each contraction:* This relaxation can be taught when a woman is in active labor if she doesn't already know it. It consists simply of the woman's taking a deep breath and letting it all out in "a big heavy sigh" after the contraction is over. This serves a double function. It not only promotes relaxation but also acts as a cleansing breath to counteract any possible hyperventilation during the contraction or to break a pattern of rapid breathing at this time. Relaxation is further promoted if you give the woman a mental image of how you want her to look and feel after her sigh. For example: "Let yourself sink into the bed and go loose like a rag doll" (or a wet dishrag or a limp noodle).

Breathing Exercises. If you have not taught breathing exercises to the woman you are working with during labor, you must be knowledgeable about and able to adapt and facilitate her efforts in whatever breathing methodology she has learned and practiced and believes in. During labor is no time to teach her your way of doing it or even to hint that her way is anything but the best. For her, her way *is* the best. If you are unfamiliar with her technique, ask her to teach you how you can best help her.

If a woman enters active labor with no preparation in childbearing and no practice in breathing exercises, you are limited in what you will be able to teach her. If she is in active labor already, you probably will not be able to teach her the Lamaze breathing techniques and the Lamaze philosophy of active "working with" participation and concentration; this method requires training and practice. You might be able to teach her a basic pant-pant-blow rhythm, which she can do faster or slower as you direct her. This gives her something to concentrate on other than the contraction and its pain.

You might be able to teach her abdominal breathing; the advantage to this is that the woman feels relief when she is doing it. Abdominal breathing is effective for two reasons: Half of the benefit is psychological because the breathing provides distraction by giving her something else to concentrate on, and half of the benefit is physiological because the breathing lifts the abdominal wall up off the contracting uterus, thereby reducing pressure and thus reducing pain. However, during transition the woman is no longer able to do abdominal breathing, and you should teach her pant-pant-blow breathing or a superficial chest breathing to use at that time.

Which of the above you teach may depend on what the individual woman responds to and is able to do. At times you may be happy just to get the woman to breathe. Some very frightened, unprepared women may simply hold their breath and not breathe throughout a contraction. This causes a certain degree of tissue hypoxia, which increases pain. Your instruction may be limited in such situations to nothing more than repeated authoritative urgings: "Breathe!"

One essential form of breathing is panting. If the woman learns the panting technique during the antepartal period, she can do a controlled form of panting. However, panting in the form of a rapid, shallow, throat breathing, which you can demonstrate and describe as "panting like a dog" is a technique that a woman can learn instantly while in labor. It is used whenever you want to prevent the woman from pushing. It does no good to tell a woman "Don't push" (no matter how loudly and forcibly you say it) without showing her *how* not to push. It is impossible for anyone to pant and push at the same time. Panting is, however, a very ex-

hausting type of breathing. Therefore, it should be used only when indicated, as in the following situations:

1. If the woman is pushing prior to complete dilatation of the cervix. Constant pushing of the presenting part against an undilated cervix serves only to make the cervix edematous; if edema is severe enough it may impede labor or, at the very least, increase the chance of cervical laceration and hemorrhage as the congested cervix becomes friable.
2. In order to deliver the head of the baby between contractions. You may instruct a woman to pant through her contraction and then push without a contraction so the head will ease out without the combined force behind it of both the contraction and the push.
3. If you discover the cord wrapped tightly around the baby's neck after the head is born and you decide to clamp and cut the cord immediately. You don't want the mother to push until you have completed this action.

The other essential form of breathing, the form used for the maternal pushing effort, is described in Chapter 67.

In all teaching of breathing, you will get the idea across to the woman most quickly and effectively if you demonstrate it to her and then do it with her. If the woman does not learn a breathing exercise until she is in active labor and so has not previously practiced it, it may be necessary for you to breathe with her during every contraction. Prepared or unprepared, a woman needs reminding, encouragement, and positive reinforcement with *each* contraction. She will not remember what you say from contraction to contraction and will quickly exhaust herself if she has to rely on herself for coaching. You may think you sound like a broken record, but for her each contraction is a new experience to be coped with and gotten through.

Prevention of Exhaustion and Provision for Rest. Prevention of exhaustion and provision for rest between contractions are other support and comfort measures. Useless exhaustion can be prevented in four ways, the latter three also providing for rest between contractions:

1. Having the woman use the proper breathing at the proper time is basic to preventing useless exhaustion. As stated previously, panting is an exhausting type of breathing, to be used only when it is mandatory that the woman not push. Controlled types of breathing, whether Lamaze or abdominal, are also tiring if used in early, latent-phase labor before they are really needed. Natural, normal breathing should be encouraged during this time.
2. Organization of necessary procedures. Plan procedures so that as many as possible are done sequentially in the shortest possible time (or number of intervals between contractions). It is exhausting to the woman when there is always something to be done after every contraction.
3. Control the environment in accord with what is most restful to the individual woman (which may vary from your idea of what is restful). This includes controlling lighting, air, external noises, room arrangement, and so forth, as well as who is in the room doing and saying what.
4. Control of who is in the room doing and saying what affects exhaustion and provision for rest. (The woman's significant others and their involvement are discussed later in this chapter. The present discussion relates to professional and nonprofessional health care personnel.) All too frequently the people in the room talk (often over and across the woman in her bed) about subjects totally unrelated to her labor and not involving her. People may be so involved in the conversation that they do not notice the woman's entry into her next contraction and they ignore her needs-for-help. This not only constitutes extreme rudeness and reflects a lack of respect but also illustrates a total misplacing of focus, which should be on the woman. The room of a woman in active labor is no place for constant chatter, either among health care personnel or of a social nature with the woman or her significant others. The old maxim "Silence is golden" is most apropos between contractions unless the woman evinces need for a social exchange (extremely unlikely during active labor) or there is need to communicate instructions or explanations. During a contraction a quiet, firm voice giving encouragement, instruction, and praise is ideal. Afterward, silence. This makes the room quiet, devoid of distractions, and conducive to rest. The focus should be on the woman and anything that will facilitate her efforts to cope and work with her labor.

Assurance of Privacy and Prevention of Exposure. Assurance of privacy and prevention of exposure are not issues in the woman's home but are of particular importance in a teaching hospital. Professional faculty and staff in a teaching hospital often think that because a patient is in their hospital they can assume

the patient's willing submission to the learning needs of a large variety of professional students. Often this is not the case. Most patients are in teaching hospitals (generally university medical centers) because of their medical condition, because of their finances, or because it is the local hospital. They are likely to have no comprehension of the bewildering array of students seemingly affronting pieces of their minds and bodies.

Privacy refers not only to respecting the woman as a human being but also to respecting her body, which is her right as an individual. Imagine the shock a woman feels as she lifts up to push with a contraction, only to confront five to fifteen pairs of eyes all zeroed in on her perineum without her prior knowledge or informed permission! What a difference it would make to discuss this with her beforehand and to request her permission for any observers (much less an extraordinary number of observers). Furthermore, observers should be introduced to the woman personally, so that their first contact, *if* she grants permission, is person-to-person rather than eyes-to-body. Remember, it is the woman's right to say no and to know that this is an acceptable response. If the woman is assured by your actions that there will be no surprises, relaxation is promoted.

Privacy and prevention of exposure also pertain to respect for the woman's sense of modesty. Ideas of modesty vary widely today. Women who are knowledgeable about and feel good about their bodies may not feel the need to be carefully draped to prevent exposure of external genitals. Some women may believe this connotes a traditional attitude of shame regarding these areas—an attitude with which they completely disagree—and they are as apt to be insulted if you drape them as the traditionally modest woman is apt to be acutely embarrassed if you do not drape her. It is best to ask the woman her preferences concerning draping.

Explanation of the Process and Progress of Labor. Women who have been prepared for childbearing are knowledgeable about the processes of labor and want and need to be kept informed of their progress. Women who have not been prepared for childbearing usually want to know what is going on inside their bodies. If you are with an unprepared woman during the latent phase of labor, you will have the time and the woman's undivided attention, if she is interested, to explain briefly the processes of labor and what she will be experiencing in relation to them (Figure 26-15). The labor plates in the *Birth Atlas* [43] published by Maternity Center Association are a useful teaching aid for this purpose. If the unprepared woman is already into active labor, then the midwife is limited to giving the briefest of explanations about the essence of labor progress, such as cervical effacement and dilatation. A quick and graphic way of explaining cervical effacement and dilatation is to use your hands to show 0 percent, 50 percent, and 100 percent effacement; and 1 centimeters, 5 centimeters, and 10 centimeters dilatation. You can explain that it takes longer to get from 0 to 5 centimeters than it does to get from 5 to 10 centimeters dilatation. It is most useful to explain effacement when differentiating between true and false labor and explaining why you want the woman to walk for a while. It is not necessary to explain effacement to a woman in active labor. Explanation of dilatation is useful at both times.

FIGURE 26-15 During early labor is a good time for a midwife to review the processes of labor with a woman.
Source: Photograph by Patricia Urbanus, CNM.

In addition to their philosophical belief about the right of individuals to know what is occurring with their bodies, midwives explain the process and progress of labor in an effort to intervene in the aforementioned fear-tension-pain cycle. Explanation reduces fear of the unknown and alleviation of fear decreases the pain resulting from tension caused by fear.

Explanation of Procedures and Imposed Limitations. Each procedure should be explained and the woman's agreement should be obtained prior to doing the procedure. In order to cope effectively with it, the woman needs to perceive the procedure as one that she needs and one that will be helpful to her. The woman also needs to understand why any imposed limits (e.g., no ambulation if the membranes are ruptured and the presenting part is breech, unengaged, or ill-fitting) are helpful or necessary.

Keeping Clean and Dry. Cleanliness and dryness promote comfort and relaxation and decrease the risk of infection. A combination of bloody show, perspiration, amniotic fluid, solutions for vaginal examination, and feces can make a woman feel messy, uncomfortable, and generally miserable. A shower can change a woman's entire outlook and feeling to one of well-being if there are no contraindications to ambulation and facilities are available. If a shower or tub bath is not possible, a sponge bath or a bed bath is also refreshing.

Subsequent attention to perineal care and keeping dry continues the feeling of well-being. This is maintained by changing the woman's gown or her clothes if what she has on becomes damp with perspiration; changing sheets if they become wet; giving perineal care to remove any solutions or discharges, using careful front-to-back technique; and frequently changing the absorbent pad beneath her buttocks. Emphasis on cleanliness of the perineum and anything that comes close to the perineum, as well as scrupulous attention to handwashing by both the woman and all in contact with her, decreases the chance of intrauterine infection developing from contamination at the vaginal introitus.

Tub Bath. A tub bath can be the most relaxing and facilitative support and comfort measure you can give the woman. The tub needs to be deep enough for the water to cover her abdomen. This provides a form of hydrotherapy and buoyancy which are soothing and help her cope with the contractions. Better yet is a Jacuzzi or tubs designed for labor and birth. Midwives familiar with water labor and birth say that at first the water brings on relaxation and the cervix dilates quickly; but after a couple of hours the contractions may start to fade in frequency and intensity and the woman needs to get out of the tub to stimulate a return to active labor [44].

Mouth Care. A woman in labor will develop bad breath, a dry mouth, dry or cracked lips, a parched throat, and coated teeth, especially if she is in labor for a number of hours without oral fluids and without mouth care. These problems make the woman uncomfortable and they are unpleasant to those attending her. Some of this can be avoided if the woman is able to ingest liquids during her labor. Some of it results from mouth breathing, slight dehydration, lack of moisture in the mouth, or passage of time without mouth care. Mouth care consists of the following:

1. Brushing teeth. Women should be encouraged to bring their toothbrush and toothpaste with them to the hospital for use during labor.
2. Mouthwash—diluted or undiluted according to the woman's preference
3. Glycerin swabs for the lips
4. Vaseline for the lips
5. Sips of water or clear liquids with sugar added for hydration and moistening of the mouth and throat if in a setting that restricts food and liquids during labor
6. Hard candies or lollipops (to prevent aspiration) for moistening the mouth and throat. Women should be encouraged to bring these with them to the hospital.
7. A moist washcloth is invaluable if the woman's oral fluid intake is restricted. Wet a washcloth with cold water and squeeze out just the right amount of water so that when the woman chews and sucks on the cloth she will get enough moisture to moisten her mouth but not enough to swallow. As crude as this may sound, the vast majority of women in this situation find it one of the most helpful comfort measures.

Contrary to popular labor room practice, ice chips are *not* recommended because they have the opposite effect from that desired. Instead of providing moisture and relief, they actually have a drying effect. Use of ice chips simply increases the discomfort of a dry mouth and dry lips and causes an insatiable craving and need for more. Sips of water are far more satisfying and thirst quenching and also contribute to hydration. Better yet is unrestricted fluid intake.

Usefulness of a Washcloth. If you are ever asked to select one item to help you provide support and comfort to a woman in labor, a washcloth is the item to choose. A washcloth can be used in multitudinous ways. Here are a few examples:

1. To refresh by cleansing/washing
2. To wipe away facial perspiration. Wet the cloth with cold water; if there is no cold water, wet it

and then cool it with air breezes like those created when used as a fan. (See "Fanning" below.)
3. To serve as a moist warm or hot pack
4. To serve as a cold compress
5. To moisten dry lips and a dry mouth as described above
6. To use as a fan
7. To use as a "security blanket"—some women clutch their washcloths like Linus does his blanket.

Fanning. Women generate a lot of heat during labor. Even in labor rooms with the best of temperature control, they will perspire and complain at times of being warm. If the environment is not air-conditioned in the summer the stickiness becomes miserable. If there are no fans you need to create means of fanning the woman. The following are three possibilities:

1. Use a washcloth as a fan: Hold the washcloth by two adjacent corners with your two hands and then flip it around on itself, first going one way and then the other. It will flip more easily if it is damp. (However, this requires a lot of your energy to create only a little amount of breeze in a very circumscribed area.)
2. Better yet is the use of a glove package. This provides a fairly stiff expanse of paper which can be used as a fan with one hand. It has the advantage of mobility and can be directed at any part of the woman's body.
3. The best method for cooling the woman's upper body is simply to grasp the lower front hem of her gown, shirt, or dress; make sure it is loose from underneath the woman at the lower sides; and flap it. This creates a breeze over her entire body from the perineum up across her abdomen, breasts, and head. Hospital gowns are ideal for this.

Back Rub. Two types of back rubs can provide support and comfort to a woman in labor. One is the usual generalized, overall back rub, which is used to promote relaxation. The second is called the OB back rub. Both express caring for the woman and ensure a sustaining human presence for as long as the back rub is given. Lotion or powder should be used to reduce friction and prevent skin irritation.

The OB back rub consists of applying pressure to a specific spot on the woman's lower spine. The woman can tell you precisely where this spot is because it is a localized pain caused by the pressure of the fetal head against her spine. This pain is exaggerated if the fetus is in an occipital posterior position; thus low back pain is often the woman's primary complaint. You will need to check with the woman frequently about the proper location of the pressure you are applying, as the pain will move downward as the fetal head descends. The application of external pressure on the spine counteracts the internal pressure on the spine by the fetal head and thus reduces the pain.

You can massage the spot and adjacent area at the same time by moving your palm in a circle without lifting your palm or moving it off of the identified spot. The woman can also guide you as to the proper amount of pressure. Too much pressure is painful; too little pressure is ineffective. Bracing your elbow against your body or against the bed will enable you to achieve greater pressure if needed. It also will enable you to continue the back rub over a longer period of time because your muscles do not tire as easily if your arm is braced. The OB back rub generally is done only during contractions; this is usually when the woman experiences the greatest discomfort or pain in her lower back. Check with the woman before beginning an OB back rub. Some women don't have this pain, and your energy could be better spent where she is feeling a need for help.

It is difficult to do the OB back rub if the woman is in a supine position; it is hard for you to reach the right area and you have to lift up to apply pressure. If the woman is supine you can provide some degree of relief by folding a small towel and placing it at the specific spot so she lies on it; she can also lie on tennis balls, which provide counterpressure.

Sterile Water Papules (SWP). Sterile water papules are intradermal injections of sterile water administered in four places in the lower lumbosacral area of the back (see Chapter 63 for procedure). Women experience an intense stinging sensation for approximately 30 to 90 seconds during the injection and then many will experience immense relief from their back pain. The majority of women who have had SWP would use them again [45, 46]. Because of the pain of the SWP when first inserted, they should be offered after other methods (e.g., position changes, counterpressure such as the OB back rub, heat, cold) have been tried without relief, unless they are the first choice of a woman who has had them before. They are particularly effective for women with occiput posterior positions.

Heat/Cold to the Lower Back. Heat applied to the woman's lower back in the area where the fetal head presses against the spine will decrease the pain. The heat increases circulation to the area, thereby combating tissue anoxia caused by the pressure. Apply heat carefully; it is easy to burn the woman not only by the temperature of the application but also by putting heat on an area to which creams or ointments have already been applied.

Some midwives have found that the application of cold decreases the pain when heat does not. Supposedly the relief results from a numbing effect, probably due to superficial vasoconstriction. Some women find alternating heat and cold comforting.

Birthing Ball. A physiotherapy ball is the right size and sturdiness to withstand weight and use. Generally a 65-centimeter ball is the right size for women over 5 feet 5 inches tall and a 55-centimeter ball is the right size for women less than 5 feet 5 inches tall. The ball is then adjusted to individual "fit" by adding or letting out air so that it is firm but gives to touch, rolls easily, and the woman's legs are bent at a 90-degree angle when sitting on the ball. Women sit on the ball with their feet about two feet apart and flat on the floor. Good posture is necessary to maintain balance on the ball. This puts the woman in an upright position from which she can rotate her hips in a circular or figure-eight pattern that both relieves back pain and encourages fetal descent. A woman can also sit on the ball and lean forward or use a birthing ball to lean against either in a kneeling (ball on floor) or standing (ball on a bed or table) position. This supports the woman's body and provides a position in which the mother can rest. It also aligns the long axis of the uterus and the fetus with the mother's pelvis and facilitates occiput anterior positions.

Abdominal Rub. The abdominal rub is a *light* rubbing (massage) of the entire abdomen usually done in a circular fashion and often concentrating twice as much rubbing in the lower abdominal area if the woman is feeling pain there. It differs from effleurage in its technique, in its rationale, and in who does it. It is done by an attendant (e.g., significant other, nurse, or midwife) using one hand while the other hand is doing something else, such as feeling the contraction, doing the OB back rub, or holding the woman's hand.

A stomach rub can be very comforting and familiar in a strange environment, and it expresses caring to the woman. It also increases circulation to the area, thereby dilating blood vessels that have become constricted from contractions, causing tissue anoxia. The increased blood flow combats the tissue hypoxia and provides a physiological basis for a decrease in pain.

Effleurage. Effleurage is a technique used in the Lamaze and other psychoprophylactic methods of childbearing. Effleurage means "feather touch," which describes the amount of pressure to be used in doing it. It is usually done by the laboring woman, using both hands and following a definite pattern over primarily her lower abdomen (symphysis pubis to just above her umbilicus) as illustrated in Figure 26-16. Using all her fingers on both hands, with the fingers loosely separated, the woman covers the entire lower abdominal area with the two circular patterns: up and outward from her umbilicus, down and around, or in a reverse pattern. Its effectiveness is both psychological and physiological—psychological in that it is one more thing to concentrate on, along with her breathing, besides her discomfort, and physiological in that the action also increases circulation to the area, combating tissue hypoxia and thus decreasing pain.

Heat to the Lower Abdomen. The application of moist heat to the woman's lower abdomen decreases pain by virtue of the resulting increased circulation that reduces tissue anoxia caused by contraction and tension. However, in order to get enough heat to be effective you need to use a hot pack of bath towels. When these are wet, even when wrung out, they are

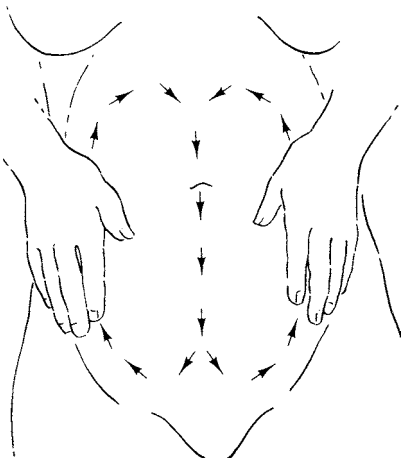

FIGURE 26-16 Effleurage pattern.

often too heavy for the woman to tolerate. They are, however, just the right relief measure for some women.

Empty Bladder. In addition to the effect of a full bladder on the progress of labor and possible later effects on bladder hypotonicity, urine stasis, and bladder infection, there is the very real fact that a full bladder accentuates, and in part creates, a woman's lower abdominal pain. This pain can be greatly relieved if the woman's bladder is emptied.

Medication. Medication was discussed as one of the midwife's management decisions earlier in this chapter. The judicious use of medication also constitutes a support and comfort measure.

Cold Compresses. Some midwives have found that if all else seems ineffective, cold compresses to the axilla and groin bring relief and calm some women.

Support During Vaginal Examinations. This subject is discussed in Chapter 56. You may not have time, or need, to go through all the components of support discussed there. At the very least, however, the following should be observed:

1. An empty bladder—desirable also for the other reasons discussed in this chapter
2. Explanation of why you are doing the examination
3. Positioning of the woman's arms beside her body
4. Help with relaxation breathing and encouragement throughout the examination
5. Super-gentle verbal and physical approach
6. Warning and explanation if what you are about to do will hurt her
7. Explanation of findings

Alleviation of Leg Cramps. Leg cramps during labor usually are so acute they capture the woman's total attention and demand immediate relief. Cramps probably are caused by pressure of the presenting part on the nerves to the extremities as they cross through the greater sciatic foramen in the pelvis.

The woman's legs must never be massaged because of the risk of unwittingly dislodging unknown thrombi developed during months of trouble with venous return and possible varicosities. There is a way of providing immediate relief for leg cramps without running this risk, which is to straighten the woman's leg and dorsiflex her foot. Alternating relaxation with dorsiflexion of her foot increases the speed of the relief. The dorsiflexion should be forcibly exaggerated to effect relief.

Use of Physical Touch. Touching the woman (e.g., on her leg, head, arm) for no other purpose than to touch her can convey caring, comfort, and understanding and can soothe, calm, dispel loneliness, and so forth. However, touching is effective only if you are comfortable touching others *and* if the woman is comfortable with being touched. Don't force yourself to touch a woman in labor if it is uncomfortable for you. The woman will sense your discomfort and the action will be rendered ineffective. On the other hand, if you are "a toucher" you must be acutely sensitive to the woman's response to your touch. If she withdraws or acts repelled, confirm her desire not to be touched and respect her wishes. Don't force touch on her. Even women who do not like to be touched, however, may find your hand better to grasp than the cold metal siderails on a hospital bed—so be sure to ask her if she wants a hand to hold. Touching can be extremely effective when both the toucher and the touched are comfortable with it.

Some women in labor are extreme touchers. Their use of touch is not the same as yours—it is more like a cry for help. Usually extreme touchers are extremely frightened younger girls, who may throw their arms around your neck and forcibly hang on to you during a contraction. It is imperative that you not reject the girl in this situation, even if you are a nontoucher. Hold her. Then, between contractions, ascertain the problems and location of pain and either find a significant other for her to hang on to or tell her you have to be free bodily to do other things to help her but that she can hang on to one of your hands.

Significant Others. The presence of significant others is the most important of all support and comfort measures. Significant others are discussed last because you need to know the other support and comfort measures in order to guide the significant others in providing them for the woman.

The first step is to identify the woman's significant other(s), those she wants with her during the childbirth process—spouse, father of the baby, partner, parent, grandparent, sibling, friend, children, other relative. In many hospital settings the woman has to identify one person who is designated and accepted as the person who will be with her in the labor room, because many hospital labor rooms cannot

philosophically or physically accommodate more than one significant other at a time. The second step is to determine whether the significant other chosen by the woman wishes to be with her during labor.

In a hospital setting the significant others may feel strange, frightened, intimidated, and insecure. They should be made to feel welcome and wanted in the labor room by the staff and viewed as important participants in the ongoing events. These persons should not be relegated to an outer corner of the room but should be given space by the side of the woman. Those significant others who are unprepared usually are glad to do anything you suggest and show them how to do. Those significant others who are prepared have probably planned beforehand with the woman what they will do. Inquire about their plans so you will facilitate rather than frustrate them.

And what do the significant others do? They do anything within their capability that is agreeable to the woman, themselves, and you. The woman will respond to the person with whom she has practiced and on whom she relies for coaching. Unprepared partners, mothers, and grandmothers learn quickly and do well in coaching breathing. The significant other can help by wiping the woman's face with a wet washcloth, hand holding, fanning, and abdominal rubbing. Men make the best back rubbers, especially for the OB back rub. It is helpful if you role model the support and comfort measures they are to provide. Lots of positive reinforcement is useful, particularly when they are learning and when labor goes on for a long period of time. You should also attend to the needs of the significant other(s) and discuss with them what would help them. You may need to suggest that they take breaks from their intense, emotionally involved supportive role. This enables them to continue to give the woman what she needs.

The fact that the midwife must carry out a procedure does not mean that the significant other has to leave the room. The decision of whether to stay in the room and support the woman during a vaginal examination is up to the woman and the significant other. Husbands in particular frequently resent being sent out of the room at this time. On the other hand, some women prefer that their husbands not be there, and some husbands prefer to leave. Determine the wishes of the woman and her significant other.

The most important thing in working with women and their significant others is to facilitate their relationship. Do not try to make yourself the most important person in the woman's eyes but rather foster the importance of the significant other (Figure 26-17). You are a vital, but transient, person in the woman's life. The relationship between the woman and her significant other involves a continuing commitment in daily life.

FIGURE 26-17 Partner supporting woman with midwife facilitating efforts of both.

CHAPTER

27

Fetal Assessment During Labor

Introduction and History

Throughout the course of labor and birth, the safe passage of the fetus is of paramount concern to all involved. Clearly, the goal of every parent and caregiver is to have a healthy newborn. Of question is what method is the most suited to assist in accomplishing this goal. Prior to methods of auscultation, assessment of fetal movement was the revered measurement of fetal well-being and was primarily the responsibility of the mother. Awareness of the fetal heart rate as a sign of fetal life and then of fetal well-being has been acknowledged for the past two centuries [1–5]. First heard by the listener's ear resting on the maternal abdomen, this required "intimate" contact with the pregnant woman [1, 2]. Then, a hollow tube was found to be useful to actually hear the baby's heartbeat and to allow the listener to maintain some distance from the woman's skin. This tube was fashioned into a Pinard fetoscope, and was eventually improved with use of a stethoscope-like listening tool. From the mid-1800s through the 1900s, it was recognized that normal ranges of a fetal heart rate were between 120 and 160 beats per minute (bpm), and that extremes above or below it were worrisome. Auscultation remained the primary means of assessment of fetal status in labor until the 1960s [1–3, 6].

Along with the development of the means of hearing the heart rate and appreciating normal and abnormal patterns of the heart, were the improvements represented by the use of forceps and by cesarean sections, making it possible to expedite the birth if the fetal heart tones were concerning. These advances along with recognition of the means of preventing puerperal fever, especially following cesarean section, allowed a major improvement in the number of infants who were born alive and healthy.

Recognition of the patterns of the fetal heart rate (FHR) in relationship to the uterine contractions led to a desire to record the heartbeat continuously through labor. Human rationale made it seem that if listening to the heart rate periodically could help identify babies who were stressed in utero, then listening through every minute of labor would clearly improve the potential to save unborn babies from hypoxia and asphyxia.

During the 1960s, the electronic fetal monitor was introduced as a tool for use with high-risk pregnancy. As soon as this new technology was utilized, the cesarean section rate increased dramatically. A decrease in perinatal mortality and morbidity were anticipated, but in fact have not materialized [4]. What seemed like such good rationale led to an increased dependence on technology, an increased operative delivery rate, and an increase in medical malpractice—without an improvement in the outcomes for babies and mothers. Introduction of continuous electronic fetal monitoring (EFM) on a widespread basis prior to scientific evidence of its effectiveness led to several generations of physicians, nurses, and women and their families who have become dependent upon this technology despite its lack of benefit [7]. Midwives have maintained use of auscultation as a primary means of assessing the fetus throughout this overwhelming trend toward use of EFM for nearly all laboring women.

With the apparent lack of impact by EFM, multiple randomized controlled trials (RCTs) have been performed to identify any differences in fetal and maternal outcomes related to the method of fetal

assessment used [8–13]. Neither these RCTs nor meta-analyses of many trials have demonstrated improved outcomes of one method of fetal heart rate assessment over the other [14–20]. Although one study indicated a decrease in neonatal seizures with EFM, there was no apparent difference in the childhood neurologic outcomes, making this difference questionable [8, 14, 17].

In 1995, ACOG published guidelines for intrapartum fetal assessment and issued the following statement: "Current data indicate that FHR monitoring is equally effective whether done electronically or by auscultation" [12]. The U.S. Preventive Services Task Force, in its 1996 evaluation of intrapartum electronic fetal monitoring, states that "electronic fetal monitoring for low-risk women in labor is not recommended. There is insufficient evidence to recommend for or against intrapartum electronic fetal monitoring for high-risk pregnant women" [20].

Midwives in the twenty-first century must use evidence-based care in an environment that reveres technology and is mistrusting of traditional noninterventional approaches to care. Assessment of the well-being of the fetus is a critical component of intrapartum management and must be considered individually for each laboring woman. Through knowledge of the various means of documenting fetal heart rate patterns and of measuring the acid-base balance of the fetus when indicated, the midwife will be able to pair the means of assessment with the pregnant woman and her fetus. Regardless of the site of birth, the information and the principles of assessing the fetus and documenting that process are the same.

Physiology and Scope of Problem

The goal of all fetal assessment in labor is to identify infants who are at risk for oxygen deprivation during labor and birth that would be significant enough to cause long-term neurologic damage to the child. Unfortunately, none of the fetal heart rate assessment tools in current use is able to give us this information directly. Thus, we use indicators that are known to be associated with untoward outcomes to guide our decision-making. Even the direct sampling of fetal blood from the scalp or cord blood is not an absolute predictor. It is thus important for clinicians to understand the incidence of intrapartum asphyxia, the major fetal and maternal indicators for depression of the neonate, and intrapartum evidence of potential risk. Consistent use of terms referring to the degrees of oxygen deprivation and signs of nonreassuring FHR patterns is important in communicating well with one's professional colleagues. Understanding the implications of decreased Apgar scores and cord pH and their relationship to neonatal outcome will help the midwife to understand the significance of an infant's condition and to assist the parents in understanding as well.

The term *fetal distress* is frequently used during the intrapartum period to describe anything from multiple mild variable decelerations through severe, prolonged bradycardia or persistent late decelerations with lack of variability. Unfortunately, this term has no specific correlation with fetal heart rate patterns or neonatal outcomes. It does, however, carry a negative connotation among staff and families, and certainly with lawyers. Therefore, the term should be avoided. Instead, specific description of the concerning changes in the fetal heart rate or specific pH values should be used.

According to Low and colleagues, "potentially significant intrapartum fetal asphyxia occurs in approximately 20 per 1000 births. Moderate and severe fetal asphyxia with newborn morbidity occurs in 3 to 4 per 1000 births, with brain damage and subsequent disability in at least 1 per 1000 births" [21, p. 735].

Apgar scores of 7 or greater at 5 minutes and normal fetal heart rate baselines with accelerations are virtually never associated with perinatal asphyxia or long-term neurologic dysfunction [21–23]. When an infant is born in a depressed state, it is commonly felt that there is a high risk of poor neurologic outcomes. In fact, this is rarely the case. In a study of 37,000 births, term infants with an Apgar score of 0 to 3 at 5 minutes had only a 1 percent incidence of cerebral palsy if the Apgar score was greater than 3 by 10 minutes [23].

Nelson et al. identified 78 children with cerebral palsy who had undergone EFM during a two-year period. Review of the fetal monitor strips found multiple late decelerations and decreased variability to have an association with an increased risk of cerebral palsy. However, the children who had late decelerations or diminished variability of the FHR "represented only 0.19 percent of singleton infants with birthweights of 2500 grams or more who had these fetal monitoring findings, for a false positive rate of 99.8 percent" [24].

Sampling of cord blood pH has been used widely to help identify acidotic fetuses. It has been strongly demonstrated that a cord pH >7.2 is invariably associated with well-being. The neonate with a cord pH <7.0 has severe acidosis and is at risk for perinatal asphyxia. In several studies of infants with cord pH <7.0, moderate to severe encephalopathy was identified in 10 percent or fewer [23].

In addition to the pH of the cord blood, metabolic acidosis is evaluated based on the umbilical artery base excess. The normal base excess ranges from –2.0 to –9.0. An increase in base excess to the range of 12 to 16 mmol/L was associated with a 10 percent incidence of moderate or severe newborn complications, while a base excess >16 mmol/L related to 40 percent of newborns with similar complications [19].

According to Goodwin, "intrapartum asphyxia is an uncommon cause of childhood neurologic dysfunction, the intrapartum insult necessary to cause long-term neurologic dysfunction is profound, and the child who does not manifest encephalopathy in the newborn period will not manifest long-term neurologic dysfunction that can be attributed to intrapartum asphyxia" [23, p. 721].

Using electronic fetal monitoring to identify symptoms of asphyxia in the fetus has been fraught with difficulty. Although decreased baseline variability, bradycardia, and late and prolonged variable decelerations are all associated with the diagnosis of perinatal asphyxia, the false-positive rate with these patterns is more than 99 percent. Only absent baseline variability *with* late or prolonged decelerations over a period of time are strongly associated with perinatal asphyxia. Of those infants, only a small percentage will sustain neurologic impairment. Because of the high false-positive rate, it is recommended that nonreassuring fetal heart rate patterns be followed by fetal scalp blood gas analysis or another means of determining fetal well-being (scalp stimulation, fetal pulseoximetry) prior to intervention in the labor [19].

Perinatal asphyxia is a progressive effect of inadequate oxygen availability to the fetus with a concomitant excess of hydrogen ions causing acidosis. Like other aspects of fetal assessment, terminology is often not well defined. The following definitions are presented by the ACOG in its 1995 Bulletin [12]:

Hypoxemia: Decreased oxygen content in blood.
Hypoxia: Decreased level of oxygen in tissue.
Acidemia: Increased concentration of hydrogen ions in the blood.
Acidosis: Increased concentration of hydrogen ions in tissue.
Asphyxia: Hypoxia with metabolic acidosis [12, p. 1].

A primary concern in monitoring fetal well-being is the prevention of hypoxic ischemic encephalopathy (HIE) in the neonate. This can occur from lack of oxygen from the maternal/placental circulation to the fetal brain and/or from a decrease in fetal blood flow to the brain, causing ischemia. The degree of damage to the fetal brain tissue depends on the gestational age, severity of the insult, and individual differences in the development of the fetal neurologic system. Most infants escape without long-term sequelae; however, for those who suffer injury, the most common outcome of HIE in term infants is spastic quadriplegic cerebral palsy [25].

Preterm Fetus

With immaturity of the fetal nervous system, the preterm fetus will demonstrate different patterns of the FHR than the term fetus. Specifically, the baseline heart rate may be in the higher ranges of normal, with an average of 155 bpm at 20 weeks. It is important to consider that the indications for prolonged monitoring of the FHR in the preterm fetus is often related to complications of pregnancy, such as preterm labor and chorioamnionitis as well as maternal hypertension, infection, or dehydration. Therefore, fetal tachycardia (still defined as FHR >160 bpm) may be related to tocolytics, maternal fever, or maternal dehydration. As always, the complete clinical scenario must be considered when evaluating fetal heart rate patterns by either EFM or auscultation.

Accelerations of the fetal heart rate, in association with fetal movement, are a developmental process. Each fetus matures at its own rate, but by 28 weeks approximately 80 percent of fetuses will have accelerations adequate to meet the standard nonstress test criteria of 15 beats in amplitude and at least 15 seconds off the baseline. Prior to 32 weeks, the amplitude of an acceleration may be only 10 bpm with a duration of 10 seconds [27], which satisfies the requirement for nonstress test reactivity in a preterm fetus. Baseline variability may be decreased in the very preterm fetus, but no standards have been determined in this regard.

It is also important to note that the preterm fetus may not tolerate nonreassuring patterns for

the same duration as the term fetus. There can be a more rapid transition from reassuring to nonreassuring tracings in the preterm infant. Twenty percent of term fetuses with a nonreassuring tracing actually have low Apgars and cord blood gases [28]. The preterm fetus however, has a 70 to 80 percent chance of having these signs of depression with a nonreassuring FHR pattern. In the case of a preterm fetus with a nonreassuring pattern, physician consultation is strongly advised [26].

One of the limitations of both auscultation of the FHR and continuous EFM is the diversity of interpretation criteria in the scientific literature as well as between professional clinicians [4, 12]. In an attempt to standardize interpretation criteria and nomenclature regarding fetal heart rate assessment, the National Institute of Child Health and Human Development (NICHD) staged a research planning workshop, reviewed a vast pool of literature, consulted current experts, and devised guidelines for the use and interpretation of intermittent auscultation and electronic fetal monitoring in future research [27]. These guidelines and those highlighted by the American College of Obstetricians and Gynecologists in their clinical guidelines [12] will be the basis of criteria used in this chapter. It is critical that all midwives be aware of the guidelines being used in their own practice setting.

Patient Education

Information regarding the use and quality of auscultation is limited to the lay public. It is the responsibility of the midwife to see that women in their care understand auscultation to be an equal option for assessment of the fetus in labor. The associated freedom of position and movement, the decreased need for analgesia, and the lower rate of operative births should be explained to all women. Withholding (or not offering) information regarding intermittent auscultation deprives women of the opportunity to make this informed choice [29, 30]. Each woman must consider all the options—including the clinical situation, risk factors, personal preferences, hospital or birth center guidelines, and the knowledge of the nursing and midwifery staff. Open discussion and planning prior to the onset of labor will allow women and their families to question their alternatives and make wise choices for themselves.

Intermittent Auscultation

Until the 1970s, auscultation was the standard means of assessment of fetal well-being in labor. As electronic fetal monitoring became more available and used more widely, auscultation diminished in use, nearly to its exclusion in many hospital settings. From the 1970s through the 1990s, nurses, physicians and midwives became less knowledgeable about intermittent auscultation (IA) and their skills with the fetoscope seriously decreased. In fact, today many obstetric providers have never seen or used a fetoscope, let alone learned to rely on the information obtained in managing the course of labor.

Sometimes in life, the "good news" and the "bad news" are the same. In the case of auscultation, skeptics of the equivalency of auscultation and EFM will cite the need for one-to-one nursing care as a drawback [31]. However, constant nursing care has been shown to improve the outcomes of labor and birth: labors are shorter and require less medication, infants have fewer low Apgar scores, and women report that the quality of their experience is better [7, 13]. Is the expense of fetal monitors, central monitoring systems, constant certification courses, increased liability costs, increased surgical fees and more anesthetic-related costs really more expensive than nursing care? What about the cost of loss of compassionate, supportive nursing care?

Auscultation of the fetal heart rate may be performed with a fetoscope, a Doppler device, or even the external ultrasound transducer of the fetal monitor. The use of a fetoscope produces quiet, muffled sounds of the fetal heart, analogous to using a stethoscope for cardiac auscultation. Fetal size, gestational age, position, quantity of amniotic fluid, uterine contractions, maternal habitus, and clinician experience and hearing are all factors involved in the potential for hearing fetal heart tones. The DeLee-Hillis and the Allen fetoscopes utilize bone conduction of the listener's cranium in order to amplify the sounds of the FHR. Because all fetoscopes require close proximity of the examiner's head to the pregnant abdomen, maternal position and activity may also be limitations to accurate assessment of the FHR with a fetoscope.

In recent years, the use of Doppler auscultation devices has made this an easier and often more predictable task. Doppler ultrasound technology works by creating a sound signal related to the movement of the fetal heart. Thus the signal produced by the Doppler is not the actual sound of the fetal heart, but an electronically created sound. Auditory counting of the fetal heart rate by Doppler and by fetoscope has been demonstrated to be equivalent [15, 32, 33]. In addition, auscultation

with a Doppler device has close similarity with the FHR documented by EFM [15, 32, 33].

Handheld Doppler devices have been designed to be used easily in small spaces and with great flexibility to accommodate the variations in fetal position, maternal abdomens, and maternal position. Digital displays of the FHR make manual counting unnecessary, and some models can be safely used underwater, allowing for use during hydrotherapy in labor and birth. The external fetal heart monitor of the EFM machine is actually a Doppler device, and so the audible sounds are the same as those emitted from handheld Doppler devices. Further information regarding the physics and safety of Doppler ultrasound can be found in Chapter 23.

Controversy exists regarding use of the EFM for intermittent documentation. Advocates find use of the EFM ultrasound transducer to be convenient, and with the associated tracing a hard copy can be made. Concern is raised, however, that when the recording is done by the EFM, data including not only the heart rate but the variability and possible accelerations or decelerations are recorded and then must be interpreted according to EFM guidelines [6, 15]. There is no standard in this regard, and the issue must be addressed by each institution and individual clinician.

When you first approach a pregnant woman with the intent of auscultation, it is important to consider the fetal lie in order to optimize the quality of the heart sounds. Listening through the fetal back gives the clearest sound. Leopold maneuvers are quite useful in determining the fetal lie in order to make the best estimate of the placement for the fetoscope or Doppler (see Chapter 53). If using a DeLee-Hillis or Allen fetoscope, the bell must be placed tightly against the maternal abdomen to have a good air seal, and the headpiece against the listener's forehead in order to utilize bone conduction. Similarly, the bell of a Pinard fetoscope is placed firmly on the mother's skin, ensuring contact with the entire rim of the bell; the listener then places an ear firmly against the earpiece for best transmission of sound. Doppler devices require use of a gel between the face of the transducer and the maternal skin in order to ensure transmission of sound without air interference.

Initial auscultation should be for a minimum of 1 minute, between contractions, to begin to determine the baseline heart rate and to listen for regularity of the rate. In order to determine a baseline heart rate, it is necessary to listen between contractions for several intervals within a 10-minute period to confirm consistency of the FHR and to identify the baseline. Then, the FHR should be auscultated following a contraction to determine if there is a significant change in the heart rate as a result of the contraction. Regularity of the rate should be listened for as well. Once a baseline regularity of the FHR and lack of significant decreases in the heart rate have been established, it is important to listen for at least 30 seconds during subsequent auscultation periods. If the woman is in active labor, the timing of auscultation should immediately follow a contraction.

Auscultation has been shown to be able to identify baseline FHRs and changes in the rhythm of the heart rate and to appreciate accelerations of the heart rate [32–34, 37]. It cannot identify long- or short-term variability [6, 12, 31]. Decelerations can be identified as a decrease of the heart rate, but specific timing of the decelerations in relationship to uterine contractions cannot be determined with assurance [6], nor can the degree of decline of the heart rate, such as sudden with a variable deceleration or gradual with an early or late deceleration. Thus decelerations cannot be categorized as early, variable, or late in character. Instead, auscultation of decreases in the FHR can be described as brief or prolonged by the auscultated duration and by the slowest rate counted or registered on the Doppler device.

The guidelines for minimal frequency of auscultation of the fetal heart arise from multiple research studies [8–10] as well as from the NICHD guidelines [27] and current ACOG guidelines [12]. Some authors advocate use of risk factors as a means of determining the frequency of auscultation [12]. Unfortunately, specific risk factors are not usually documented, and this area of the guidelines has been ambiguous. Risk factors should include any maternal or fetal indication of risk of decreased blood flow and oxygenation to the fetus during labor. This would include, but is not limited to, the following factors: maternal hypertension, insulin-dependent diabetes, IUGR, oligohydramnios, unexplained vaginal bleeding, multiple gestation, and oxytocin-induced labors. The suggested time frames for auscultation are noted in Table 27-1.

When auscultation is used as an assessment technique, then the uterine contractions must be assessed by palpation as well as by observation of the mother. The frequency, duration, and intensity of the contractions must be identified [6, 35, 37]. The frequency of this assessment is not necessarily done

TABLE 27-1 Guidelines for Intermittent Auscultation

Minimum Frequency of Auscultation
Without risk factors: q 30 min in active phase q 15 min in 2nd stage With risk factors: q 15 min in active phase after a contraction q 5 min in 2nd stage
After establishment of a baseline and regular rhythm, listen for 30 sec minimum after a contraction.
Also auscultate prior to: AROM ambulation immersion in water or shower administration of analgesics/anesthesia
Assess and document FHR following: ROM recognition of abnormal uterine contraction patterns expulsion of an enema vaginal examination ambulation evaluation of analgesia and/or anesthesia

or documented with every episode of auscultation. The midwife and nurse or labor assistant may individualize this for each woman. (See Chapter 26 for a detailed discussion of assessing contractions in labor.)

If changes in the baseline heart rate are identified, decelerations noted, or fetal arrhythmias heard, consideration must be given to closer assessment of the FHR pattern. A longer listening period may be initiated, or increased frequency of auscultation. If a deceleration is persistent, or the heart rate is bradycardic, the woman should be turned to her side and reevaluated, a different listening device may be used, or fetal scalp stimulation may be performed as a test of fetal oxygenation [6]. If a nonreassuring pattern persists, consultation should be sought, oxygen therapy considered, and intravenous fluids initiated or increased depending on the clinical situation. If concern for the fetus is such that delivery must be effected as soon as possible, frequent auscultation and documentation of results must continue while keeping the obstetric team apprised of the FHR pattern.

In some cases, an EFM tracing may be initiated to confirm fetal status. Explain the concern and reasons for changing monitoring methods to the laboring woman and her support persons. If the EFM strip confirms an abnormal FHR pattern, clinical management should progress as indicated. If, however, the strip is reassuring, then a return to auscultation may be considered. Documentation of the FHR findings as well as interpretation and management considerations are essential (see Figure 27-1). Tables 27-2 and 27-3 identify benefits and limitations of IA and EFM.

Documentation of IA is critical in management of the course of labor as well as for retrospective review of the chart to evaluate care of the fetus in labor. As with other vital signs, IA must be documented after each episode of auscultation as there is no hard copy being recorded as there is with a fetal monitor strip [15]. The graph for documentation of IA should be simple and straightforward, allowing for little extra time to be wasted with excess documentation. However, one of the biggest problems from a medical-legal point of view is the lack of timely documentation of IA according to the guidelines of the birth site.

Electronic Fetal Monitoring

The electronic fetal monitor allows for display of the fetal heart rate pattern and the uterine contraction pattern. It can be used with either external or internal devices, dependent on the clinical situation. For external fetal heart rate monitoring, an ultrasound transducer is secured to the maternal abdomen, over the area of the fetal heart, by an elastic strap. A uterine pressure tocodynamometer (toco) can be similarly secured, resting on the maternal fundus. External fetal monitoring is appropriate for the majority of women. In most situations, with careful placement of the abdominal transducer and toco, the FHR and contractions will print out adequately for interpretation. The equipment and its electrical cords limit the distance a woman can move about. In addition, maternal movement can cause interference in the signal, sometimes obscuring or making unreadable the data being collected.

In the event that the fetal heart rate or the contractions are not being adequately displayed, then internal monitoring of one or both components may be considered. Particularly if the fetal heart rate pattern is nonreassuring, an internal fetal electrode may be desirable in order to collect the most accurate information. With earlier fetal monitors (first generation), external monitoring displayed too much interference to allow accurate interpretation of baseline variability. External fetal monitoring with autocorrelation (all current instrumentation) can be used with nearly the same reliability as internal monitoring [27]. Therefore, only if there were minimal to

absent variability would internal monitoring be indicated for the purpose of evaluating baseline variability. If the fetus is very active or the mother is obese or unable to remain relatively still, or if there are multiple decelerations rendering the strip difficult to interpret with external monitoring, then internal monitoring should be considered to optimize documentation of the data being interpreted.

Internal monitoring can be accomplished, after rupture of the membranes, by means of a fetal scalp electrode, which is a curved wire that is placed on the fetal scalp and secured by twisting the electrode until the fetal scalp is pierced and the electrode is secured superficially under the skin (see Chapter 65). The wires extending from the electrode are entrapped in an electronic transmission device that is then secured to the maternal thigh with an elastic or Velcro belt. The fetal scalp electrode then transmits the fetal electrocardiogram to the monitor, which displays a digital signal of the FHR as well as a continuous graph of the heart rate.

Documentation of contractions by the external tocodynamometer allows for the tracing to demonstrate the onset, peak, and resolution of contractions as well as the time between them. It also provides the information against which to determine the periodicity of any decelerations of the fetal heart rate. However, the external toco cannot determine the actual strength of contractions. Tightening the monitor straps or changing the posi-

TABLE 27-2 Benefits and Limitations of Intermittent Auscultation

Benefits
Neonatal outcomes are comparable to those with EFM.
Cesarean birth rates are lower.
Technique is noninvasive.
Woman's freedom of movement is not impaired.
The FHR can be assessed if the woman is immersed in water.
The equipment is less costly than EFM equipment.
Hands-on, individualized care must be provided.
Limitations
The use of a fetoscope may limit the ability to hear the FHR (e.g., in cases of maternal obesity or increased amniotic fluid).
FHR variability cannot be detected.
Periodicity of FHR decelerations (variable, late, early) cannot be determined.
There is no permanent visual record of the data.
There is a potential need to increase or to realign staff to meet the 1:1 nurse-to-patient ratio that is recommended based on RCTs that compare auscultation and EFM.
Some women may feel auscultation is more intrusive.

TABLE 27-3 Benefits and Limitations of EFM

Benefits
Recorded data provide for collaborative decision-making and education.
Continuous recording is perceived by nursing administrators to decrease need for 1:1 nursing care.
It is an excellent predictor of fetal well-being.
Recorded strip demonstrates FHR and contractions simultaneously.
Some women are reassured with use of high tech.
May offer assistance with coaching to identify onset of contractions.
Limitations
Increased cesarean sections (which then includes increased rates of general anesthesia and infection).
Interrater reliability is poor.
Prevents normal movement, walking during labor.
Creates false sense of security.
There is no consensus on guidelines for interpretation of FHRs.
There is no agreement regarding need for or timing of intervention.
Terminology is varied and not precise.
Cannot be used in water.
There is increased operative vaginal delivery (forceps and vacuum assist).
Uses expensive equipment.
There is a high false-positive rate for suspected fetal compromise.

tion of the toco can show very different apparent intensity of contractions. Internal uterine monitoring is accomplished by placing an intrauterine pressure catheter (IUPC) through the cervix and into the uterine cavity (see Chapter 64). The IUPC has the advantage of providing specific information about the resting tone of the uterus, the actual pressure generated by the contractions, and very accurate timing of the onset, peak, and completion of the contraction. In the event of induction of labor, especially if the progress of labor is slower than expected, an IUPC may be indicated. If amnioinfusion is needed, it will be done through the same catheter as the IUPC (see Chapter 64).

The fetal monitor strip has an upper and lower display area on the paper. The upper portion will display the fetal heart rate pattern with increments of 10 bpm graphed on the vertical axis. The lower

portion displays the uterine contractions with gradations for 0 to 100 Montevideo units on the vertical axis (only for interpretation with an IUPC). The horizontal is marked into 10-second and 1-minute segments. Therefore, the FHR pattern, the contraction pattern, and the timing and relationship of each are displayed.

Interpretation of a fetal monitor strip should progress in a predictable fashion, using standardized nomenclature. The definitions used in this chapter are from research guidelines for interpretation issued in 1997 by the NICHD [27] (see Table 27-4). A lack of standardized language, definitions, and interpretation has been identified as a major concern with EFM.

TABLE 27-4 Definitions for Interpretation of Fetal Heart Rate Patterns

The individual components of the FHR patterns that are defined do not occur alone and generally evolve over time. Therefore a full description of FHR tracing requires a qualitative and quantitative description of the following:

1. Baseline rate
2. Baseline FHR variability
3. Presence of accelerations
4. Periodic or episodic decelerations
5. Changes or trends of FHR patterns over time

Definitions of FHR Patterns

Periodic patterns: Those patterns associated with uterine contractions.

Episodic patterns: Those patterns not associated with uterine contractions. To determine uterine activity, a tocodynamometer tracing of good quality is required.

Recurrent decelerations: Tentatively defined as those decelerations that occur with > or = to 50% of uterine contractions in any 20 minute segment.

Baseline FHR: The approximate mean FHR rounded to increments of 5 beats per minute (bpm) during a 10 minute segment, excluding the following:

1. Periodic or episodic changes
2. Periods of marked FHR variability
3. Segments of the baseline that differ by >25 bpm

In any 10 minute window, the minimum baseline duration must be at least 2 minutes or the baseline for that period is indeterminate. In this case it may be necessary to refer to the previous 10 minute segment(s) for determination of the baseline.

If the baseline FHR is <110 bpm, it is termed *bradycardia*; if the baseline FHR is >160 bpm, it is termed *tachycardia*. Bradycardia and tachycardia are quantitated by the actual FHR in beats per minute, or the visually determined range if the FHR is not stable at one rate.

Baseline FHR variability: Deemed as fluctuations in the baseline FHR of two cycles per minute or greater. These fluctuations are irregular in amplitude and frequency and are visually quantitated as the amplitude of the peak-to-trough in beats per minute as follows:

1. Amplitude range undetectable: absent FHR variability
2. Amplitude range > undetectable < or = to 5 bpm: minimal FHR variability
3. Amplitude range 6 to 25 bpm: moderate FHR variability
4. Amplitude range >25 bpm: marked FHR variability

No distinction is made between short-term variability (or beat-to-beat variability or R-R wave period differences in the electrocardiogram) and long-term variability because in actual practice they are visually determined as a unit. Hence the definition of variability is based visually on the amplitude of the complexes, with exclusion of the regular, smooth sinusoidal pattern.

Acceleration: A visually apparent abrupt increase (defined as onset of acceleration to peak in <30 seconds) in FHR above the baseline. The increase is calculated from the most recently determined portion of the baseline. The acme is > or = to 15 bpm above the baseline, and the acceleration lasts > or = to 15 seconds and <2 minutes from the onset to return to baseline. Before 32 weeks of gestation, accelerations are defined as having an acme > or = to 10 bpm above the baseline and a duration of > or = to 10 seconds.

Prolonged acceleration: More than or equal to 2 minutes and <10 minutes in duration. Acceleration of > or = to 10 minutes is a baseline change.

TABLE 27-4 Definitions for Interpretation of Fetal Heart Rate Patterns (*continued*)

Late deceleration of the FHR: A visually apparent gradual (defined as onset of deceleration to nadir > or = to 30 seconds) decrease and return to baseline FHR associated with a uterine contraction. The decrease is calculated from the most recently determined portion of the baseline. The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction. In most cases the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively.

Early deceleration of the FHR: A visually apparent gradual decrease (defined as onset of deceleration to nadir > or = to 30 seconds) and return to baseline FHR associated with a uterine contraction. The decrease is calculated from the most recently determined portion of the baseline. It is coincident in timing, with the nadir of the deceleration occurring at the same time as the peak of the contraction. In most cases the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively.

Variable deceleration of the FHR: A visually apparent abrupt decrease (defined as onset of deceleration to beginning of nadir <30 seconds) in FHR below the baseline. The decrease is calculated from the most recently determined portion of the baseline. The decrease in FHR below the baseline is > or = to 15 bpm, lasting > or = to 15 seconds, and <2 minutes from onset to return to baseline. When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive uterine contractions.

Prolonged deceleration of the FHR: A visually apparent decrease in FHR below the baseline. The decrease is calculated from the most recently determined portion of the baseline. The decrease from the baseline is > or = to 15 bpm, lasting > or = to 2 minutes, but <10 minutes from onset to return to baseline. Prolonged deceleration of > or = to 10 minutes is a baseline change.

Any deceleration is quantitated by the depth of the nadir in beats per minute below the baseline (excluding transient spikes or electronic artifact). The duration is quantitated in minutes and seconds from the beginning to the end of the deceleration. Accelerations are quantitated similarly.

Source: From National Institute of Child Health and Human Development, Research Planning Workshop. Electronic fetal heart rate monitoring: research guidelines for interpretation. *Am. J. Obstet. Gynecol.* 77(6):1385–1390, 1997.

Fetal heart rate patterns are caused by or associated with many clinical situations. It is important for the midwife to understand the range of influences that can effect changes in the FHR. Identification of the cause of the abnormal FHR patterns, when possible, allows the midwife to implement corrective measures and further develop the management plan.

In the term fetus, fetal tachycardia alone is not usually associated with poor outcomes. Fetal tachycardia—combined with either late decelerations or prolonged variable decelerations, and absent variability, with or without meconium—is indicative of fetal hypoxia. The preterm fetus, whose organ systems are immature, and the postterm fetus, in whom the placenta has begun aging, may not tolerate these changes as effectively as the term fetus. Every effort should be made to identify the cause of fetal tachycardia, alleviate the problem when possible, and obtain other measures of fetal well-being such as scalp stimulation or scalp blood sampling.

Tachycardia without other fetal heart rate changes may indicate the following:

1. Prematurity (<28 weeks gestation); sympathetic tone develops in the autonomic nervous system before parasympathetic tone.
2. Maternal hyperthermia, either systemic or from chorioamnionitis.
3. Fetal hypoxia; decelerations are an early sign of hypoxia, but, severe, prolonged hypoxia may result in baseline tachycardia [12].
4. Administration of drugs, including beta sympathomimetics such as terbutaline (Brethine); drugs used to treat asthma such as theophylline (Slo-Bid, Theo-Dur, Uniphyl); and drugs used to treat hypertension such as hydralazine (Apresoline) and atenolol (Tenormin).
5. Congenital anomalies, especially those that are cardiac in origin.
6. Maternal dehydration, with or without hyperthermia, such as that precipitated by heat stroke, diabetic ketoacidosis.
7. Fetal anemia; related to Rh sensitization, nonimmune hydrops, fetal-maternal bleed, abruptio placentae.
8. Hyperthyroidism, especially if it is poorly controlled or leads to the development of thyroid storm.

Fetal bradycardia >80 bpm, that is accompanied by adequate variability, is rarely associated with fetal acidemia. However, bradycardia without variability, in the presence of prolonged or late decelera-

tions is often related to hypoxia and metabolic acidosis. Bradycardias that result from severe hypoxia have absent variability and will not return to the baseline. Instead, they will progressively worsen with increasing acidosis and may be seen immediately prior to intrauterine fetal death.

A low baseline FHR of 100 to 120 bpm alone may indicate the following:

1. Maternal hypothermia
2. Prolapsed cord: occult, complete, or intermittent cord compression
3. Fetal hypoxemia or asphyxia (acute or chronic)
4. Vagal stimulation resulting from maternal Valsalva, vaginal exam, rapid descent, or posterior or transverse position of the fetal head in a vertex presentation
5. Cardiac anomalies; sustained fetal bradycardia with positive fetal movement is associated with complete or incomplete atrioventricular heart block
6. Administration of drugs such as propranolol, local anesthetics

In the presence of fetal bradycardia (<110 bpm) the midwife should assess for the following:

1. Presence of prolapsed cord
2. Duration of bradycardia
3. Presence or absence of variability
4. Late or prolonged variable decelerations
5. Expected length of time until delivery

Minimal or Absent Variability

Since the advent of internal fetal heart rate monitoring, heart rate variability has become the most significant indicator used by the experienced clinician to evaluate neurological status and normal cardiac response (see Figure 27-2). Average variability in the fetal heart rate indicates that the fetus's autonomic nervous system, which controls the fetal heart rate, is mature and well oxygenated [35]. Diminished variability (minimal or absent) can be due to a variety of causes such as fetal sleep, drugs, anemia, or hypoxia. When variability is minimal, without the presence of decelerations, it is rarely caused by asphyxia [35]. However, when the variability is absent, especially with associated periodic decelerations, the risk of asphyxia acidosis is high [27]. The following are the most common causes of decreased or absent variability:

1. Fetal sleep cycles, which should persist no longer than 80 minutes in the average fetus
2. Prematurity (<28 weeks gestation)
3. Administration of drugs such as analgesics/narcotics, barbiturates, tranquilizers, phenothiazines (Phenergan), beta adrenergic agents (terbutaline), and anesthetics
4. Congenital neurological anomalies such as anencephaly or cardiac anomalies with conduction system defects
5. Fetal hypoxia and acidosis—the most ominous explanation for decreased variability

Accelerations

Acceleration patterns are transient increases of the fetal heart rate above the baseline (see Figure 27-3). Accelerations are associated with fetal movement. Accelerations in the antepartum and intrapartum period are a reassuring indicator of fetal well-being and are associated with a normal pH. In addition to spontaneous fetal movement, events that may trigger accelerations include fetal scalp stimulation and acoustic stimulation.

Deceleration Patterns

Early Deceleration Early deceleration is thought to be caused by head compression (see Figure 27-4). It is associated with cervical dilatation of 4 to 7 centimeters and is thought to be initiated by the pressure of the dilating cervix across the posterior fontanel in a normal presentation. The pattern may return shortly before delivery when the head receives pressure from the perineal floor during contractions. Early decelerations are not considered to be a pattern that requires treatment or intervention as long as they are carefully differentiated from a late deceleration pattern.

Variable Deceleration Variable decelerations are thought to be caused by umbilical cord compression. A variety of causes of umbilical cord compression have been postulated. In vertex presentations these include positioning of the cord around the neck and body, true knots in the cord, frank and occult prolapse of the cord, and compression due to decreased amniotic fluid. Variable decelerations vary both in duration and in shape from occurrence to occurrence in relation to uterine contractions. They have been described variously as V-shaped, U-shaped, and W-shaped. Thus the pattern is one of variable shape (see Figure 27-5). The onset of variable decelerations is unpredictable and occurs at different times in relation to the onset and duration of the uterine contractions.

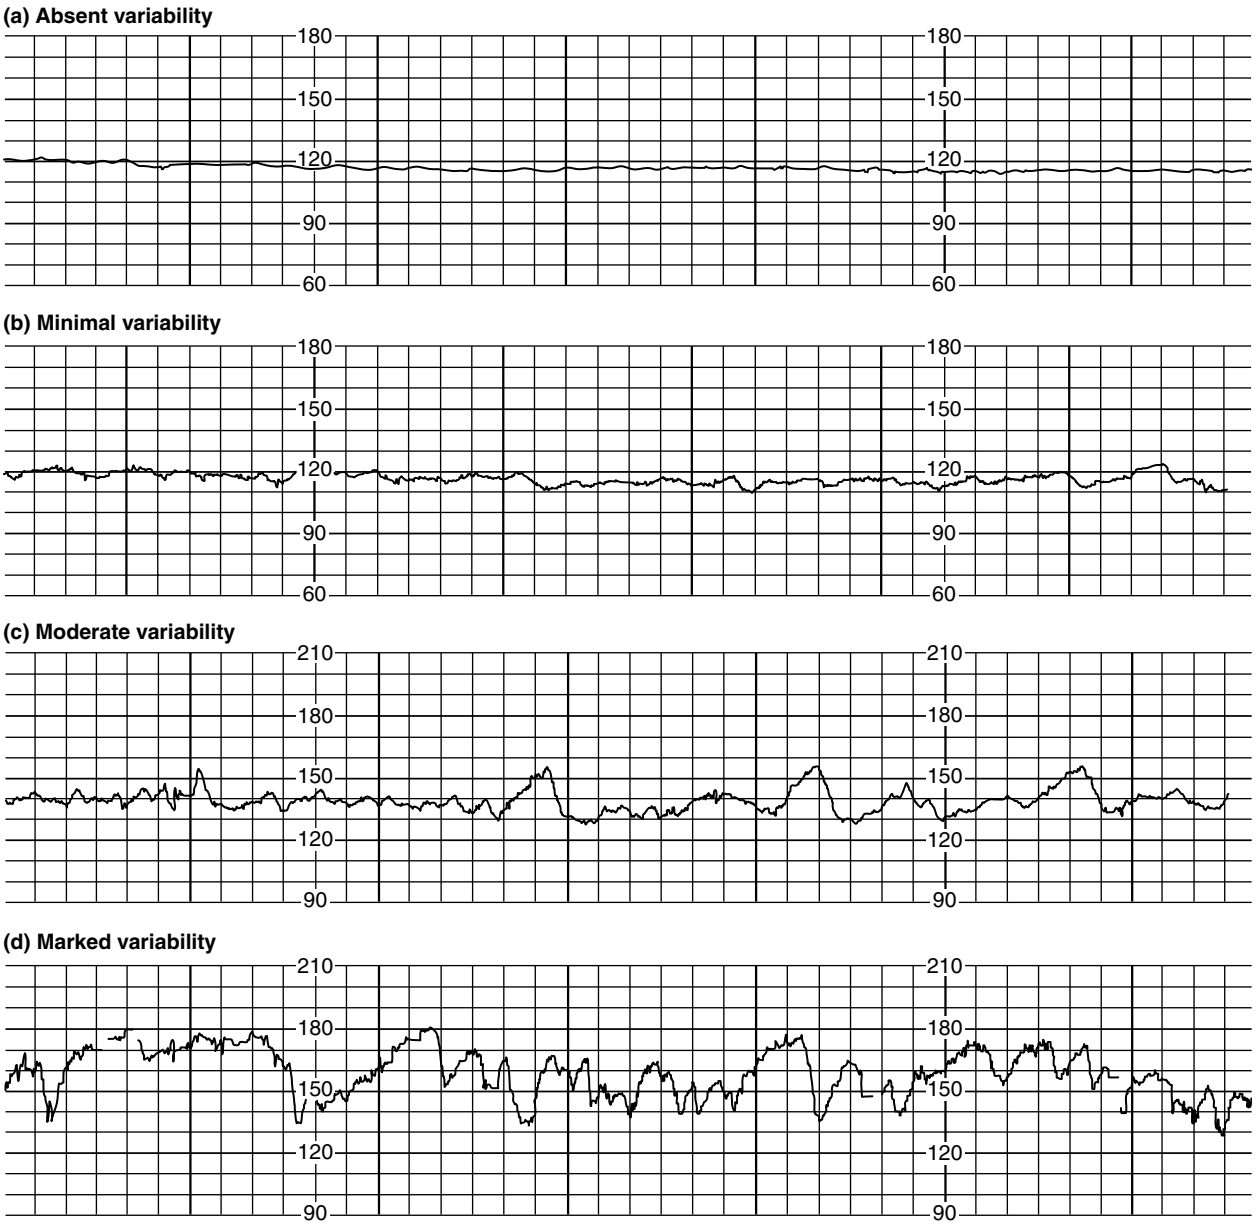

FIGURE 27-2 Range of FHR variability.

Variable decelerations are the most common FHR changes seen in labor and are not usually associated with abnormal outcomes. The seriousness of variable decelerations depends on their frequency, depth, rate of return, effect on baseline fetal heart rate, and variability. Variable decelerations that quickly return to a normal baseline with average variability are not associated with hypoxemia and acidosis. Variables are considered to be nonreassuring when they become progressively repetitive and deeper, last longer, and are associated with tachycardia and/or diminished variability. Variable decelerations that drop to less than 70 bpm for more than 60 seconds and those which have a slow return to the baseline are considered nonreassuring. When nonreassuring variable decelerations are accompanied by a diminished variability or tachycardia, they are more frequently associated with fetal acidosis [12].

Late Deceleration A pattern of late decelerations is thought to be due to uteroplacental insufficiency and a subsequent decrease in oxygen availability to the fetus. Late decelerations are caused by decreased pla-

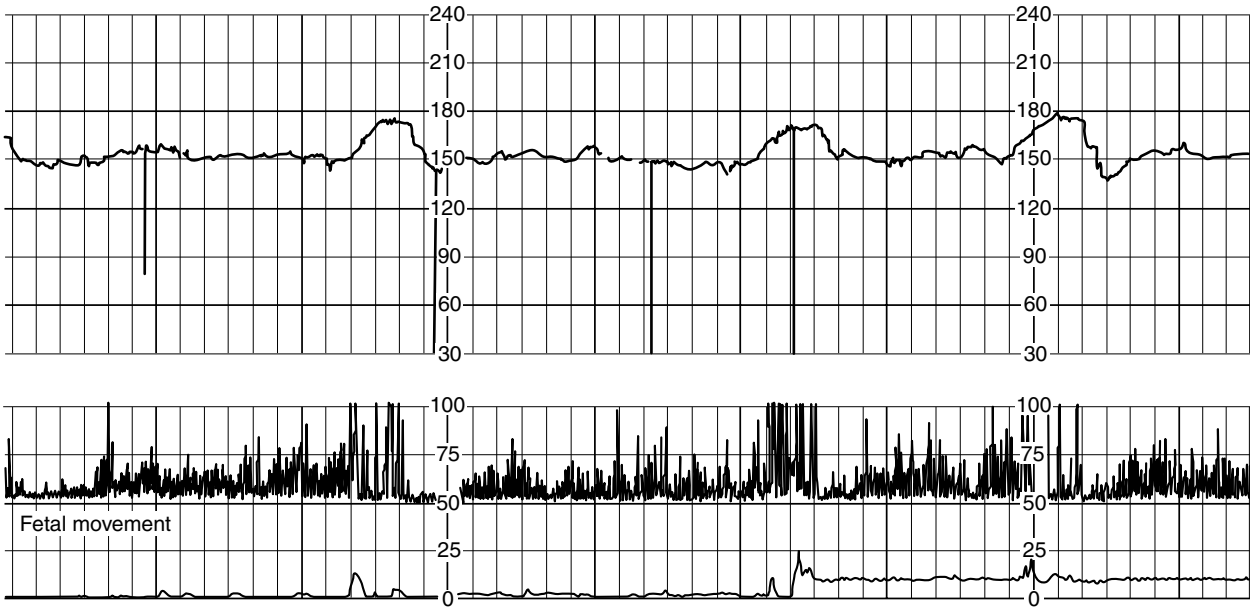

FIGURE 27-3 Accelerations of the fetal heart rate. Note the correlation with fetal movement.

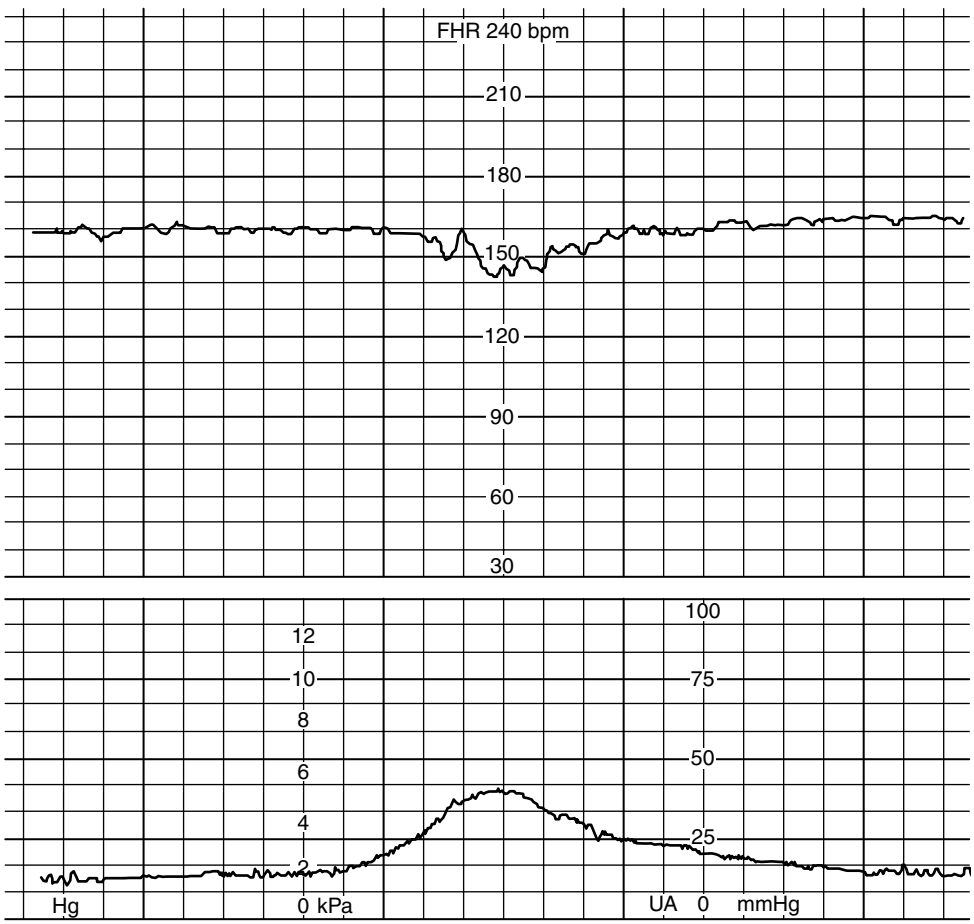

FIGURE 27-4 Early decelerations. Note that the onset and nadir are consistent with the peak of the contraction.

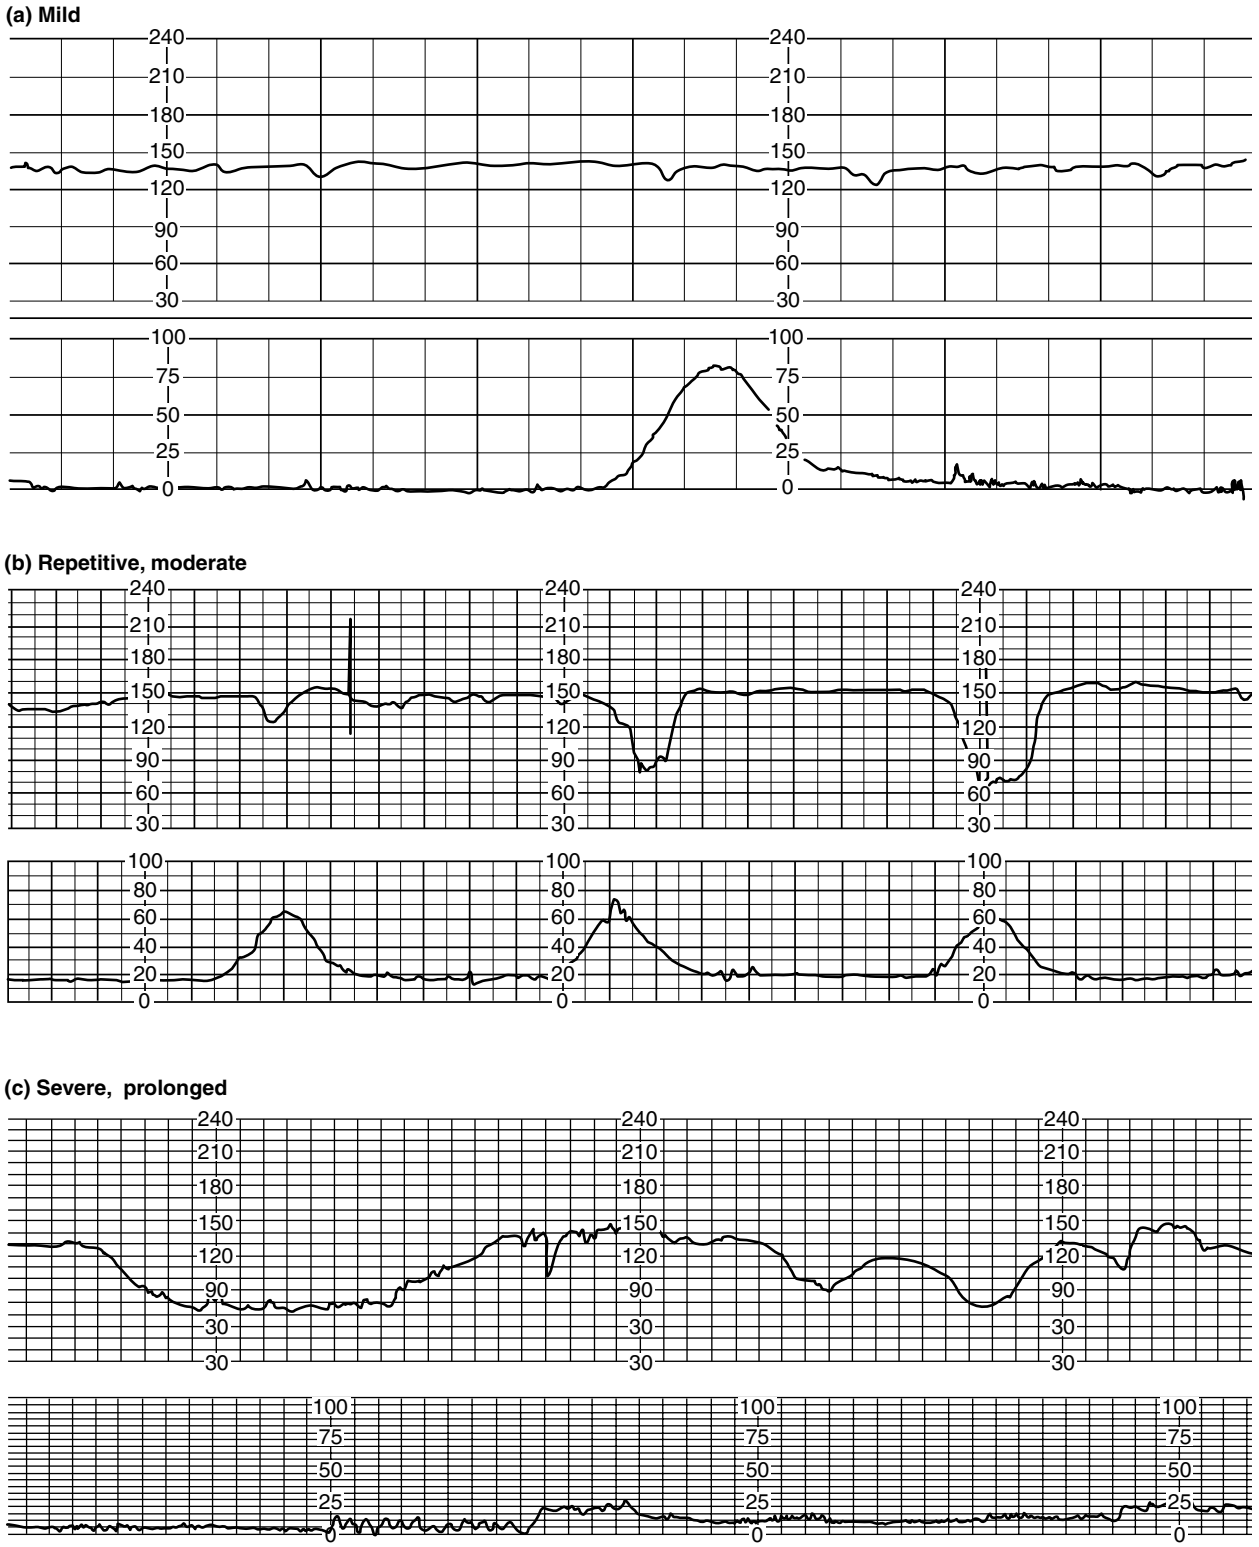

FIGURE 27-5 Variable decelerations.

cental perfusion caused by uterine contractions. As the contraction strengthens, the blood supply diminishes and the fetal heart rate decelerates until the contraction has peaked and blood flow again improves, allowing adequate oxygenation of the fetus with a resultant increase in the FHR. Thus the deceleration is uniform in shape with the drop in FHR beginning near or after the peak of the contraction and resolution of the deceleration occurring after the contraction has subsided (see Figure 27-6). In the absence of

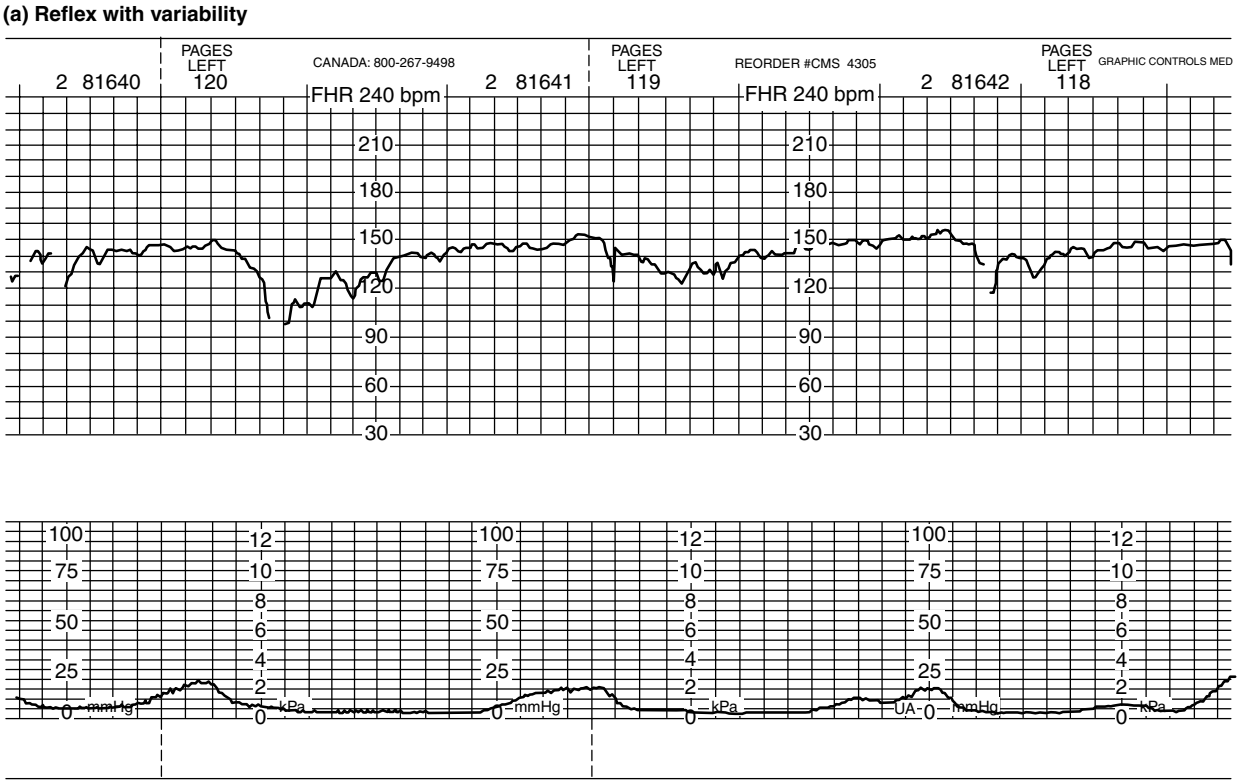

FIGURE 27-6 Late decelerations.

acidemia, this is a reflex mechanism only and may occur intermittently, which is not considered to be nonreassuring. With prolonged hypoxic events, metabolic acidosis develops and myocardial depression begins to occur; the decelerations are persistent, occurring with a majority of contractions, and they are considered to be nonreassuring. Uncorrected uteroplacental insufficiency is a life-threatening condition and always requires intervention to correct it or expeditious delivery must ensue. The fetal heart rate in a late deceleration will usually be within the normal range and can be as shallow as 10 bpm below the baseline rate. The severity of the fetal hypoxia cannot be measured by the depth of the deceleration.

The causes of chronic and acute uteroplacental insufficiency include the following:

1. Intrauterine growth retardation associated with maternal chronic hypertension, lupus erythematosus, poorly controlled diabetes, hyperthyroidism, or intrauterine infection
2. Hypertensive disorders (pregnancy-induced hypertension, chronic hypertension, chronic hypertension with superimposed PIH)
3. Maternal hypotension syndrome associated with supine positioning, conduction anesthesia, severe dehydration, or septic shock
4. Hypertonic uterine contractions such as those caused by administration of oxytocin or prostaglandins
5. Postmaturity
6. Abnormal placentation (placenta previa, vasa previa, infarction of one or more lobes)
7. Fetal anemia associated with RH sensitization, nonimmune hydrops, or fetal-maternal hemorrhage

Prolonged Deceleration Pattern Prolonged decelerations are defined as decelerations of the fetal heart rate lasting longer than 60 to 90 seconds and usually occurring as isolated events (see Figure 27-7).

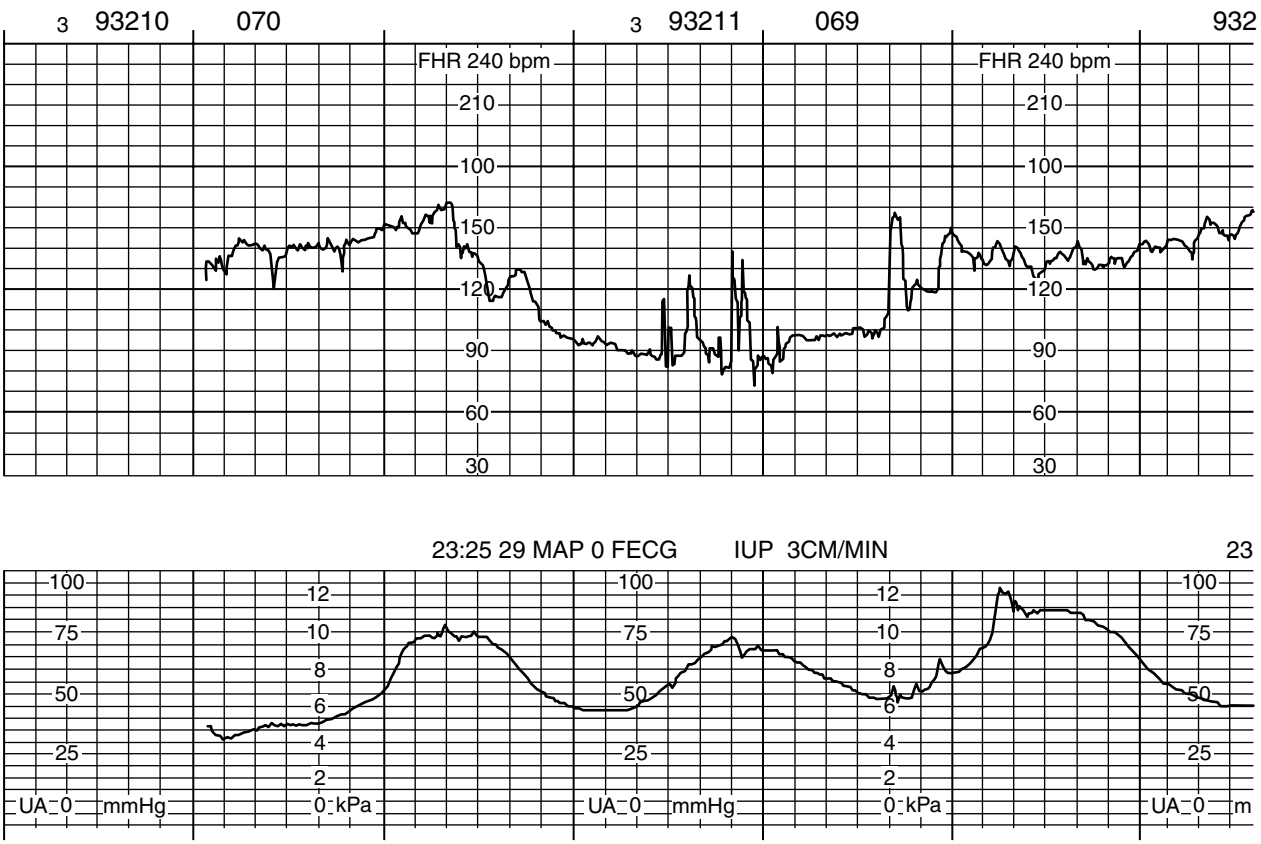

FIGURE 27-7 Prolonged deceleration pattern.

They have a variety of mechanisms and therefore have multiple pathophysiological causes. Known precipitating factors associated with prolonged decelerations include the following:

1. Umbilical cord compression
2. Profound uteroplacental insufficiency
3. Hypotension related to supine positioning or epidural or spinal anesthesia
4. Paracervical anesthesia, which can cause decelerations by one of three mechanisms (direct fetal uptake of local anesthetic, maternal hypotension, and uterine hypertonus)
5. Hypertonic or tetanic uterine contractions
6. Administration/ingestion of drugs such as Dramamine or Demerol when combined with Phenergan and cocaine
7. Maternal hypoxia associated with seizures or acute respiratory depression
8. Pelvic exam
9. Maternal Valsalva
10. Rapid descent of the fetal head

Management of prolonged decelerations depends on the cause, length of deceleration, and recovery of the fetus following the pattern. It is common for the fetus to recover with a period of tachycardia, decreased variability, and occasionally late decelerations. If the precipitating cause is alleviated, the fetus will usually recover spontaneously. Occasionally the decelerations become protracted and may precede fetal death. If prolonged decelerations recur, the midwife should notify the consulting physician and prepare the woman for cesarean birth.

Sinusoidal Pattern A sinusoidal pattern is one in which there is an undulating, repetitive, uniform fetal heart rate equally distributed 5 to 15 bpm above and below the baseline for at least 10 minutes (see Figure 27-8). The undulation has no relationship to either the contraction pattern or fetal movement. It occurs at a rate of 2 to 6 cycles per

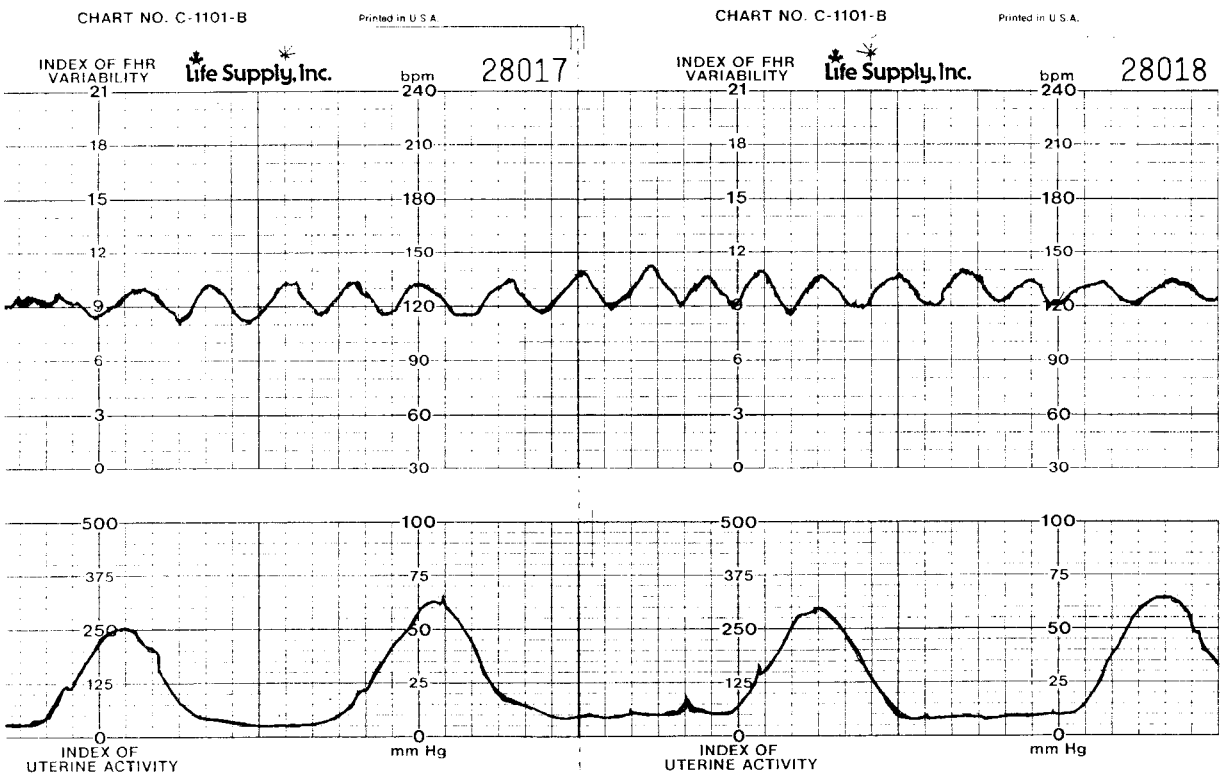

FIGURE 27-8 Sinusoidal pattern. (Courtesy of Nancy McCluggage, CNM, MA)

minute and is identified by an absence of short-term variability and no fetal heart rate accelerations following its occurrence. True sinusoidal patterns are extremely rare.

Significant sinusoidal fetal heart rate patterns are associated with chronic fetal anemia, as seen in isoimmunization and abruptio placentae and severe hypoxia with acidosis. Under these conditions, a sinusoidal heart rate pattern is always an ominous fetal heart rate pattern, and immediate intervention must occur if fetal death is to be prevented. The midwife should notify the consulting physician immediately and prepare the woman for emergency cesarean birth. The neonatal team should be notified to prepare for a potentially severely anemic, hypoxic, or acidotic newborn.

Wandering Baseline The wandering baseline appears to be a very late development in the progression of fetal deterioration (see Figure 27-9). It is an extremely rare finding diagnosed when the midwife has been unable to establish a baseline fetal heart rate. The wandering baseline is usually within the normal baseline parameters of 120 to 160 bpm but is identifiable by its total absence of short-term variability. This is an ominous indicator of fetal distress and requires immediate notification of the consulting physician and preparation for emergency cesarean birth.

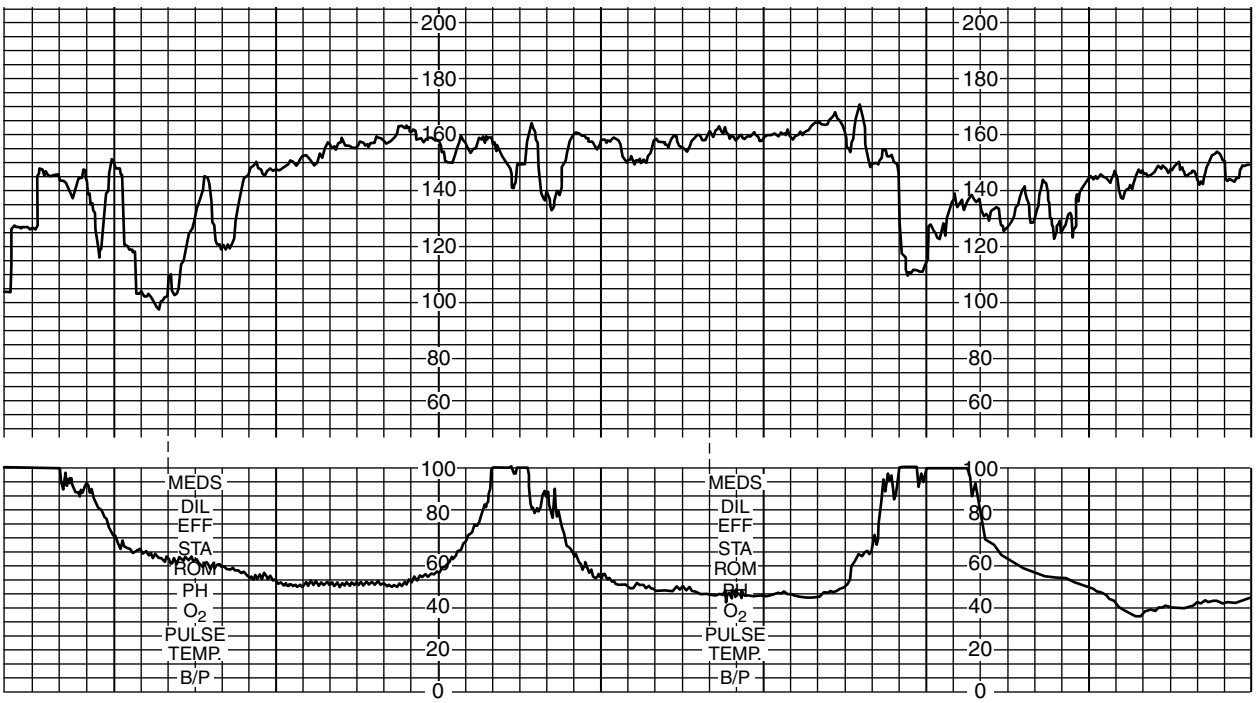

FIGURE 27-9 Wandering baseline.

Midwifery Management of Nonreassuring Fetal Heart Rate Patterns

All abnormal fetal heart rates and patterns require that the midwife notify the consulting physician immediately if there is not a clear cause of the pattern such as narcotic administration or if the pattern does not resolve with usual attempts to resuscitate the fetus in utero. Detection and identification of these abnormalities are essential. When a nonreassuring heart rate is present, it must be considered in reference to other factors in the clinical scenario such as the following:

1. Maternal complications that increase the risk for uteroplacental insufficiency (e.g., preeclampsia, hypertension, diabetes, lupus erythematosus)
2. Fetal complications (e.g., postdates, intrauterine growth retardation, decreased amniotic fluid index)
3. The differential diagnosis of the fetal heart rate pattern
4. Presence or absence of tachycardia and/or decreased variability
5. Whether attempts to correct the underlying problem are successful
6. Acid-base status of the fetus determined either through scalp or acoustic stimulation or via direct fetal scalp blood sampling
7. Presence or absence of meconium
8. Gestational age (with the preterm fetus having a lower tolerance for hypoxia than the term infant)
9. Anticipated time until birth
10. Availability of consultant physician, emergency operative staff and facility

Midwifery management of nonreassuring fetal heart rate patterns will be determined by the actual FHR pattern and its duration and severity. If a fetus has recently had a reassuring pattern and now develops a nonreassuring pattern that is not emergent, such as decreased baseline variability of short duration (<60 minutes) without decelerations, multiple mild or moderate variable decelerations with rapid return to baseline and adequate variability, or transient tachycardia, the following steps may be taken:

1. Position the woman on her side to achieve the following:
   a. Redistribute uterine contents in an attempt to alleviate any cord compression.
   b. Alleviate supine hypotension syndrome.
   c. Decrease frequency of uterine contractions.
2. Assess hydration and start or increase IV hydration with a solution that does not contain glucose.
3. Consider potential causes of the changes, such as fetal sleep cycle, response to narcotic administration, oligohydramnios.
4. Consider use of fetal scalp stimulation or acoustic stimulation.
5. If using intermittent auscultation, consider use of external EFM for documentation of the FHR pattern.
6. If using EFM, consider internal fetal scalp electrode for better definition of the FHR tracing and as a means of scalp stimulation.
7. Notify the consulting physician if unchanged within a reasonable period of time.

If nonreassuring patterns of the FHR are persistent, do not respond to the above measures, or are severe (such as prolonged bradycardia or persistent late decelerations with minimal variability) the midwife must act quickly to reassure fetal well-being or prepare for delivery. The following steps may be taken by the midwife or other available staff at the direction of the midwife to expedite this management:

1. Notify the consulting physician.
2. Perform a vaginal examination to determine the following:
   a. Rule out a prolapsed umbilical cord. If the cord is prolapsed, elevate the presenting part and implement emergency delivery procedures (see Chapter 29).
   b. Ascertain if there has been rapid descent of the head.
   c. Ascertain the expected length of time until birth.
   d. Perform fetal scalp stimulation.
   e. Initiate internal fetal monitoring if indicated.
3. Begin IV hydration with a solution that does not contain glucose.
4. Discontinue any pitocin stimulation to decrease uterine activity and alleviate any resulting uteroplacental insufficiency.
5. Administer oxygen via a well-fitting face mask at 8 to 10 L/min. A well-fitting mask provides more oxygen for any level of oxygen transfer that is occurring in the presence of uteroplacental insufficiency. It is not effective when the problem is complete cord compression.
6. Perform scalp, acoustic, or abdominal stimulation of the fetus. If no acceleration occurs in response, prepare to obtain a fetal scalp blood sample.

7. Administer tocolytic therapy with 0.25 mg terbutaline subcutaneously or 0.125 to 0.25 mg intravenously to allow for intrauterine resuscitation if decelerations are related to uterine hyperstimulation or if there will be an unavoidable delay to operative intervention. Tocolytic therapy should not be used to delay intervention.
8. Perform amnioinfusion if the problem is because of umbilical cord compression. Do not delay preparations for intervention while carrying out this procedure. It may, however, be successful in correcting the problem, thus preventing the need for emergency delivery.
9. If the FHR pattern is progressively worsening or is severe, initiate preparations for delivery by cesarean section.
10. Explain the seriousness of the situation to the mother and her support persons while taking steps to alleviate the problem or preparing for delivery.

Amnioinfusion

There are two primary indications for amnioinfusion: (1) cord compression that may improve with restored intra-amniotic fluid and (2) meconium-stained amniotic fluid that may be diluted or rinsed away. Amnioinfusion has been shown to improve fetal and maternal outcomes in labors complicated by variable decelerations, oligohydramnios, and thick meconium in the amniotic fluid [38–40]. The presence of meconium with signs of fetal hypoxia (i.e., persistent late decelerations, variable decelerations, loss of variability and tachycardia, or sinusoidal pattern) is a serious indicator of fetal distress that requires prompt attention. Aspiration of thick or particulate meconium by the fetus may be decreased by amniofusion.

Amnioinfusion is a simple method used to restore the normal amount of fluid surrounding the fetus. This is accomplished by instilling sterile saline or lactated Ringer's solution through an intrauterine pressure catheter (IUPC) (see Chapter 64). The membranes must be ruptured and the cervix dilated to at least 2 centimeters to allow for insertion of the IUPC and to be safely guided into the correct placement.

Indirect, Noninvasive Means of Assessing Fetal Acid-Base Balance

Use of fetal scalp blood sampling is time consuming, uncomfortable for the woman, expensive, and not available in all settings. In addition, the single pH reading is only valid at the actual time of sampling. Both fetal scalp stimulation and vibroacoustic stimulation are simple, quick means of identifying the fetus with nonreassuring FHR patterns that actually has a normal blood pH. This has the potential to decrease the need for more invasive and expensive fetal scalp blood sampling or operative intervention. The midwife should understand the use and implications of both tests.

Fetal Scalp Stimulation A simple test of fetal well-being is stimulation of the fetal scalp through the dilated cervix. This can be done with the examining finger with 15 seconds of gentle massage of the fetal head [41–43]. If that is not adequate, an Allis clamp can be used to pinch the scalp. The anticipated response is an acceleration of the fetal heart rate of at least 15 bpm for a minimum of 15 seconds (see Figure 27-10). A reactive response correlates with a pH of >7.20; however, lack of response appears to occur in fetuses with normal pH approximately 50 percent of the time.

When performing a vaginal examination, note on the EFM strip when there is an acceleration associated with exam as an example of fetal well-being. Similarly, if auscultation is being performed during the exam and an acceleration is audible, document this in the record as well. Remember that there does not have to be a nonreassuring situation to be aware of and document signs of wellness.

Vibroacoustic Stimulation in Labor Vibroacoustic (sound) stimulation (VAS) of the term fetus with simultaneous continuous auscultation by Doppler monitoring is a noninvasive test for fetal well-being. When the FHR pattern is nonreassuring, this is a simple, quick method of indirectly obtaining information regarding fetal oxygenation. Several investigators have demonstrated that fetal heart rate accelerations in response to vibroacoustic stimulation are associated with a pH >7.25 [41, 43, 44]. Smith et al. found that of 34 fetuses who remained nonreactive following VAS, 18 had confirmed acidosis with pH <7.20 [43].

Vibroacoustic stimulation is performed using a handheld vibroacoustic stimulator (artificial larynx), which is applied to the maternal abdomen over the region of the fetal head, where it delivers a sound stimulus for 3 to 5 seconds. This may be repeated if indicated. Observe the EFM strip for the fetal response. Discussion of the use of VAS in the antepartal period is detailed in Chapter 23.

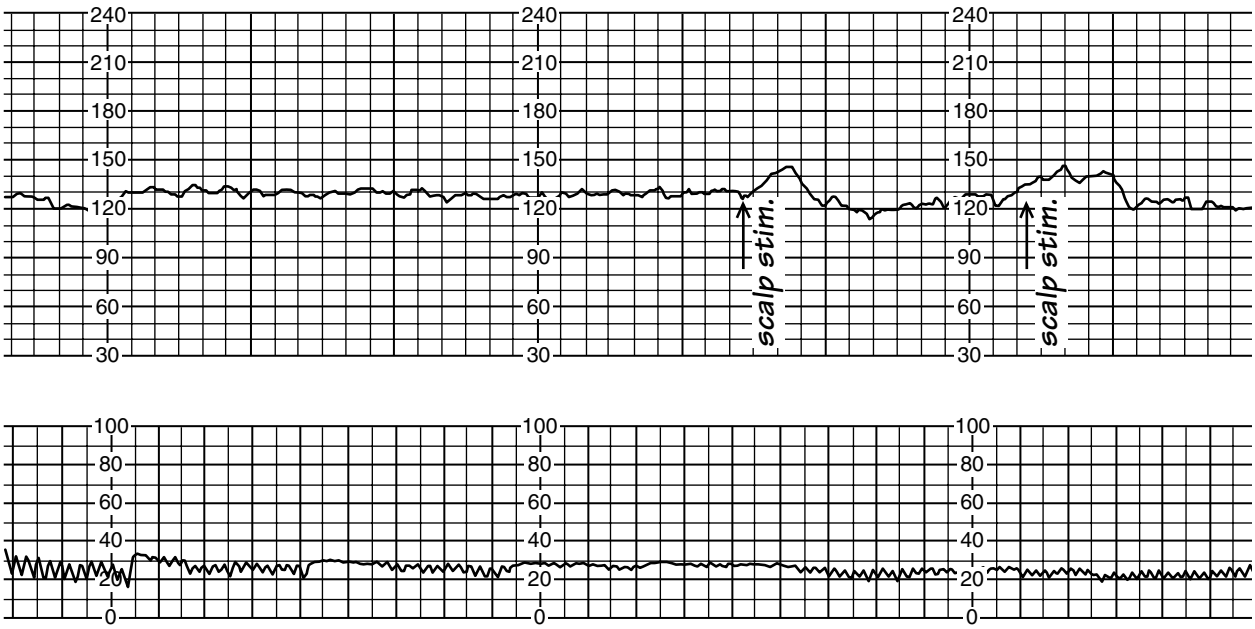

FIGURE 27-10 Fetal heart rate tracing with FHR acceleration immediately following stimulation of the fetal head with the examining finger.

Methods to Evaluate Fetal Acid-Base Balance Directly

Fetal Blood Sampling

Fetal blood sampling (FBS) of the fetal blood is the only direct means of determining fetal acid-base status. When nonreassuring FHR patterns occur, the midwife and physician must consider the severity of the patterns, maternal and fetal complications, potential for intrauterine resuscitation of the fetus, and time anticipated to birth. In some situations—for example, prolonged bradycardia in an IUGR fetus at 4 cm dilation or sudden onset of deep variable decelerations with the fetus at a +2 station—the choice of rapid cesarean or vaginal birth is an obvious choice. However, when the tracing is equivocal and birth is not imminent, more specific data regarding fetal well-being may be needed to make an appropriate management decision about the course of the labor. In the event of severe FHR patterns, time should not be squandered with the collection of FBS instead of delivering the infant as soon as possible [28].

In this case, a sample of fetal blood from the presenting part may offer the opportunity to make decisions based on the actual acid-base status of the fetal blood. In order to perform the procedure, the cervix must be dilated to 2 to 3 cm, and the membranes must be ruptured. In order to avoid supine hypotension with its potential to cause bradycardia and hypoxia, the mother should be positioned on her side. Her upper leg must be supported to allow for introduction of an amnioscope into the vagina to rest on the presenting part. A light source makes visualization of the fetus possible. The fetal skin is cleansed, a drop of silicone gel is applied, and then a 2-millimeter blade on a long handle is used to puncture the fetus. A drop of blood is then collected into a heparinized capillary tube for analysis in a blood gas analyzer (see Figure 27-11). This procedure may be repeated within a few minutes if a confirmatory sample is desired, or intermittently through the remaining course of labor as determined by the EFM tracing and serial FBS [28]. A scalp pH <7.20 is confirmation of fetal acidosis. A pH value between 7.20 and 7.25 is considered to be equivocal and should be repeated within 5 minutes. A value over 7.25 is normal, but must be repeated every 20 to 30 minutes as long as the nonreassuring FHR pattern persists [3].

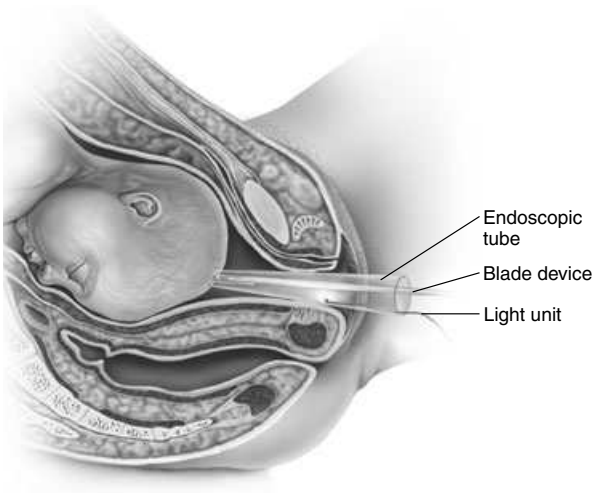

FIGURE 27-11 Technique of fetal scalp blood sampling.

TABLE 27-5 Normal Blood Gas Values of Umbilical Artery and Vein

	Mean Value	Normal Range
Artery		
pH	7.27	7.15 to 7.38
PCO_2	50	35 to 70
Bicarbonate	23	17 to 28
Base excess	−3.6	−2.0 to −9.0
Vein		
pH	7.34	7.20 to 7.41
PCO_2	40	33 to 50
Bicarbonate	21	15 to 26
Base excess	−2.6	−1.0 to −8.0

Source: From Garite, T. J. Intrapartum fetal evaluation. In Gabbe, S. G., Niebyl, J. R., and Simpson, J. L. (Eds.) *Obstetrics: Normal and Problem Pregnancies*, 4th ed. New York: Churchill Livingstone, 2002, p. 425. Reprinted by permission.

The limitations to FBS include the need for intervention to mother and fetus—including the rupture of membranes and puncture of the fetal skin, not to mention the awkward, uncomfortable positioning of the mother. Frequency of sampling is also quite cumbersome. Equipment calibration is commonly a problem thereby providing misleading results. Serum pH is dynamic and can change very quickly. A normal pH at one point in time may no longer be accurate a few minutes later or in a different phase of the contraction.

Midwives may be involved in performing the collection of the fetal blood sample if they have obtained the skills necessary to collect the sample. However, if the fetal heart rate pattern requires evaluation with FBS, the consulting physician should be involved in collaborating on care of the woman and infant.

Umbilical Cord Blood Gas Analysis

Determination of fetal acid-base status at the time of birth is done by the collection of arterial and venous fetal blood samples from the umbilical cord. This information may be very useful in interpreting the potential for or presence of perinatal asphyxia. Severe acidemia is necessary to cause damage to fetal brain tissue. Cord pH values in the normal range (see Table 27-5) may refute a diagnosis of perinatal asphyxia in a depressed or compromised infant [3, 45]. The Apgar score has been used for many years as a surrogate for the definition of perinatal asphyxia. While a 5-minute score of 7 or greater virtually negates the possibility of fetal acidosis, the converse is not true. Apgar scores were created as a guide for the need for infant resuscitation. As previously discussed in the chapter, low Apgar scores are not a measure of neonatal status. Therefore, measurement of the blood gases in the umbilical cord can serve as documentation of the actual acid-base status at the time of birth. Thorp and Rushing state that, "cord blood gas analysis . . . excludes the diagnosis of birth asphyxia in approximately 80 percent of depressed newborns" [45].

In some hospitals, cord blood gases are collected with every birth [44]. Most departments find this to be unnecessary and limit these samples to situations where there have been nonreassuring fetal heart rate patterns, meconium-stained fluid, or the need for infant resuscitation, or with an antepartum diagnosis of IUGR or other high-risk situations.

Sampling of the cord blood gases is performed by double-clamping a 10- to 30-centimeter segment of the cord at the time of birth when the cord is clamped and the infant separated from the cord [3]. Samples of both arterial and venous blood are withdrawn into heparinized syringes and then taken to the lab for blood gas analysis. This should be done as soon as possible because delayed collection or interpretation will result in decreasing pH values. This has been a concern for midwives who prefer not to cut the cord until it has stopped pulsating. If the infant is vigorous, there may be no need for cord blood sampling. In the event of a depressed infant, the cord will need to be cut to allow for im-

mediate care of the newborn, and the cord may be clamped and sampled at that time.

Fetal Oxygen Saturation Monitoring

Fetal oxygen saturation monitoring (FS_pO_2), also known as fetal pulse oximetry, was introduced worldwide in the early 1990s and approved by the FDA in January 2000. The technique is used as an adjunct to EFM when nonreassuring or uninterpretable patterns arise. It is intended to assist clinicians with determining the actual level of fetal oxygenation in order to make decisions regarding the continuation of labor or need to move rapidly to delivery. Because EFM has a high false-positive rate with an accompanying increase in operative interventions, the goal of FS_pO_2 is to more accurately determine which FHR patterns actually represent a compromised fetus [6, 14, 46–48]. It is hoped that this technology will decrease unnecessary intervention in normal labor [6, 14, 46].

Fetal oxygen saturation monitoring uses the same technology as the adult pulse oximetry used on the finger, toe, or ear lobe. By monitoring the light absorption of oxyhemoglobin and deoxyhemoglobin during cardiac systole, the percentage of oxygen in the observed tissue is calculated [49]. To utilize this technique, a single-use S_pO_2 reflectance sensor is inserted through the cervix, into the uterus and rests on the fetal cheek, temple, or forehead, supported by the uterine wall (see Figures 27-12 and 27-13). A continuous real-time tracing of the fetal oxygen saturation is displayed on the fetal monitor strip, overlaying the uterine contraction graph [6, 46].

The normal range of FS_pO_2 for the fetus during labor is 30 to 70 percent. When the FS_pO_2 returns to 30 percent or more between contractions, the results are considered to be reassuring, and labor should be allowed to continue. However, if the FS_pO_2 remains less than 30 percent or the signal is not obtainable for more than 10 minutes, then intervention is warranted in the absence of other reassuring indicators [46]. A single FS_pO_2 reading is not sufficient for evaluation; instead the trend should be assessed in addition to the EFM tracing and other clinical data.

It is critical that the data from FS_pO_2 be interpreted cautiously. Several authors have identified difficulty in obtaining accurate readings when the fetal blood pH is in the acidotic range below 7.16

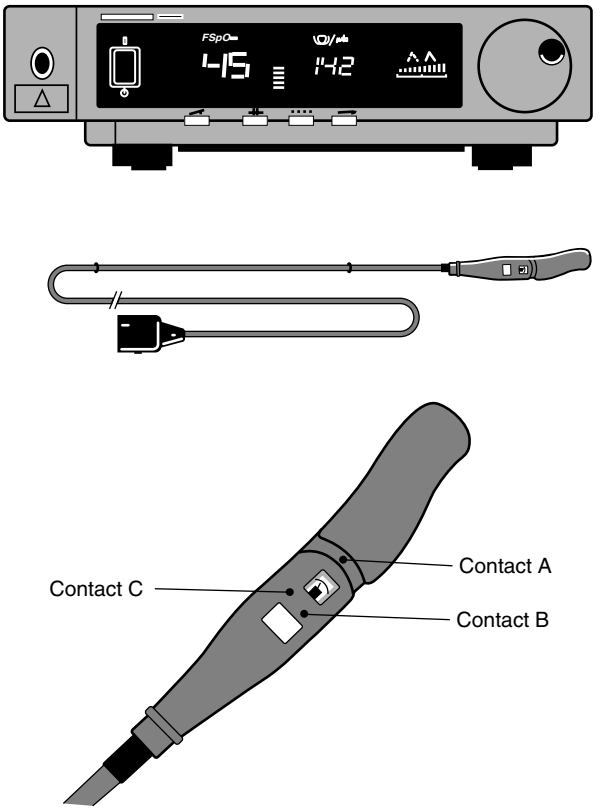

FIGURE 27-12 A fetal pulse oximeter.

FIGURE 27-13 Proper placement of the pulse oximeter on the fetal cheek.

[46–49]. In addition, it is known that common situations such as fetal scalp edema, caput succedaneum, dark, thick, curly hair, or very light hair color, skin thickness, and vernix caseosa may alter the pulse oximetry readings [48, 49]. A study by Schmidt et al. of 128 fetuses monitored with FS_pO_2

found that the readings did not aid in management of labor or improve fetal outcome: "Fetal distress and impaired condition of the newborn are not identified or predicted during routine application of FS_pO_2 monitoring in the fetus during labor with adequate safety" [47].

The utilization of FS_pO_2 requires that the following criteria be met:

1. Ruptured membranes
2. Singleton pregnancy
3. Vertex presentation
4. At least 36 weeks' gestation
5. Cervical dilatation of at least 2 centimeters
6. Fetus at –2 station or below [45, 49]

Contraindications include the following:

1. Placenta previa
2. Ominous FHR pattern requiring immediate delivery
3. Need for immediate delivery (unrelated to FHR pattern)—for example, because of active vaginal bleeding
4. Maternal HIV, active genital herpes, or hepatitis B infections

Fetal pulse oximetry has the promise of being able to identify oxygen levels of the fetus during labor. At this time, the technology is still new, shortcomings are being evaluated, and large randomized controlled trials have not yet been completed to the extent necessary to introduce this technology into general clinical practice [50]. Care must be taken not to allow the same situation to occur with this or any other technology—as was the case with electronic fetal monitoring, which was utilized on a widespread basis prior to scientific confirmation of its impact on neonatal and maternal outcomes.

Admission to L&D and Establishing Initial Well-Being

Labor admission tests (LATs), an initial electronic fetal monitor assessment of the fetus, are commonly used to assess the status of the fetus at the time of admission. The concept behind this is that the EFM strip is indicative of fetal status. If the strip is reactive or reassuring, this may be felt to be a reassuring sign of fetal well-being for the duration of the labor. A nonreassuring strip would then require continuous EFM and evaluation. The LAT, however, has not been shown to have adequate predictive value to use as an admission screening tool in high-risk or low-risk women and does have a high false-positive rate [51]. A study by Mires and colleagues randomized women with normal pregnancies to either EFM or auscultation on admission to L&D. Their findings were that, "admission cardiotocography does not benefit neonatal outcome in low-risk women. Its use results in increased obstetric intervention, including operative delivery" [13].

Impey and colleagues performed a randomized controlled trial of admission electronic fetal monitoring versus auscultation alone. In their group of 8580 women, the EFM at admission did not improve neonatal outcomes. There was an increase in use of EFM and fetal blood sampling, but no change in operative births [52].

AWHONN states, "Each health care facility should develop a policy that defines when . . . to use EFM and auscultation [15]. Figure 27-14 illustrates a suggested method of selecting women for auscultation only, electronic fetal monitoring only, or a combination if indicated. This is based on evidence found in the literature and allows for flexibility.

Midwives will most likely find that there are necessary times to make compromises between their own philosophy of care, the evidence in the literature, the woman's desires, and the opinions and policies of physician, nursing, and administrative colleagues. A thorough knowledge of the literature and issues is useful in making guidelines for midwifery practice.

Medical Legal Aspects

A common concern of clinicians and risk managers is that the lack of a fetal monitor strip will be problematic in the event of a malpractice suit. An increase in medical malpractice cases has been felt to be an additional legacy of EFM [53]. Symonds noted that "seventy percent of all claims concerning intrapartum care in relation to fetal brain damage are based on abnormalities of the cardiotocograms and electronic fetal monitoring" [54]. Because a clear link between neonatal hypoxic encephalopathy and specific fetal monitor patterns has not been demonstrated, the EFM strip may actually pose a greater risk. Some fear that a tracing demonstrating abnormal FHR patterns in a child who is born brain damaged will increase the likelihood of a lawsuit despite specific evidence that the practitioner was not at fault. As interpretation of EFM is quite varied among experts, the strip may indeed be a

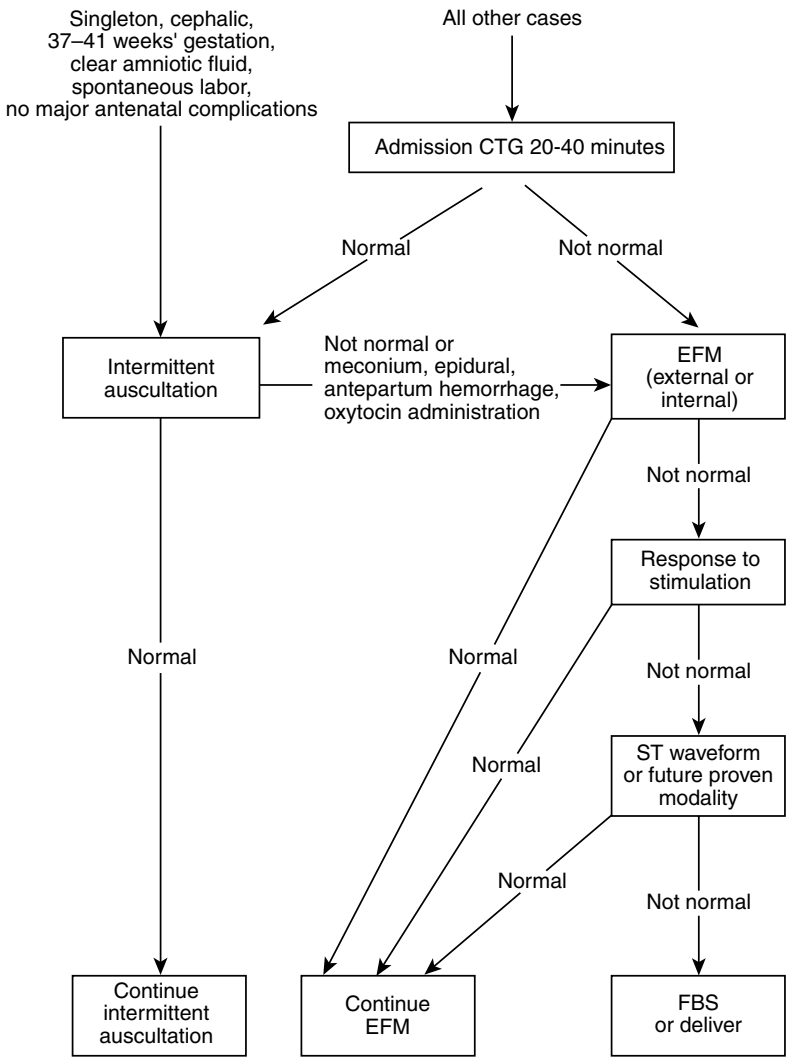

FIGURE 27-14 A proposed clinical management of fetal monitoring based on current research evidence.

Source: From Greene, K. R. Scalp blood gas analysis. *Obstet. Gynecol. Clin. North Am.* 26(4):653 (December) 1999. Reprinted by permission.

greater liability than if there were an auscultation graph with appropriate interventions documented.

Documentation of auscultation used according to the guidelines of the birthing site is the best defense in case of a malpractice suit. Accompanying progress notes with the rationale for decision-making and interventions initiated for abnormal findings offer strength to defending a case. Conversely, incomplete documentation will give the impression that inadequate care was provided. As providers of obstetric care, midwives cannot prevent all poor outcomes and cannot prevent legal actions, but they can diminish the risk for judgment against themselves.

Summary

The assessment of fetal well-being should be a critical element considered in managing labor and birth. However, it must be looked upon as an overall part of the supportive care for the mother. Regardless of the use of intermittent auscultation, electronic fetal monitoring, or a combination of the

two, the focus must be on the care of both mother and fetus, not just documentation of electronically generated data [2, 15].

As with many areas of practice, assessment of the fetus in labor is complex, and research information is being gathered continuously. The midwife must be very knowledgeable regarding the full scope of techniques used in order to optimally utilize the technology, to know when further information is necessary, and to be able to educate women and their families about their options and any interventions that may become necessary.

All midwives must utilize the methodologies that promote normal labor and birth while screening for and managing deviations from normal. The midwife may be the primary supporter of IA and the educator of other professionals in the birthing environment. It is a clear opportunity to blend the art and science of midwifery in a way that can make substantive social change.

CHAPTER

28

The Normal Second Stage of Labor

The second stage of labor begins with complete dilatation of the cervix and ends with the birth of the baby. It is known as the stage of expulsion.

Database for the Second Stage of Labor

The database for determining the well-being of the mother and fetus during the second stage of labor is a continuation of the database collected and evaluated during the first stage of labor. The components of the database include the following:

1. Continuing evaluation of any significant findings from the history, physical and pelvic examinations, and laboratory work done during the initial evaluation of the mother and fetus in labor
2. Continuing evaluation of the progress of labor
3. Continuing evaluation of the fetus
4. Continuing evaluation of the woman
5. Continuing screening for signs and symptoms of obstetrical complications and fetal distress. (These are discussed in Chapters 27, 29, and 30.)

Again, the midwife must know the parameters of normal in order to evaluate the specific pieces of information obtained for each component of the database.

The Progress of Labor

In nulliparas, engagement usually occurs by the onset of true labor and no later than during the active phase of the first stage of labor. Philpott and Castle found that African Rhodesian primigravidas did not have engagement until the late first stage of labor [1]. Lack of engagement at the onset of the second stage of labor in multiparas is abnormal. The fetal presenting part begins descending during the first stage of labor and, according to Friedman, reaches its maximum speed during and toward the end of maximum speed in cervical dilatation [2, p. 203], and continues to descend through the second stage of labor until reaching the perineal floor. Friedman determined that the average maximum rate of descent is 1.6 centimeters per hour in nulliparas and 5.4 centimeters per hour in multiparas [2, p. 206]. The average length of the second stage, according to Friedman, is 46 minutes for primigravidas and 14 minutes for multiparas [2, pp. 37, 40]. Generally, a second stage that lasts longer than 2 hours for a primigravida or 1 hour for a multipara is considered abnormal by those who agree with Friedman. There has been acknowledgement, however, that the 2 hour limit does not indicate a need to deliver the baby by forceps or vacuum extractor as long as there is progressive descent and absence of fetal distress. A study by Kilpatrick and Laros of nearly seven thousand women who were "allowed to labor without interference until spontaneous delivery" determined a statistically significant difference in the length of both first and second stage labor dependent on whether conduction anesthesia was used; see Table 28-1 [3]. Any discussion of length of labor, thus, has to take into account whether the woman has an epidural block as this may make the labor significantly longer. The average length of the second stage of labor for 1472 women with no anesthesia in a study by Albers, Schiff, and Gorwoda had similar findings of 53 minutes for nulliparas and 17 minutes for multiparas [4]. Within their study population, they found a statistically significant shorter second stage of an average of 43

TABLE 28-1 Mean Lengths of the First and Second Stages of Labor

	No Conduction Anesthesia		Conduction Anesthesia	
	First Stage (hr)	*Second Stage (min)*	*First Stage (hr)*	*Second Stage (min)*
Nulliparous Mean	8.1	54	10.2	79
Multiparous Mean	5.7	19	7.4	45

All differences in the means are statistically significant ($P<.0001$).

minutes for American Indian nulliparas compared to an average of 60 minutes for non-Hispanic white nulliparas. A study by Diegman, Andrews, and Niemczura found further ethnic differences with an average length of second stage labor of 31.6 minutes for African-American nulliparas and 44.3 minutes for Puerto Rican nulliparas [5].

In the natural course of labor there is often a lull, or quiet period, between first and second stage. The hard contractions of transition are now past and the cervix is fully dilated. The woman's body seems to "take a breath" before starting expulsive efforts. The contractions space out and are not so intense. The woman rests and may even nap. This quiet period may last as long as an hour and is longer in primigravidas than in multigravidas. Gradually momentum builds as the fetal head descends through the pelvis; the contractions become more forceful and the woman begins to bear down voluntarily with expiratory, grunty, short pushes. The woman's grunts may be gutteral and her face may contort with effort (Figure 28-1).

Aderhold and Roberts identified this lull as the first of three phases of second stage labor, as follows [6]:

Phase I, the lull: From complete dilatation until the urge to bear down or the onset of frequent, rhythmic bearing-down efforts

Phase II, active bearing down: From the onset of rhythmic bearing-down efforts or the urge to push until the presenting part no longer retreats between bearing-down efforts (crowning)

Phase III, perineal: From crowning of the presenting part until the birth of the entire body

FIGURE 28-1 Children who have been prepared for the sounds and sights of labor and delivery are not disturbed by them and instead focus on being able to see more of the baby's head as it appears at the introitus.

Contractions during the second stage are frequent, strong, and slightly longer—that is, approximately every 2 minutes, lasting 60 to 90 seconds—of strong intensity, and becoming expulsive in nature. After the painful contractions she experienced during transition, the woman usually feels relief to be in second stage and able to push if she so desires. For most women, pushing gives utmost satisfaction, inasmuch as it contributes to a feeling of active involvement and accomplishment and that their effort is rapidly bringing about the climax of their labor. A sense of anticipation pervades this period. Women usually do not find the contractions very painful; instead they find the combination of the contraction and the work of pushing exhausting. On the other hand, some women feel acute pain with each push and fight the contractions and any effort to get them to push. Usually such a person is quite frightened; frequently her resistance diminishes as she is reassured and helped to push effectively and as some degree of natural anesthesia occurs because of the pressure of the baby's head against the pelvic musculature and other tissue.

As in the first stage of labor, the woman's behavior and physical manifestations during the second stage can also reflect progress. An irresistible desire to push usually signals the arrival of the sec-

ond stage of labor. This is not always true, however, particularly if the fetal head has not descended well into the pelvis. In such instances the woman may not feel the urge to push because the reflex mechanism that makes her feel like pushing does not occur until the fetal head presses against the pelvic floor. For a woman to feel like pushing after she has entered second stage informs you that some degree of descent has taken place. Descent can also be detected by a progressively lower location of the fetal heart tones and a progressively lower point of back pain. Confirmation, when necessary, is by vaginal examination.

On the other hand some women feel like pushing before second stage. This occurs when the fetal head is very low in the pelvis. The reflex mechanism (Ferguson's reflex) is initiated too early and makes the woman feel in constant need of having a bowel movement. Consequently she frequently asks for a bedpan or to go to the toilet. This is a difficult situation for her because she must not push prior to complete dilatation of the cervix. Such action will make the cervix edematous and friable and may lead to subsequent cervical lacerations, which, in turn, can be the cause of hemorrhage.

Rectal bulging, perineal bulging, and progressive visibility of the fetal head at the vaginal introitus are indicative of approaching delivery (see Figure 28-2). If a woman close to or in second stage suddenly says that she wants to go to the bathroom, the midwife should ask the woman if she has to urinate or if she is feeling like having a bowel movement. If her answer is the latter, then the midwife needs to ascertain if indeed the woman is going to have a bowel movement or is just feeling pressure—perhaps what she is feeling is the baby coming. Another almost infallible signal of imminent delivery is the woman's verbal expression, "My baby's coming!" In 99.99 percent of instances in which this occurs the baby is indeed coming, often in spite of a vaginal examination with findings to the contrary a few minutes earlier. Failing to listen to the woman is one of the biggest mistakes a practitioner can make.

FIGURE 28-2 Perineal bulging. Note the relaxation and control of this nonanesthetized woman.

The Mechanisms of Labor

Engagement and descent are two of the mechanisms of labor. The mechanisms of labor are the positional movements that the fetus undergoes to accommodate itself to the maternal pelvis. These movements are necessary inasmuch as the larger diameters of the fetus must be in alignment with the larger diameters of the maternal pelvis in order for the full-term fetus to negotiate its way through the pelvis to be born.

Understanding the mechanisms of labor involves a knowledge of the essential average diameters of the fetal head, as shown in Figure 28-3 and in the list below. The related cephalic presentation is indicated in brackets.

- *Biparietal* (9.5 centimeters): the distance between the two parietal eminences; the largest transverse diameter of the fetal head, used in definition of engagement (see Figure 26-8)
- *Suboccipitobregmatic* (9.5 centimeters): the distance from the junction of the neck and the occiput to the bregma (anterior fontanel) [vertex]
- *Occipitofrontal* (11.5 centimeters): the distance from the occiput to the bridge of the nose [sincipital]
- *Occipitomental* (12.5–13.5 centimeters): the distance from the posterior fontanel to the mentum (chin); the largest diameter of the fetal head [brow]
- *Trachelo* (submental) bregmatic (9.5 centimeters): the distance from the junction of the neck and lower jaw to the bregma [face]

In order to evaluate progress of the fetus through the pelvis, screen for developing complications, and facilitate the birth appropriately, it is important to be well versed in the mechanisms of labor for each fetal presentation, position, and variety. The mechanisms of labor for all varieties of the cephalic vertex presentation are covered in this chapter. Mechanisms of labor for cephalic face and breech presentations are presented in Chapter 30.

There are eight basic positional movements that take place when the fetus is in a cephalic vertex presentation. These are as follows:

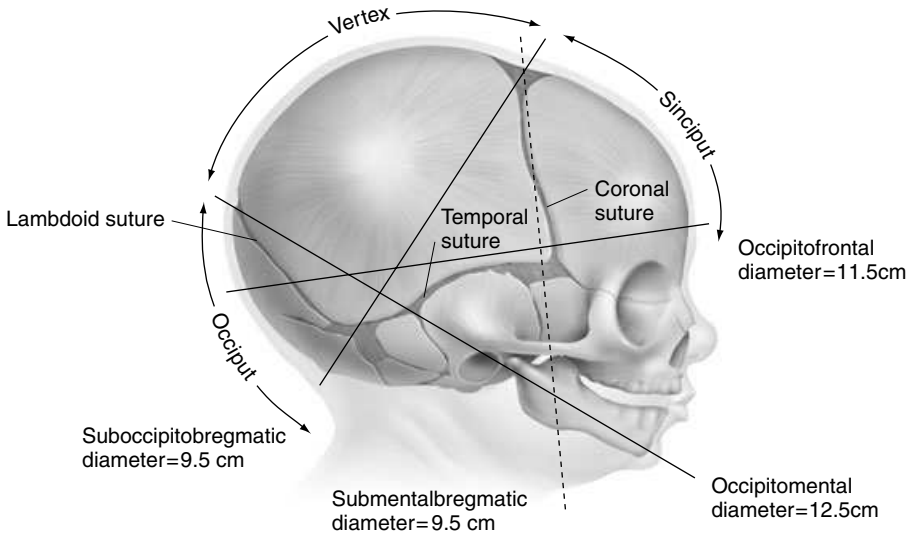

FIGURE 28-3 Diameters of the term fetal head.

1. Engagement
2. Descent throughout
3. Flexion
4. Internal rotation ___° to the ___ position
5. Birth of the head by _____
6. Restitution 45° to the ___ position
7. External rotation 45° to the ___ position
8. Birth of the shoulders and body by lateral flexion via the curve of Carus

Although the mechanisms of labor are listed separately, some overlap or occur simultaneously.

Engagement takes place when the biparietal diameter of the fetal head has passed through the pelvic inlet. See Chapter 26 for an explanation of the contribution of asynclitism to descent of the fetal head into the true pelvis.

Descent occurs throughout labor and is therefore both requisite to and simultaneous with the other mechanisms. Descent is the result of a number of forces, including contractions (which straighten the fetal spine, bring the fundus into direct contact with the breech, and cause the fundus to exert pressure on the breech) and, in second stage, the pushing the mother accomplishes by contraction of her abdominal muscles.

Flexion is essential to further descent. Through this mechanism, the smaller suboccipitobregmatic diameter is substituted for the larger fetal head diameters that exist when the fetal head is either not completely flexed, or in a military attitude, or in some degree of extension. Flexion occurs when the fetal head meets resistance; this resistance increases with descent and is first met from the cervix, then from the side walls of the pelvis, and finally from the pelvic floor. Some degree of flexion, therefore, may occur prior to engagement.

Internal rotation brings the anteroposterior diameter of the fetal head into alignment with the anteroposterior diameter of the maternal pelvis. Most commonly the occiput rotates to the anterior portion of the maternal pelvis, beneath the symphysis pubis. If internal rotation has not occurred by the time the fetal head has reached the pelvic floor it takes place shortly thereafter. Internal rotation is essential for vaginal birth to occur, except with abnormally small babies. To understand why, one need only look at the dimensions and planes of the pelvis. The inlet has a larger transverse diameter than anteroposterior diameter; the midplane and outlet have larger anteroposterior diameters than transverse diameters. Internal rotation is effected by the V-shape of the pelvic floor musculature and the decreased dimensions of the pelvic cavity because of the ischial spines. The amount of internal rotation is determined by the distance the occiput has to travel from its original position on entering the pelvis to the occiput anterior or occiput posterior position. The distance is expressed in degrees, as it is a portion of the arc of a circle that is being traversed (Figure 28-4).

When the occiput rotates from an LOP, ROP, LOT, or ROT position, the shoulders also rotate with the head until the LOA or ROA position has

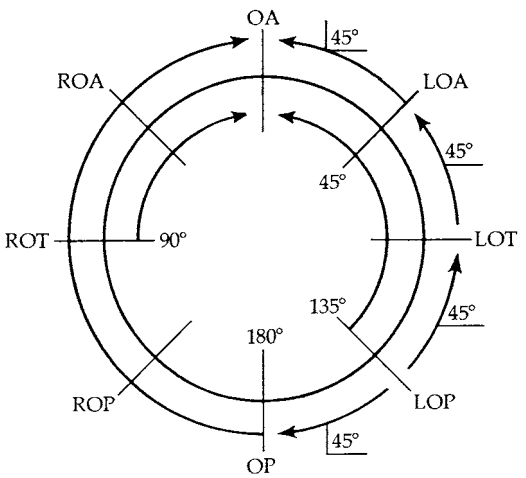

FIGURE 28-4 Degrees of internal rotation.

been reached. As the occiput rotates the final 45° into the occiput anterior position, the shoulders do not continue their rotation with the head but, instead, enter the pelvic inlet in one of the oblique diameters (the left oblique diameter for an LOA and the right oblique diameter for an ROA). The entire mechanism, therefore, has the effect of twisting the neck 45°.

Birth of the head is by *extension* for occiput-anterior deliveries. The mechanism is different when the occiput rotates to an occiput-posterior position, as explained later in this chapter. Extension must occur when the occiput is anterior because of the resistant force of the pelvic floor where it forms the curve of Carus, which directs the head upward to the vulval outlet. The suboccipital region, or nucha, impinges under the symphysis pubis and acts as a pivotal point. The fetal head is now positioned so that further pressure from the contracting uterus and maternal pushing serve to further extend the head as the vulvovaginal orifice opens (see Figures 28-2 and 28-5). Thus the head is born by extension as the occiput, sagittal suture, anterior fontanel, brow, orbits, nose, mouth, and chin sequentially sweep over the perineum. The suboccipitofrontal diameter is thus the largest diameter to pass through the vulvovaginal orifice.

Restitution is the rotation of the head 45° to either the left or the right, depending on the direction from which it rotated into the occiput anterior position. In effect, restitution untwists the neck and brings the head so it is again at a right angle with the shoulders. The sagittal suture is now in one of the oblique diameters of the pelvis and the bisacromial diameter of the fetus is in the other oblique diameter of the pelvis.

External rotation occurs as the shoulders rotate 45°, bringing the bisacromial diameter into alignment with the anteroposterior diameter of the pelvic outlet. This causes the head to rotate externally another 45° into the LOT or ROT position, depending on the direction of restitution.

Birth of the shoulders and body is by lateral flexion via the curve of Carus. The anterior shoulder comes into view at the vulvovaginal orifice, where it impinges under the symphysis pubis; the posterior shoulder then distends the perineum and is born by lateral flexion. After the shoulders are delivered the remainder of the body follows the curve of Carus and is readily born.

The *curve of Carus* is the lower exiting end of the pelvic curve. The fetus and placenta must follow this curve in order to be born. The pelvic cavity actually resembles a curved cylinder, so that the direction of either the baby or the placenta coming through it is first downward from the axis of the inlet to just above the tip of the sacrum and then forward, upward, and outward to the vulvovaginal orifice.

Occiput Anterior Variations of the eight basic positional movements are determined by the position and variety of the fetus and must be delineated for each. The mechanisms of labor for a fetus that begins labor in the LOA, LOT, LOP, ROA, ROT, or ROP position and delivers in an occiput anterior position are as follows (see Figure 28-6):

1. Engagement takes place for LOT and ROT positions with the sagittal suture of the fetus in the transverse diameter of the pelvic inlet and the

biparietal diameter of the fetus in the anteroposterior diameter of the pelvic inlet. For LOA, ROA, LOP, and ROP positions, engagement of the fetal head takes place with the sagittal suture in one of the oblique diameters of the pelvis (the right oblique diameter for LOA and ROP positions and the left oblique diameter for ROA and LOP positions). The biparietal diameter is thus in the oblique diameter of the pelvis opposite from the one the sagittal suture is in. The sagittal suture is used as the fetal landmark that determines in which oblique diameter the fetal head is entering the pelvis.

2. Descent occurs throughout.
3. Flexion substitutes the suboccipitobregmatic diameter for the diameter that entered the pelvic inlet.
4. Internal rotation takes place:
   45° (for LOA and ROA positions)
   90° (for LOT and ROT positions)
   135° (for LOP and ROP positions—long arc rotation)

   The fetal head is now in an occiput-anterior position in the anteroposterior diameter of the mother's pelvis.

5. Birth of the head by extension.
6. Restitution 45° to the LOA or ROA position: the fetal head moves left if it started the mechanisms of labor with the occiput in the left side of the pelvis and right if it started the mechanisms of labor with the occiput in the right side of the pelvis.
7. External rotation 45° to the LOT or ROT position: the direction of the rotation of the shoulders is determined by the direction of restitution. External rotation brings the bisacromial diameter of the shoulders into the anteroposterior diameter of the maternal pelvis.
8. Birth of the shoulders and body by lateral flexion via the curve of Carus

Persistent Posterior A persistent posterior position occurs when a right or left occiput posterior position undergoes internal rotation through a short arc of 45° to a direct occiput posterior position in the anteroposterior diameter of the maternal pelvis instead of a long arc rotation of 135° to a direct occiput anterior position, as described earlier. Short arc rotation is much less common, occurring approximately 6 to 10 percent of the time and most frequently in conjunction with an anthropoid or android type of pelvis.

Persistent posterior is considered a variation of normal. Its effect on the length of labor is debatable; if there is an effect, it is only slight and does not warrant delay in consulting with a physician in the event that any phase or stage of labor is prolonged beyond the parameters of normal. What is not debatable is the added and often excruciating back pain women have with a persistent posterior position.

Diagnosis of a posterior position is by abdominal examination and is confirmed by vaginal examination. Observation of the contour of the woman's abdomen may give the first clue of a posterior position. A depression the shape of a saucer is commonly seen at or just below her umbilicus. This depression occurs because the shoulder is posterior rather than anterior, so there is not a smooth anterior curve but rather what looks like a gap between the cephalic and podalic poles of the fetus. If the head is not engaged, there is a bulge between the symphysis pubis and the saucer-shaped depression. The total contour thus resembles a full bladder, which must be ruled out.

The mechanisms of labor for a fetus that begins in the LOP or ROP positions and delivers in an occiput posterior position (see Figure 28-7) are the same as for those that rotate to an occiput anterior position except as noted and explained below:

1. Engagement takes place in the right oblique diameter for the ROP position and in the left oblique diameter for the LOP position.
2. Descent occurs throughout.
3. Flexion.
4. Internal rotation takes place: The fetal head rotates 45° to an occiput posterior position in the anteroposterior diameter of the mother's pelvis.
5. Birth of the head by the double mechanism of flexion and then extension. The sinciput impinges beneath the symphysis pubis and becomes the pivotal point for delivery of the head. The head stays flexed as the occiput distends the perineum and is born to the nape of the neck. The remainder of the head is then born by extension, starting with the anterior fontanel and ending with the chin, as the head falls back toward the rectum with the face looking upward.
6. Restitution: The fetal head rotates 45° to the LOP or ROP position, depending on whether internal rotation was from the LOP or ROP position.
7. External rotation: The fetal head rotates 45° to the LOT or ROT position.
8. Birth of the shoulders and body by lateral flexion via the curve of Carus.

Fetal Well-Being

Evaluation of the fetus during the second stage of labor includes evaluation of the amount of caput succedaneum and molding, as discussed previously for the first stage of labor; evaluation of the normalcy of progress being made in the mechanisms of labor; and continuing evaluation of the fetal heart tones (see Chapter 27).

Maternal Physiological Changes

The normal maternal physiological changes described in the database for the first stage of labor (Table 26-5, pages 752–753) continue through the second stage of labor. Any variations in these are noted below.

Blood Pressure Blood pressure may rise another 15 to 25 mm Hg with contractions during the second stage. Maternal pushing effort also affects the blood pressure, causing it to increase and then decrease and end at a level slightly above normal. It is important, therefore, to evaluate the blood pressure well between contractions. An average rise in blood pressure levels of 10 mm Hg between contractions when a woman has been pushing is normal.

Metabolism The steady rise in metabolism continues through the second stage with the maternal

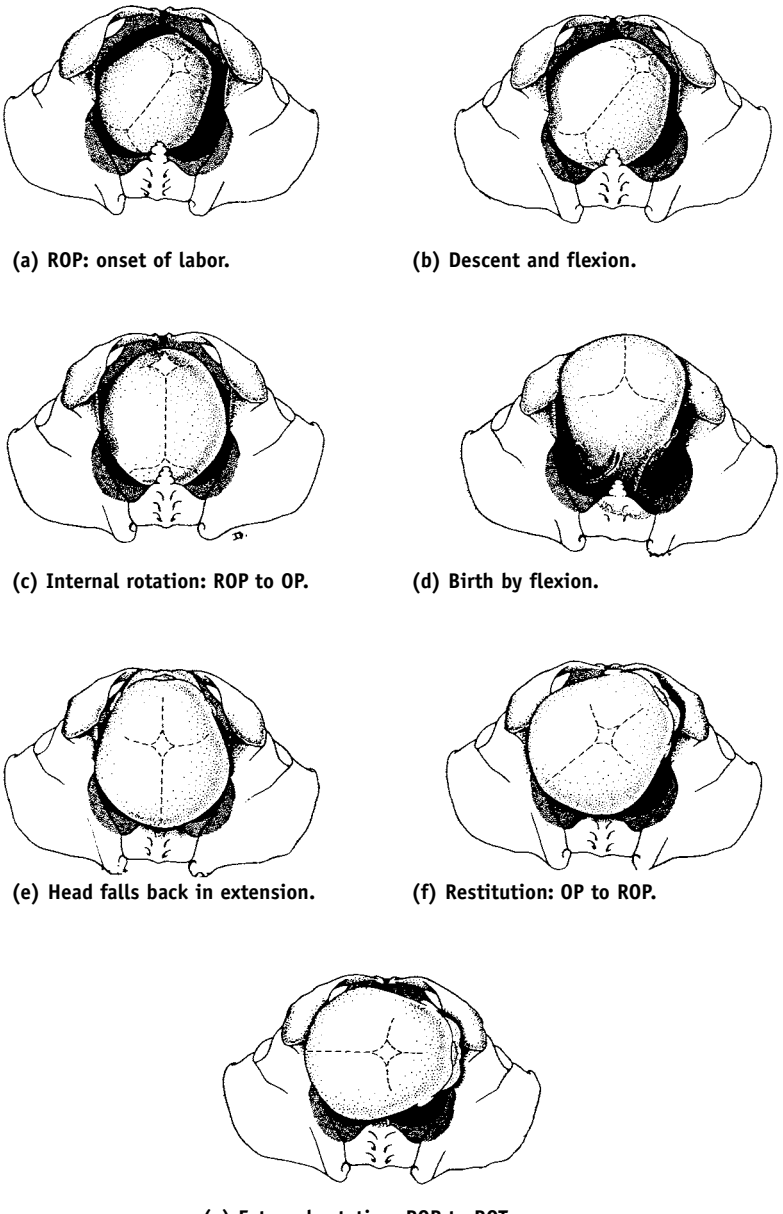

FIGURE 28-7 ROP to OP short arc rotation mechanisms of labor.
Source: From Oxorn, H. *Oxorn-Foote Human Labor and Birth*, 5th ed. Norwalk, CT: Appleton-Century-Crofts, 1986, p. 173. Reproduced by permission.

pushing effort adding further skeletal muscle activity to contribute to this increase.

Pulse The pulse rate varies during each maternal pushing effort. Overall, it is elevated throughout the second stage with a definite tachycardia reaching a peak at the time of birth.

Temperature The highest elevation of temperature occurs at the time of birth and immediately thereafter. A normal increase is 1 to 2°F (0.5 to 1°C).

Respirations Respirations are the same as during the first stage of labor.

Gastrointestinal Changes The severe reduction in gastric motility and absorption continues through the second stage. Usually the nausea and vomiting of transition subside during the second stage but

they may persist for some women. Vomiting, when it occurs, is normally sporadic. Persistent, constant vomiting at any time during labor is abnormal and may be indicative of obstetric complications such as uterine rupture or toxemia.

Renal Changes These changes are the same as during the first stage of labor.

Hematologic Changes Hematologic changes are the same as during the first stage of labor.

Management Plan for the Second Stage of Labor

Management of care of the second stage of labor is a continuation of the midwife's responsiblities during the management of care of the first stage of labor, as follows:

1. Continuing evaluation of maternal well-being
2. Continuing evaluation of fetal well-being
3. Continuing evaluation of the progress of labor
4. Bodily care of the woman
5. Supportive care of the woman and her significant others and family
6. Continuing screening for signs and symptoms of maternal and fetal complications (discussed in Chapters 27, 29, and 30)

In addition, the management of care during the second stage of labor includes these responsibilities:

7. Preparation for birth
8. Management of the birth
9. Making management decisions for the second stage of labor

Second stage management decisions include the following:

1. Frequency with which the woman's vital signs (blood pressure, pulse, and temperature) are to be checked
2. Frequency with which the fetal heart tones are to be checked
3. Whether to encourage the woman's pushing effort
4. Location of the birth
5. When to prepare for birth
6. Position of the woman for birth
7. Whether the woman needs to be catheterized immediately prior to birth
8. Whether to support the perineum, and if so, how
9. Whether to cut an episiotomy
10. If the decision is to cut an episiotomy, what type to cut
11. Type of analgesia/anesthesia
12. Whether to deliver the baby's head with a contraction or between contractions
13. Whether to use a Ritgen maneuver
14. When to clamp and cut the umbilical cord
15. Whether there is a need for physician consultation or collaboration

The decisions may vary depending on the woman, her desires, her condition, and her situation. Each decision is made in relation to the unique individuality and circumstances of a particular woman at a given moment. There are, however, specific factors to be considered in making each decision as it relates to the management responsibilities identified above and to the woman's progress through the second stage of labor. These factors are presented in the discussion below.

Continuing Evaluation of Maternal Well-Being

Continuing evaluation of maternal well-being during the second stage of labor includes the items used to evaluate the first stage of labor. The following list includes additional items specific to the second stage of labor. These are marked with an asterisk.

1. Vital signs
   - a. blood pressure
   - b. temperature
   - c. pulse
   - d. respirations
2. Bladder
3. Urine (see Chapter 26, page 775)
   - a. protein
   - b. ketones
4. Hydration
   - a. fluids
   - b. nausea or vomiting
   - *c. perspiration
5. General condition
   - a. fatigue and physical depletion
   - b. behavior and response to labor
   - c. pain and coping ability

*6. Maternal pushing effort
7. Need for analgesia or anesthesia
*8. Perineal integrity

Vital Signs The parameters of normal and their significance were discussed in Chapter 26. The frequency with which vital signs are checked increases during the second stage of labor. This frequency may vary somewhat from setting to setting or from clinician to clinician, but the generally accepted standard for a normal woman during the second stage of labor is that the woman's blood pressure should be checked every 15 minutes and her temperature, pulse, and respirations should be checked every hour (whether the membranes have ruptured no longer affects this frequency). It is important to remember in interpreting the blood pressure that the blood pressure *between* contractions (which is when it should be taken) is now normally increased by an average of 10 mm Hg if the woman has been pushing.

Bladder Management of the woman's bladder during the second stage of labor and the rationale for this management are the same as discussed for the first stage of labor. In addition, the midwife must decide whether the woman needs to be catheterized immediately prior to birth. The phrase "immediately prior to birth" means as part of the sequence of events in preparing for the birth, so this would be toward the end of the second stage of labor. If catheterization is required, it is usually done before any other procedure such as pudendal block or cutting of an episiotomy. This timing is chosen so that the catheter can be inserted before the fetal head gets any lower in the pelvis, since further descent makes the catheterization more difficult.

The following factors should be considered in deciding whether to catheterize the woman at this time:

1. The discomfort to the woman. Catheterization is an uncomfortable if not painful procedure. On the other hand, a distended bladder may add to the pain she is experiencing in her lower abdomen.
2. Whether her bladder needs emptying:
   a. Is it distended?
   b. Has the woman urinated within the last 2 hours?
   c. What has her fluid intake been since she last urinated?
3. The increased risk of a bladder infection with catheterization.
4. Whether you are anticipating a potential complication (e.g., immediate postpartum hemorrhage; shoulder dystocia). Management of both of these complications includes that the woman have an empty bladder. Precious time can be gained if an empty bladder is already ensured.

Generally speaking, if the woman's bladder is obviously distended and she is unable to urinate and empty her bladder, your decision should be to catheterize the woman in order to avoid further trauma to the bladder, decrease the discomfort in her lower abdomen, and circumvent a problem with the bladder in the event of the aforementioned complications. If her bladder is not obviously distended, the decision is based on your calculation of the probability of the woman's having one of the two complications. A low probability does not warrant catheterization. High probability does warrant catheterization if the woman has not recently urinated, even if a distended bladder is not obvious. The woman should end this phase of labor with an empty bladder. Ensuring that she does requires careful monitoring of her bladder during first and second stage labor (see Chapter 26) and use of all measures to get the woman to void naturally (see Chapters 26 and 33). It is uncommon for a woman cared for by a midwife to need catheterization.

If catheterization must be performed and the fetal head is in the true pelvis, the direction of the catheter is different from usual. The urethra is displaced by the fetal head and conforms with its contour. Therefore, immediately after inserting the catheter into the urethra, it is necessary to direct it upward and over the fetal head while going inward. Otherwise, by going straight in as usual you simply won't be able to get the catheter in and you will only have succeeded in traumatizing the urethra. Sometimes it is helpful to splint the urethra vaginally by placing a finger below it as the catheter is being inserted. Going up and over the fetal head also means that more of the catheter than usual will be inserted before reaching the bladder. (These same pointers apply if it is necessary to catheterize a woman during the first stage of labor and the fetal head is in the true pelvis.)

Hydration and General Condition Management of these two areas during the second stage of labor and the rationale for their management is the same as for the first stage of labor. Hydration, however, is further affected during the second stage of labor by fluid loss through the skin in the form of perspiration. The woman may perspire profusely from the effort of pushing, especially if the environment is not air-conditioned and you are in a geographic area that is both hot and humid. This makes attention to fluid intake even more vital.

The general condition of the woman during the second stage will depend on her general condition at the end of the first stage of labor. If she enters the second stage of labor exhausted, she is going to have difficulty mustering the energy required for pushing, especially if she is a primigravida. This is because the average length of a primigravid second stage is longer than that of a multipara. This problem is often overcome, however, if the woman believes that birth is near. Thus, the midwife should foster this thought in the woman's mind. This is not difficult, as it is true—birth *is* near, especially in comparison with the length of the first stage of labor. Most women respond well to evidence of progress. There can be no greater encouragement than for a woman to see for herself the bulging of her rectum and perineum and the color of her baby's hair (if a cephalic presentation) and to touch the baby's head. A mirror placed so she can see the effect of her pushing effort is invaluable for this purpose (Figure 28-8).

Maternal Pushing Effort The maternal pushing effort must be evaluated for effectiveness. Proof of effectiveness is the progressive descent of the fetal head and the sequence of the mechanisms of labor that the fetus undergoes. This is generally evidenced by the sequential bulging of the rectum, then the perineum, and finally being able to see an ever-increasing amount of the fetal presenting part at the enlarging vaginal orifice. In the absence of progress it is essential to reevaluate pelvic adequacy and rule out arrest in the mechanisms of labor by careful vaginal examination. If neither of these difficulties exists, the problem is probably either ineffectual pushing or a psychological obstacle. That a psychological obstacle can affect the progress of labor is an old observation that has been discovered anew. The effects of a woman's psychological state on labor are more apt to be seen in out-of-hospital settings where the woman's emotions are less controlled by external environmental forces. Dramatic change in the progress of labor can be effected by working through whatever psychological block the woman has.

FIGURE 28-8 Partner and midwife supporting a woman during second stage. A mirror has been placed between her legs so she can see the progress she is making with her pushing efforts.

Proponents of spontaneous or "physiologic" pushing continue to struggle against the entrenched breath-holding sustained pushing effort urged upon women when completely dilated as determined by vaginal examination. There are two issues involved in this controversy. The first is *when* to start pushing and the second is *how* to push.

When to start pushing is heavily influenced by concern over any policies, guidelines, or protocols regarding the length of the second stage of labor before intervention will occur if second stage is not completed within that time frame. Rigid adherence to the often used 2 hour limit that evolved from Friedman's graphico-statistical analysis of labor length [2] motivates many clinicians to vigorously encourage the maternal pushing effort as soon as the woman is known to be completely dilated. This is done in an effort to "beat the clock" before the trauma of instrument or surgical intervention is imposed. Excessive encouragement to push reflects a general impatience, which is fostered by the need to see immediate evidence that the fetus is progressing safely through the mechanisms of labor.

Missing in this scenario is clinical decision-making based on the well-being of both the mother and the baby and on the progress of labor. If the condition of the mother and fetus is good and there is evidence of progress in the descent of the fetal head, there are no grounds for rigid adherence to a preset time limit. Research has shown that there is no significant relationship between second stage duration and perinatal mortality, 5-minute Apgar scores below 7, neonatal seizures, or admission to the newborn intensive care unit [7]. However, if there is evidence of maternal exhaustion, or fetal intolerance of the stress of second stage labor or fetal distress, then immediate intervention is indicated.

Absolute lack of progress in descent or internal rotation in 2 hours is also an indication for intervention.

The more significant parameter in the duration of second stage is the length of time the woman is actively pushing rather than the time from complete dilatation to birth [8, 9]. The start of second stage is difficult to precisely ascertain as it can only be determined by vaginal examination. Not checking the woman's cervix until she evinces an urge to push gives some reality to the duration of second stage and redefines the start of second stage as a combination of complete dilatation and spontaneous pushing effort [10].

How to push is a matter of breathing and positioning (see also Chapter 67). There are generally two very different types of breathing related to pushing. One is the often used Valsalva maneuver of inhaling a deep breath, holding it, and pushing against a closed glottis as hard as possible for as long as possible—typically to a count of 10. The woman is encouraged to get three "good" pushes out of every contraction. There is evidence of potential detriments in the Valsalva maneuver, closed glottis sustained pushing efforts. Detrimental effects include decreased oxygenated blood to the placenta resulting in fetal hypoxia [8, 10–13], a higher incidence of perineal trauma (lacerations, episiotomies) [13–16], maternal exhaustion, and potential for cystocele and urinary stress incontinence [10] and for uterine prolapse from stretching of the cardinal ligaments.

The other type of breathing is spontaneous or physiologic in which the woman exhales as she involuntarily pushes for short periods of 5 to 7 seconds or less and takes several breaths between pushes. This type of open glottis pushing occurs when the fetal presenting part is at +1 station and has reached the pelvic floor. Pressure on the pelvic floor stimulates Ferguson's reflex and the woman feels an urge to push. This maternal response to Ferguson's reflex is triggered with each contraction and activated shortly after the onset of the contraction when it has started to build toward its acme. Studies have shown that there is no change in arterial umbilical cord blood pH [17, 18] and that the second stage of labor is either the same length or shorter [14, 17–19]. No detrimental effects have been shown, and the detrimental effects of the Valsalva maneuver type of breathing and pushing are avoided. Having the woman push only when she wishes is a much more natural approach that eliminates what at times is frenzied harassment of the woman to push and disruption of a possibly heretofore calm, relaxed situation of breathing and working with the contractions.

Positioning that facilitates second stage pushing can be summed up as anything but supine. The supine position is detrimental to uterine perfusion and alignment of the fetal head with the maternal pelvis. Especially facilitative of descent of the fetal presenting part during second stage are the upright positions such as standing, sitting, and squatting. Side-lying, sitting, squatting, and knees-hands positions have not been shown to have detrimental effects [12]. However, there is some evidence of increased risk of blood loss with birthing chairs [13] and of third-degree lacerations with the standing position [20].

It is possible to teach a woman how to push effectively who is not experiencing the Ferguson reflex such as happens with epidural anesthesia or when the fetal head has not yet descended to the pelvic floor. It is also critical to teach a woman how to push in those times when she is developing a complication and needs to push before she feels a natural urge to do so. There are also times when the natural maternal pushing effort is ineffectual and the woman needs to be taught how to push effectively as sometimes happens with a frightened woman who has had no preparation for childbirth. Breathing that simulates spontaneous physiologic pushing, body position, and arm position and action are essential to teaching a woman how to push (see Chapter 67).

Need for Analgesia/Anesthesia Analgesia during the second stage of labor usually is provided by the continued action of analgesia given the woman during the first stage of labor, as discussed in Chapter 26.

Anesthesia is for the delivery itself. Midwives may perform either a pudendal block or a local infiltration of the perineal body, or a combination of both, to provide anesthesia when necessary for normal spontaneous vaginal births, cutting an episiotomy, or, after birth, for repair of an episiotomy or lacerations. Correctly performed, both methods of providing anesthesia are safe procedures with minimal to no effect on the baby and constitute the safest known methods (for both mother and baby) of providing regional and local obstetric anesthesia.

If an episiotomy is planned, then pudendal block is the method of choice, for the following reasons:

1. It anesthetizes a larger area, so if there are lacerations in an area other than the perineal body (e.g., periurethral lacerations) or if it is necessary

to extend the episiotomy, those areas are anesthetized as well. A pudendal block anesthetizes the perineum and vulva including the clitoris, labia majora, labia minora, perineal body, and rectal area. A local infiltration anesthetizes only the tissue infiltrated with an anesthetic agent.

2. There is no tissue distortion with a pudendal block because the trunk of a major nerve is anesthetized, thereby anesthetizing all its branches and the tissue it innervates. Local infiltration distends the tissues into which the anesthetic agent is injected, thereby distorting their size and making proper approximation of tissue layers more difficult.
3. Pudendal block also anesthetizes the lower vaginal tract, thereby alleviating any discomfort or pain a woman may have from the tissue stretching caused from distention by the fetal head. The sensation of stretching may be actually more frightening than painful for some women, especially those who did not have any preparation for childbirth, because of their fear of "ripping open." This alone may constitute a reason for performing a pudendal block. If an episiotomy is being cut, a pudendal block spares the unprepared woman from being frightened by the sudden sensation of her "bottom splitting open" at the time the cut is made. A pudendal block is also sometimes used for the sole purpose of relaxing the perineal musculature, especially if the woman is tightening up from pain and fear. An episiotomy may or may not subsequently be necessary.

Selection of a local infiltration as the anesthesia of choice is discussed in Chapter 69, as are the different techniques used for performing a local infiltration both prior to delivery (for cutting an episiotomy) and after delivery (for repair of an episiotomy or lacerations). The technique, relevant anatomy, and necessary equipment and materials for performing a pudendal block are discussed in Chapter 68.

Perineal Integrity Perineal integrity is evaluated in order to determine if birth can possibly occur over an intact perineum or if an episiotomy is indicated. This decision is continually reevaluated until the baby is born.

A number of techniques facilitate birth over an intact perineum. Each has its advocates and detractors. The first division of thinking is between those who believe in "hands on" and those who believe in "hands off." The hands-off proponents believe that hands on interferes with the natural timing and stretching by the mother, especially in squatting and standing positions. They believe that touching stimulates muscle contraction and is distracting to the woman. Some birthing women in other positions have expressed distress at being touched on the perineum, because the area is already supersensitive and hyperstimulated. These women find perineal massage or any stretching technique irritating.

The hands-on advocates believe that a number of techniques are protective of the woman's perineum. They disagree among themselves as to which single or combined techniques are the best. There is now evidence that some of these techniques are indeed protective while others are associated with an increased incidence of lacerations or episiotomy [21]. Others are of unproven value. The techniques include the following:

1. Prenatal digital stretching of the vaginal outlet by the woman or her partner. This technique is usually advocated for nulliparous women with very muscular perineums or women expressing considerable fear or anxiety about perineal tearing or cutting. It is of unproven value but makes good sense. It also familiarizes a woman with the sensation of pressure.
2. "Ironing out" the perineum by sweeping your fingers back and forth from side to side while exerting considerable pressure on the posterior vaginal wall just ahead of the fetal head. The pressure applied to iron out, or stretch, the muscles also stimulates the pushing reflex. There may be justified occasions for you to use this technique to stimulate the pushing reflex but the technique is uncomfortable to the woman and may traumatize the tissue, making it friable and more prone to tearing. When possible, there are other ways to encourage descent and pushing, such as upright positions.
3. Warm compresses applied to the perineum. These increase circulation to the area, thereby promoting muscle relaxation, and have been shown to be protective of the perineum [21].
4. Perineal massage, usually done with warmed oils or lubricants. The warm oil increases circulation to the area and prevents friction from the massage. The massage is to stretch the tissues and promote perineal relaxation. This has been shown, however, to increase lacerations [21]. This may be the result of massaging highly vascularized tissues that are now additionally at risk for edema. Perineal massage may also be perceived by the woman as irritating or distracting. Concern has been expressed about the oil possibly getting inside the vagina thereby creating the risk of getting into the baby's mouth or respiratory tract during its passage.

5. Perineal support at the time of birth is done one of two ways. Some clinicians do this by directly bracing the perineal body with their hand. This may have the effect, however, of impeding gradual fetal head extension thereby directing the head into the perineum and increasing the risk of laceration. It also directs tissue away from the midline thereby flattening it and leaving it vulnerable to tearing. The other method of perineal support avoids this problem and is done by placing your thumb and middle finger across from each other in the left and right groin and pressing inward to provide a little extra give across the perineal body (see Figure 28-9). There should be a slight gap between your hand and the woman's perineum so that neither your fingers nor your hand will be in the way of the oncoming head.
6. Fetal head control by the application of pressure against the fetal head to keep it well flexed followed by gradual extension as the perineum stretches (Figure 28-9). This is absolutely essential in lithotomy and most dorsal positions in order to prevent tears. Some clinicians believe that if the fetal head is controlled properly there is no need to touch the perineum. Other clinicians combine fetal head control with perineal support at the time of crowning.

Maternal self-control is key to whatever method of delivering over an intact perineum you use. A woman who is out of control is more apt to tear or need an episiotomy.

FIGURE 28-9 Combination of fetal head control and perineal support at the time of crowning. (Photograph by Artemis/Harriette Hartigan.)

Need for, and Type of, Episiotomy The perineum should initially be evaluated prior to the time of birth for its length, thickness, and distensibility. This evaluation aids in determining whether an episiotomy is indicated and, if so, what kind of episiotomy. An extremely thick perineum may be found in athletes, the result of muscular overdevelopment, and is apt to be rigid and resistant to distension, thereby necessitating an episiotomy. A short perineum may indicate the need for a mediolateral episiotomy rather than a median (midline) episiotomy, if an episiotomy is necessary, in order to avoid injury to the rectal sphincter and wall.

The primary indication for an episiotomy is fetal distress. An episiotomy enables the mother to more quickly deliver her baby for you to assess and institute appropriate resuscitation measures. Another indication for an episiotomy is evidence of poor tissue integrity that may predispose to extensive lacerations. The primary reason not to do an episiotomy is that, with the exception of the indications just given, it is generally not necessary to cause the mother this pain. Some women feel as though an episiotomy is an assault on their body. Most women who state a preference usually request that an episiotomy not be done. They generally respond well to a plan of not cutting an episiotomy unless absolutely necessary in your judgment (i.e., to expedite birth because of maternal or fetal distress). If episiotomy does become necessary, you should inform the woman and discuss it with her to the extent that you can, given the situation.

There are some other considerations to take into account that may affect your decision-making about the need for an episiotomy. All aspects of this decision should be discussed with the woman during the prenatal period.

1. *Your beliefs about whether it is better to cut an episiotomy or let the woman tear* if delivery over an intact perineum is impossible and tearing is inevitable. Your thoughts about this may be influenced by findings that a severe laceration (third or fourth degree) is much more likely in women who have midline episiotomies than in women without episiotomies [22] and that there is a greater delay in perineal healing with an episiotomy than with no episiotomy [23].

   Some midwives believe that they can do a better anatomical repair of an episiotomy than of a laceration, which may be jagged. An inevitable laceration of the perineal body is evidenced by narrow white lines resembling stretch marks and visible just beneath the per-

ineal skin. These appear just prior to laceration and probably represent beginning tearing of the underlying tissues. A quick episiotomy prior to the moment of crowning is possible and can substitute for an inevitable tear.

2. *The need for space in which to perform necessary interventions and manipulations*, such as in the case of fetal malpresentations and malpositions or an anticipated shoulder dystocia. A malpresentation or malposition in an average-sized baby means that (1) the widest diameter of the fetal head coming through the pelvic outlet and vaginal orifice is larger than usual, thereby creating a higher probability of laceration, and (2) you or your consulting physician may need room for manual or instrument manipulations in order to effect a safe birth. This latter reason may also be true for anticipated shoulder dystocia.
3. *The size of the baby*. Cutting a good-sized episiotomy may be indicated for birth of the preterm or SGA (small-for-gestational-age) baby, depending on the relaxation of the perineum. Also, *depending on the length and distensibility of the perineum and the control of the woman*, a baby estimated to be 4000 grams (9 pounds) or more may cause need for an episiotomy either to prevent laceration or in anticipation of a possible shoulder dystocia.
4. *Self-control of the woman.* A woman who is in good control of herself—that is, able to respond to directions to push or to breathe in order to slowly ease the baby's head out—is a far better candidate for no episiotomy and for delivering over an intact perineum. An uncontrolled woman is nearly guaranteed to lacerate, and some midwives would prefer to cut an episiotomy than to repair a laceration in that case.

If you make a decision to cut an episiotomy, then the next decision is what type of episiotomy will be cut: midline (median) or mediolateral. Several factors should be considered in making this decision.

First, consider how much room is needed in relation to the length of the perineal body and to the reason for the episiotomy. If the distance between the posterior fourchette and the rectal sphincter is unusually short, a mediolateral episiotomy is indicated in order to prevent severe and extensive laceration through the rectal sphincter and into the rectum. If the episiotomy is being cut to prevent a perineal laceration, then the amount of room you get from cutting a mediolateral episiotomy is not needed and a midline episiotomy would be the better choice.

A second consideration is that a midline episiotomy is less painful than a mediolateral episiotomy during the healing process. This is because there are fewer nerve branches in the locale of a midline episiotomy and its repair. Also, the arrangement of the muscles that have been cut across and into in a mediolateral episiotomy causes points of stretch that pull on the incisional repair line, thereby causing pain. This is in contrast with a midline episiotomy, which is cut into the central tendinous point of the perineum and only separates the two sides of pairs of muscles rather than cutting across the muscles themselves.

Finally, a midline episiotomy is easier to repair than a mediolateral episiotomy. This is because a mediolateral episiotomy is cut on a slant in relation to the perpendicular midline of the perineum. This means that the size of the bites for each half of a single stitch on either side of the incisional line will be deliberately unequal; that there is an increased risk of entering the rectum during the repair because of greater retraction of the medial aspect of the incision; that manipulation of the necessary equipment and materials is more awkward; and that it is more difficult to approximate the tissues in order to have good functional results.

Chapter 79 discusses how to cut the episiotomy you have decided on and describes the relevant anatomy. When cutting an episiotomy, it is vital to remember that with the cut the force that previously restrained progress of the head is suddenly released. Depending on when you cut it (i.e., during a contraction or not, while the woman is pushing or not) and on how distended the vaginal orifice is, it is possible for the fetal head to suddenly "pop"—a totally uncontrolled delivery of the head. Since this can be damaging to both the baby and the woman, you need to control the baby's head as you cut. You do this with the back of your vaginal hand, which is already delineating the area to be cut and protecting the baby's head.

Continuing Evaluation of Fetal Well-Being

Continuing evaluation of fetal well-being during the second stage of labor is a continuation of the evaluation of the well-being of the fetus during the first stage of labor, including evaluating the following:

1. Normality of the fetal lie, presentation, attitude, and variety
2. Fetal adaptation to the pelvis (synclitism or asynclitism, molding of the fetal skull, the formation of caput succedaneum)

3. The fetal heart rate and pattern (see Chapter 27)
4. Evaluation of the normality of progress being made in the mechanisms of labor

Numbers 1, 2, and 4 are determined during a vaginal examination. The first two were discussed in Chapter 26, relating to the first stage of labor. The normality of progress being made in the mechanisms of labor is evaluated by noting the progress of the fetus through the pelvis (engagement and descent) and the cardinal turning movements of the fetus (flexion and internal rotation) as identified by the changing position (variety) of the fetal head prior to delivery.

Continuing Evaluation of the Progress of Labor

Continuing evaluation of the progress of the second stage of labor is based on the following:

1. Contraction pattern
2. Length of second stage
3. Descent/station
4. Progress through the mechanisms of labor other than descent and engagement

The norms for these items were discussed earlier in this chapter.

Management decisions relating to the continuing evaluation of the progress of labor include the following:

1. When to prepare for the birth
2. Whether it is necessary to consult with your consulting physician

When to prepare for the birth was discussed in Chapter 26. The midwife may need to make a decision concerning physician consultation as she or he (1) continues to evaluate the normality of the progress of labor, the well-being of the fetus, and the well-being of the mother, (2) continues to screen for abnormalities and complications, and (3) anticipates potential problems based on the interpretation of findings resulting from this database evaluation. Screening for the collaborative management of complications during labor, including when to consult with the physician, is discussed in Chapters 29 and 30.

Evaluation of progress through the mechanisms of labor is essential to detecting deep transverse arrest and concomitant second stage hypotonic uterine dysfunction (see Chapter 29). Generally, the fetus is not in danger if hypotonic uterine dysfunction occurs and *is not ignored*.

The fetus is in danger when there are strong, expulsive contractions and maternal pushing effort but failure to progress because of some form of fetopelvic disproportion, including deep transverse arrest. The fetus in this situation is subjected to a literal battering. It is mandatory that the progress of labor as determined by progressive descent be carefully assessed. Detection of progressive descent was discussed earlier in this chapter and includes the following:

1. Progressively lower location on the woman's spine of back pain due to pressure from the fetal head
2. Progressively lower location in the woman's abdomen of the point of maximum intensity of the fetal heart tones
3. Increasing desire of the woman to push, which indicates descent of the fetal head to the pelvic floor and subsequent initiation of the Ferguson reflex mechanism for pushing
4. Vaginal examination findings indicative of a change in station, which is evidence of descent and progress through the pelvis
5. Rectal and perineal bulging
6. Appearance of the presenting part at the vaginal orifice
7. The woman's assertion that her baby is coming, confirmed by either observation or examination

Engagement should have occurred during the active phase of the first stage of labor in the nullipara and by the onset of the second stage of labor in the multipara. Failure of engagement to have occurred by entry into the second stage of labor is a signal of a potential problem.

Simkin and Ancheta have described a number of positions for a woman to assume and movements for her to make that help the fetal head be in alignment with her pelvis and in the most favorable or optimal position. Such alignment and rocking facilitate the movement of the fetus through the pelvis via the mechanisms of labor and may prevent labor dystocia. They have also detailed a "toolkit" of related comfort measures [10].

Bodily and Supportive Care of the Woman

Bodily and supportive care during the second stage of labor are continuations of the care begun during the first stage of labor, modified to meet the woman's changing needs as she progresses through labor. The effectiveness of the support and comfort measures depends on how each woman experiences and accepts them. There are a few additional measures and considerations specific to the second stage of labor—those pertaining to breathing, pushing, and the woman's significant others.

Breathing The woman should use a controlled form of breathing, such as that used during the ac-

FIGURE 28-10 Partner actively involved in birth of baby in birthing room.

tive phase of the first stage of labor, through the contractions if she does not yet feel like pushing. This type of breathing starts with a cleansing breath, then goes into a slow chest breathing that increases in speed as the contraction reaches its acme, then slows down as the contraction tapers off, and ends with another cleansing breath.

A woman may need help with her breathing and in making effective use of her natural pushing effort (see Chapter 67). The breathing to be used as she is pushing was discussed in detail earlier in this chapter.

The woman needs to be instructed to pant if she feels like pushing but you don't want her to push. Panting may be a quick inhalation followed by a forcible exhalation and repeated immediately. It may also be a rapid, shallow throat breathing as described in Chapter 26. The woman's ability to pant and not push can be critical, and she should be taught how to do this when she enters the second stage of labor if she has not been taught before.

Pushing A woman who feels like or needs to push can be helped in a number of ways in order to make her effort as effective as possible. Helping her push will make her partner feel important, contributing, and participating in the experience (Figure 28-10). These techniques are described in detail in Chapter 67.

Significant Others Ideally, whom the woman wants present at the time of birth has been discussed and planned for some time in advance. The birth setting without restrictions on whom will be present for the birth, except those placed by the woman, is the home. Birth centers also generally have few to no restrictions. The most restrictive setting is a hospital delivery room in which the number of significant others usually is limited to one or two. Depending on the size of the labor room or if birth is going to take place in an LDR or LDRP (labor/deliver/recovery/postpartum room), more significant others might be permitted. The policies regarding the presence of significant others at the time of birth vary with hospital settings. More enlightened hospitals allow siblings to be present during labor and at the time of birth. Restrictive hospital policies have been one of the reasons for couples to seek out-of-hospital childbirth alternatives.

If children are to be present for the birth (see Figure 28-11), regardless of setting, there needs to be a familiar adult designated as the person primarily responsible for them and their care. Children need to be able to leave the birthing environment if they so choose, or if necessary. Children should be prepared for the sights and sounds of birth and be involved in preparations for the birth and the baby [24, 25].

If birth is going to be in a delivery room, the midwife should welcome the partner and make the person feel wanted and needed, as was done in the labor room. Give the person space beside the woman, provide a stool to sit on, and emphasize his or her importance in being there. If the significant other has to change clothes in order to be in the delivery room, allow plenty of time so that he or she doesn't miss the

FIGURE 28-11 A sibling present at birth. (Photograph by Artemis/Harriette Hartigan.)

birth. Include the significant other in your explanations of the ongoing activities.

The significant other's activities during the second stage of labor again depend on the person's capabilities and wishes and how much participation is agreeable to the woman, the person, and you. For example, partners can continue what they were doing during the first stage of labor (e.g., back rubbing, coaching breathing, timing contractions, fanning). They might also help the woman in the technique of pushing, encourage her, wipe her face, share the anticipation and then the moment of birth with her, and cut the umbilical cord.

Preparation for Birth

It is the midwife's responsibility to ensure that all is in readiness for the birth. Management decisions included in preparation for birth involve the location of the birth and the position of the woman for giving birth. Since subsequent preparations depend somewhat on these two decisions, these decisions will be discussed first.

Location of the Birth The location of the birth should have been planned long before labor begins. Whether they can have what they want—significant others present, a certain position for birth, no routine episiotomy, no separation from their baby, and so forth—will determine for some women whether to give birth in a hospital, a birth center, or at home. The alternatives for delivery within a hospital are the delivery room, the labor room, a birthing room, or an LDR or LDRP. Newer hospitals often are designed with birthing rooms or some combination of labor/delivery/recovery/postpartum rooms for women with normal pregnancies. In a childbirth center birth takes place in a birth room. Part of the planning for birth at home is discussion of where in the home the birth will take place. Sometimes it is a bedroom; other times it is a special arrangement of mattress/bedding/beanbag chair/birth stool or the like in another room. The planned location of labor and birth may change because of unforeseen circumstances (e.g., the birth room is already occupied) or because the development of complications necessitates either a transfer into the hospital from an out-of-hospital setting or, within the hospital, to the delivery room.

Water birth is an alternative to the traditional birth practices that are detailed here and can occur in the home, birth center, or hospital. Differentiated from water labor, in which a woman spends some portion of her labor in water, water birth is when the infant is actually born under water. This sometimes happens by plan and sometimes by accident when a woman simply does not want to remove herself from an environment that is giving her pain relief and comfort. Although not able to breathe when born under water and thus posing no risk of aspiration, the baby's face/head is immediately brought to the surface where the air stimulates it to breathe before the placenta ceases to fully function. Meticulous care must be paid to water temperature and infection control when using a tub/pool for either labor or birth.

Position of the Woman for Birth Women can give birth in the lithotomy, dorsal, lateral, squatting, standing, knee-chest, or hands-knees position or on a birth stool or birth chair. Any of the alternatives to the lithotomy position are possible in out-of-hospital settings and in enlightened hospital labor or birth rooms. The usual positions in a hospital delivery room are lithotomy or dorsal. Midwives believe that in neither of these positions does the woman have to be flat on her back; rather, they encourage a semi-sitting, or "back up" and "legs down," modification of these positions (see Figure 28-12). Liu showed that women in a 30-degree upright position (as opposed to lying flat) have a shorter second stage of labor, which is further shortened if the woman uses physiological pushing [19]. In deciding which of these two positions a woman in a delivery room should use, the midwife should consider the following:

1. The woman's preference. Although the dorsal position is a more natural position, some women prefer the lithotomy position with the metal leg supports because they feel more comfortable when their legs are supported. Many labor beds are also designed for birth and usually have foot rests for support. If it is necessary for the woman to be in the delivery room, she can just be wheeled into that room and remain in this kind of birthing bed rather than transferred to the delivery table.
2. The condition of the woman's legs. A woman with severe varicosities should be delivered in dorsal rather than lithotomy position. This position avoids pressure on the legs and in the popliteal space, which is exerted by both the full-leg and knee-break stirrups and causes circulatory interference. The risk of thrombophlebitis would be quite high with the woman in stirrups.
3. Any existing or anticipated complications. In the event of any existing complications (e.g., malpresentations, multiple gestation) or anticipated complications (e.g., shoulder dystocia), the woman should be in a lithotomy position because the clinician needs best possible visualization and needs room in which to function with ready, direct access to the woman.

FIGURE 28-12 Midwife helping woman with "back up, legs down" positioning in a delivery room.

General Preparations The general preparations depend, in part, on the location of the birth. The pacing of the preparations depends on the woman's progress of labor. The ideal pace is one of steady progression with neither frantic haste nor a long wait for the actual birth after all is in readiness.

Certain preparations are the same regardless of setting:

1. Wash/scrub your hands.
2. The woman settles into the place prepared for her to give birth.
3. If needed, clean off the woman's perineal area and place clean dry underpads beneath her buttocks.
4. Her significant others know that birth is imminent, are in attendance, and have their cameras, videotapes, or whatever the mother wants ready for recording of the birth.
5. Blankets for the baby are warmed.
6. Whatever equipment and supplies you need for the birth are ready and their sterility protected (e.g., gloves, clamps, scissors, bulb syringe).
7. Put on whatever protective gear you will be wearing.
8. Put on your gloves.
9. Continue to keep the woman and her significant others informed and involved in the ongoing progress and activities.
10. Patiently wait, watch, and encourage.

The delivery room in a hospital setting requires the most complex and detailed preparations involving multiple policies and personnel. As a midwife, you may from time to time be in a delivery room. It is important to know how to function and be comfortable in this setting. The following are basic steps in preparing for a birth in the delivery room:

1. Notify the nursing staff that the woman you are caring for is nearing birth by informing them of your findings and estimation of how soon you are going to want to move her to the delivery

room. You should notify the staff approximately on entry into transition for a multipara and into second stage labor for a primigravida.

2. Make sure that the woman's significant others have already changed into acceptable attire for the delivery room, or that they do so now.
3. Make sure that the newborn resuscitation equipment and supplies are present and in working condition.
4. Request that blankets be warmed for the baby if there is not a blanket warmer in the setting.
5. Make sure that the source of heat for the baby is functioning (e.g., radiant heater, incubator).
6. Decide when to move the woman to the delivery room.
7. Notify the nursing staff of your decision.
8. Assist with moving the woman from the labor room to the delivery room.
9. Depending on the availability of nursing staff, assist with moving the woman safely onto the delivery room table and removing the labor room bed or transport cart from the room.
10. See to it that the significant others are capped and masked, if required, prior to entering the delivery room and that they are safely seated on stools beside the woman and out of the way of the nursing personnel, general activities going on in the room, and sterile fields.
11. Inform the woman and her significant others that you are leaving the room to scrub but that you will be right outside the door. Tell them that you will keep an eye on her, as will the nurses in the room, and that the next time they see you, you will be in a cap and mask.
12. Inform the nursing staff of the following:
    a. that you are leaving to scrub
    b. the position of the woman for birth (lithotomy or dorsal), as this makes a difference in what they do with the stirrups and the end of the delivery table
    c. what size gloves you wear
    d. whether you want a pudendal set, Iowa trumpet, and/or needle and syringe for local infiltration, and what local anesthetic
    e. anything else you are going to want that the circulating nurse must get or do while she is doing her other tasks (e.g., extra 4 × 4s, exam jelly, catheter)

    Midwives who are former labor and delivery room nurses remember what it was like to try to jump in six different directions at the same time and resent having to try while wishing that the person giving the orders was better organized. Experienced delivery room nurses have developed a routine that allows them to accomplish a myriad of essential tasks in a short amount of time while also continuing to support and instruct the woman. If you tell them what you will need before you need it, they can incorporate your requests smoothly into their routine and have everything ready for you by the time you're back in the room from scrubbing. If you wait until you are scrubbed and in the room to tell them your glove size and ask for other needed items, you not only disrupt an effective routine but frustrate both the nurse (who can't get it all at once) and yourself, as you end up waiting—which, depending on the circumstances, may or may not matter.
13. Don a cap, mask, and pair of booties if you haven't already done so. Although it is considered better technique to have on a cap and mask whenever you enter the delivery room, it is not generally considered a serious breach in technique to have been in the delivery room without wearing a cap and mask if none of the sterile packs is open or sterile fields uncovered, as is usually the situation when the woman is moved into the delivery room.
14. Perform a surgical scrub. If you did a surgical scrub upon entry to the labor and delivery suite (a good idea), then the length of your scrub now can be cut in half. Remember to put on your cap and mask, in that order, before starting your scrub. Otherwise, when you realize that you have not yet done so, you have to break scrub, put on your cap and mask, and then start your scrub over again.

    It is essential while scrubbing to keep an eye on what is going on in the delivery room and to watch specifically for signs of imminent birth. Most delivery rooms are adjacent to the scrub sinks, which enables you to look in easily while scrubbing. (Needless to say, a controlled birth of the fetal head is eminently more important than a complete—or any—scrubbing of your hands.) Scrub time is also a good time to mentally review, even if quickly, your management plan for delivery of this individual woman and baby.
15. When you reenter the delivery room from scrubbing, the woman will be positioned for delivery, the sterile delivery table of supplies and instruments will be uncovered, chart forms will be started, and so forth. You should be familiar with the delivery room, where equipment and supplies are, the routines of the circulating nurse, and how to function within the room so if need be you know how to operate the delivery room table, fix stirrups, adjust lights and mirror, and so on.
16. Dry your hands and arms, using surgical technique.

17. Gown, using sterile technique.

18. Glove, using sterile technique.

19. The person who does the perineal prep varies. In some settings it is the circulating nurse; in other settings it is the midwife or physician helping the woman deliver her baby. (See Chapter 66 for the procedure.)

If the woman is in lithotomy position, the perineal prep is the time when the table is broken. *Once the table is broken it is imperative that you keep at least one eye on the woman's perineum at all times no matter what else you are doing*. This is vital to protect the safety of the about-to-be-born baby.

20. Drape the woman in accord with the drapes provided and institutional procedure. After the woman is draped, if she is in stirrups, you can more easily keep your eye on the perineum if you bring the instrument table up beside you with the end slanted under her draped leg.

21. If the woman so desires, have the overhead or portable mirror adjusted so that she and her significant others can watch the birth of the baby. It helps in adjusting the mirror for you to hold your hand right in front of the vaginal orifice and ask the woman and her partner if they can see your hand—a hand may be more recognizable to them. After the mirror is adjusted you can point out landmarks and the area to watch and describe what they can expect to see.

22. Request either sterile normal saline or an antiseptic solution such as benzalkonium (Zephiran), Betadine, or Hibiclens to be put in either a separate sterile splash basin or in a kidney basin if there is one on the instrument table. Use the solution to wet your gloves for vaginal examinations and rinse off your gloves of powder, blood, and so on.

23. Organize your instrument table. (It is set up in an organized way but you will need to organize it further.) It is helpful to separate what you will need for the birth of the baby (i.e., two clamps and a pair of scissors for clamping and cutting the umbilical cord; a cord clamp, and a bulb syringe for oropharyngeal and nasal suctioning) from the other instruments and supplies on the table. Then if you need any of these items in a hurry you will have them available rather than having to try to find them and losing precious time. It also helps to separate out the scissors for cutting an episiotomy, even if you do not plan to do one, in case you reverse this decision at the last minute. The table can be reorganized as events progress and you need different items; for example, reorganize the table for repair work when you are ready to do this by separating the needle-holder, suture scissors, pickup forceps, suture, and local infiltration apparatus from the other instruments and supplies.

24. Do a vaginal examination

- **a.** Reconfirm the presentation and position of the baby.
- **b.** Ascertain the station, if necessary.
- **c.** Evaluate the distensibility of the woman's perineum again.

25. If indicated, perform either a pudendal block or a local infiltration (see Chapters 68 and 69).

26. If indicated, cut the appropriate type of episiotomy (see Chapter 79).

Throughout all these preparations for birth, you will have continued to keep the woman and her partner informed of and involved in the ongoing activities, coached her in her breathing and pushing effort, and responded to any questions or concerns they might have. You will also have assumed management of the delivery room. Remember that you are responsible not only for the birth, the mother, the baby, and the significant others but also for everything that is going on in the delivery room, as it all affects directly or indirectly these central people. In this capacity you must not only be aware of everything happening in the room but also redirect any activity with which you do not agree. You are the one the staff will look to for direction and instructions. You must control the situation for the safety of mother and baby and to provide the best possible experience for them.

An effective learning tool for thinking through the responsibilities and the multiple preparations for birth is to play a mental game in which you envision yourself making the decisions, performing some preparatory acts, and directing others in the performance of other preparatory acts in a given situation. Once you have drilled and mastered the basics, you can alter the game by changing variables in the situation (e.g., primigravida versus multipara, different settings [e.g., home versus hospital delivery room], precipitous second stage). Mentally envision what you would do from beginning to end, in sequence, in each situation. The value of the mental game is that when faced with the actual situation, you have already thought through your actions and will thus face and manage the situation with greater equanimity and more seasoned judgment.

Management of the Birth

Management of the birth includes using the proper hand maneuvers to assist the baby's birth and pro-

viding immediate care of the newborn. In managing the birth the midwife must decide the following:

1. Whether to deliver the baby's head with a contraction or between contractions
2. Whether to use a Ritgen maneuver
3. When to clamp and cut the umbilical cord

Hand Maneuvers The hand maneuvers for birth of the baby in an occiput anterior (OA) position with the mother in a lithotomy position, a dorsal position, on hands and knees, and squatting are detailed in the skills section of this book (Chapters 70–73). The hand maneuvers for other presentations and positions of the baby are detailed in the discussion of the mechanisms of labor and managing the birth for each (i.e., breech, face) in Chapter 30. The hand maneuvers for a persistent occiput posterior (OP) position are the same as for an occiput anterior except for control of the head. The direction of pressure to help maintain the head in flexion and then to allow gradual extension when the head is occiput posterior is exactly opposite from the direction of the pressure exerted for the same purpose when the head is occiput anterior.

You must thoroughly drill and master the hand maneuvers you use for delivering a baby in every position before you need to use them so they become second nature to you. Those used infrequently should be reviewed periodically and practiced, so you will know them when you need them.

Birth of the Baby's Head Whether to deliver the baby's head with a contraction or between contractions or to use a Ritgen maneuver may not be your decision. A woman who is out of control and pushing with all her might despite all efforts to get her to stop will determine how the head is born.

Between Contractions. The idea behind delivering the baby's head between contractions is that the combination of the contraction and the maternal pushing effort exerts a double force at the moment of birth. This makes the birth of the head more rapid and the release of restraining pressure more abrupt, both of which increase the risk of intracranial damage to the baby and lacerations to the woman. If the woman is in control of herself it is possible for her to follow your instructions and to pant through a contraction and then gently push in between contractions, which will ease the baby's head out with the least amount of trauma to the baby and to the woman.

Ritgen Maneuver. The Ritgen maneuver, or modified Ritgen maneuver, is a technique by which the clinician controls the delivery of the baby's head (see Figure 28-13). It is performed as follows:

1. One hand remains on the occiput for control of the baby's head.
2. The other hand is covered with a towel to protect it from contamination.

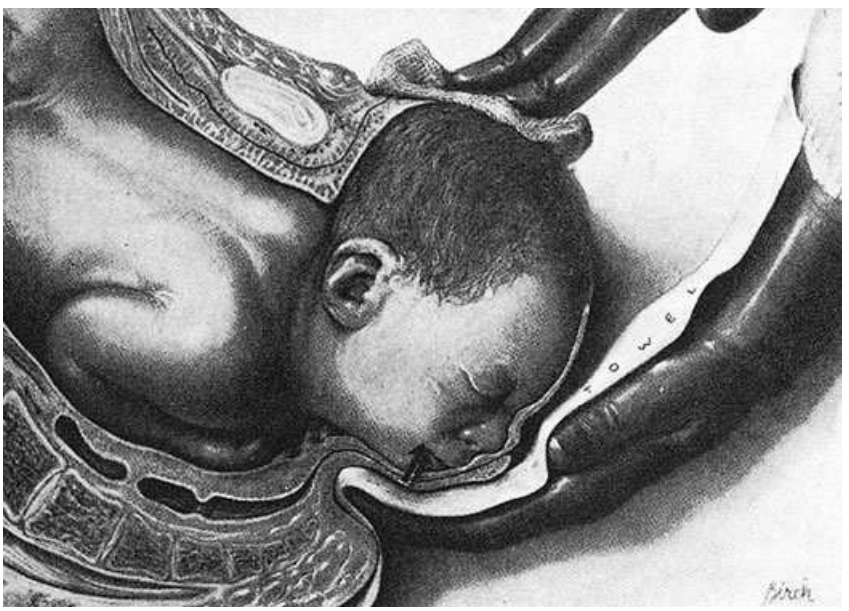

FIGURE 28-13 Ritgen maneuver. The arrow indicates the direction of moderate pressure applied to the fetal chin by the posterior hand.

Source: From Pritchard, J. A., and MacDonald, P. C. *Williams Obstetrics*, 15th ed. New York: Appleton-Century-Crofts, 1976. Reproduced with permission of the McGraw-Hill Companies.

3. The draped hand then exerts inward pressure posterior to the woman's rectum until the baby's chin is located and in the grasp of the fingers.
4. Forward and outward pressure is then exerted on the underneath side of the chin and the head is controlled between this hand and the hand exerting pressure on the occiput.

Most midwives do not routinely use the Ritgen maneuver. They believe the baby's head can be controlled in other ways (see Chapters 70–73) that are better for the baby and mother because they allow gradual natural processes to unfold, interfere less, and are less uncomfortable than the Ritgen maneuver. Discomfort arises from the fact that the anus is extremely distended with the bulging of the rectal wall into it. The Ritgen maneuver increases this anal stretching and most likely subjects it and the rectal wall to direct pressure and the rough surface of the towel. It is also associated with an increased incidence of periurethral lacerations.

However, it is useful to know how to do the Ritgen maneuver because it does enable you to "get hold of" the baby's head earlier and to deliver the baby's head faster in a controlled fashion if there is an urgent need for immediate delivery. It is possible to institute the Ritgen maneuver when the head is distending the vulva about half as much as it will when crowning, at which time the vulva encircles the largest diameter of the head at the moment before birth. A combination of an episiotomy and a Ritgen maneuver will shorten the end of the second stage of labor and bring it to a quick conclusion, if need be.

Clamping and Cutting the Umbilical Cord The umbilical cord is clamped by placing two instrument clamps on the cord with enough room between them to allow for easy cutting of the cord. After applying the first clamp, experienced clinicians routinely strip the cord the distance to the planned location of the second clamp. This prevents blood from spurting from a distended umbilical vessel at the time of cutting. When a clamp has been applied, the weight of the clamp must be supported and it should not be allowed to hang and exert pull or tension at the site of insertion into the baby, especially when the mother is in lithotomy position. Many clinicians prevent this when the mother is in lithotomy position by hooking the ring of the finger hold of the clamp over a finger of the hand that is holding or supporting the baby. This leaves the other hand free for cutting. The pull on the umbilicus by the clamp is not as much of a concern when the baby is born onto the bed or immediately placed on the mother's abdomen before the cord is cut. There is no pain for either the baby or the woman at the site where the umbilical cord is cut.

The timing of cutting the umbilical cord is a long-standing controversy between those who advocate delayed clamping of the cord and those who don't think it makes any significant difference when the cord is clamped [26]. In fact, neither early nor late clamping and cutting of the umbilical cord has any effect on the rate of infant mortality in term gestations. The more significant issue is whether to deliberately hold the preterm infant at or below the level of the vaginal introitus, thereby holding the baby at or below the level of the placenta. Lowering the infant, combined with delayed cord clamping, will result in a transfusion of approximately 80 milliliters of blood from the placenta into the baby. This transfusion gives additional blood volume, which is thought to facilitate physiological processes involved in the transition from fetal life to life after birth that may be critical to the very low birth weight preterm newborn [27]. This action has to be balanced against the baby's need for warmth and possible resuscitation. One workable compromise by Mercer and colleagues is to receive the baby into a warm blanket. The baby is then lowered the length of the umbilical cord, without tension on the cord, in order to obtain maximum placental infusion for 30–45 seconds before clamping and cutting the cord [27]. It is clear, however, that placental transfusion is *not* desirable if there is a known blood incompatibility between the mother and the baby.

Leboyer, in his plea for decreasing the violence of childbirth to the baby, advocates delayed clamping of the cord because he believes that the baby makes the transition to breathing air more easily without trauma and without danger of anoxia [28]. This is accomplished with patience and by allowing the newly born baby to have two sources of oxygen during the transition: (1) from the lungs and (2) from the placenta through the umbilical cord. Then when the gradual transition from dependence on the placenta to dependence on the lungs is completed, as evidenced by cessation of cord pulsations, the umbilical cord is clamped and cut. This process is completed approximately 4 to 5 minutes after birth.

Immediate Care of the Newborn Immediate assessment and resuscitation of the newborn are detailed in Chapters 37 and 38. However, it does not hurt to reemphasize vital points of care during the first minute of life, as this is the climax of the second

stage of labor. From the end of the birth of the baby, the usual steps of care are as follows:

1. Establish a clear airway. In normal births this usually involves
   a. holding or positioning the baby so that the head is lower than the body and is turned somewhat to the side for drainage
   b. wiping off the baby's face and head and wiping fluid from the nose and mouth
   c. suctioning the nasal and oral passages with a soft rubber bulb syringe
2. Keep the baby warm. The warmest place for the baby is on the mother's chest and abdomen. Wipe and dry the baby off so body heat is not lost, put a stockinette cap on the baby's head, and cover the baby with a warm blanket. If in a hospital and the baby has to be separated from the mother (e.g., for resuscitation), the baby is dried off and kept warm under a radiant heater.
3. Show the baby to the mother and her significant others or place the baby on the mother's abdomen if not already there (Figure 28-14).
4. Clamp and cut the umbilical cord (see preceding discussion). Many midwives simply use the cord clamp as one of the two clamps when clamping can be done without haste. Having the partner cut the cord is often an appreciated and special experience for the couple.
5. Assign the 1-minute and 5-minute Apgar scores (preferably done by someone other than you).

If you are in the hospital and take the baby to a warmed crib, incubator, or Kreiselman, take along the bulb syringe as well as the cord clamp and scissors for the final clamping and cutting of the cord, if this is not already done. During this minute of life, while doing the above, you should also grossly examine the baby for any visible deformities or congenital defects.

FIGURE 28-14 Midwife placing baby on mother's abdomen immediately after birth. Note the baby's open eyes.

While you are applying the cord clamp approximately 1 to 2 centimeters from the baby's skin edge, cutting off the excess cord, and completing your gross examination, *remember to keep one eye on the mother's perineum to note any sudden hemorrhaging or signs of placental separation.*

An alternative to the management and immediate care of the newborn presented in this chapter is to use all or part of the Leboyer approach to childbirth and the immediate care of the baby.

Leboyer Methodology The Leboyer approach to childbirth and to transition of the baby from intrauterine to extrauterine life is geared toward making this transition as atraumatic, painless, and nonfrightening as possible for the baby. This requires a reeducation process for parents and professionals alike. A full discussion of the methodology and its effect may be found in Dr. Frederick Leboyer's book, *Birth Without Violence* [28]. The following is a listing of specific actions, in sequence, suggested in his book:

1. Extinguish or dim lights to the minimum needed for birth; dim the lights still further after birth. Overhead lights or spotlights are not really necessary at this time.
2. Maintain silence. Any essential communication should be done in very low, muted voices toward the end of labor, reducing to a whisper at the time of birth and thereafter.
3. Practice patience throughout.
4. Support the baby's body without touching the baby's sensitive head during the delivery and place the baby on the mother's abdomen. Normally the baby emits one to three good, clear cries, no more, and settles into breathing. If the cries are not good, clear, and vigorous and the baby is limp, then resuscitation efforts are indicated.
5. Place the baby initially on the mother's abdomen with the limbs underneath the body. After the baby has stretched and the limbs are moving, turn the baby onto one side because this position facilitates relaxation of the limbs. Then, briefly, place the baby on his or her back.
6. Cut the umbilical cord when it has stopped pulsating. (The cord is cut immediately if necessary during birth if it is tight around the baby's neck.)
7. While the baby is on its abdomen, on the mother's abdomen, someone (preferably the mother) should massage the baby's body. Begin

the massage by letting the hands lie motionless yet attentive, responsive, and loving. Then massage in slow, continuous waves down the baby's back, over and over in measured fluidity.

8. The baby is then placed in a basin for a water bath. The temperature of the water should be 98° to 99°F (36.6° to 37.2°C). The baby is placed in the water extremely slowly and remains in the bath until completely relaxed. Bathing the baby is a good role for the woman's partner, as it allows this person to remain involved in events and bond with the baby. The baby most likely will open his or her eyes during the bath and may also smile and indulge in exploratory play (Figure 28-15).
9. Remove the baby slowly from the water bath, reimmerse, and then remove her or him from the water again. This facilitates the baby's adjustment to gravity.
10. Place the baby on a warmed diaper and wrap him or her in warm blankets without restraining the baby's hands.
11. Place the baby on one side with back support.
12. Leave the baby alone in stillness. This does not mean that the baby is no longer under continuing observation.

This entire process takes approximately 10 minutes, depending on the length of time in the water bath.

The Leboyer method dovetails nicely with attachment processes, maternal-infant bonding, and the initiation of the parenting continuum. Further contact with the mother, including breastfeeding and eye-to-eye contact, may be smoothly initiated after completion of the Leboyer method.

FIGURE 28-15 Father giving his baby a Leboyer bath with help of mother and siblings.

A more recent study in Sweden, however, showed that newborns with uninterrupted contact with their mother begin to make crawling movements toward her breast after 20 minutes and by an average of 50 minutes most of the newborns were correctly sucking and breastfeeding [29]. Most of the other group of newborns, who were separated from their mothers after 20 minutes for routine procedures and then returned to them, did not demonstrate the crawling behavior, nor did they suck correctly when put to breast. This raises questions not only about the timing of newborn procedures (weight, footprints, examination, bath, dressing) but also about any separation from the mother. It also calls into question accepted theory regarding motor development, which places crawling at 28 weeks of life [30].

CHAPTER

29

Screening for and Collaborative Management of Selected Complications During the First and Second Stages of Labor

The conditions and complications discussed in this chapter are the more common ones, and they actually may occur before or without labor (e.g., premature rupture of membranes, umbilical cord prolapse). No effort has been made to differentiate them by stage of labor because most of them can occur in either the first or the second stage.

The midwife must be familiar with these complications in order to recognize their development or existence as early as possible. The midwife then enters into a collaborative relationship with the consulting physician for the management of care of women with these conditions. In addition to contributing to the medical management of care, the midwife also contributes advocacy for a woman, provides continuity of care, protects the normal labor process insofar as possible, and promotes family-centered care and safe labor and birth options (including delivery by the midwife) appropriate to the situation.

This chapter reflects the fact that the recognition and evolution of a complicated clinical situation usually involve progressive levels of intervention. The midwife should evaluate the need for each intervention, the safety of nonintervention, the disruption in the normal process an intervention will cause, and the risk-benefit ratio of intervention and nonintervention. Some of the complications discussed in this chapter alter the normal physiological condition of the mother and the environment for the fetus. These alterations compromise the mother's and the fetus's normal reserve, thereby dictating the need for earlier and more aggressive intervention than is indicated for a normal progressive labor.

Other complications that are rarely seen in obstetric practice (either because they are so catastrophic that there is no question of urgent need for a physician (e.g., amniotic fluid embolism) or because they are rare results or causes of other complications for which physician consultation will have already been sought) are not discussed in this chapter. Examples of the latter category include Bandl's retraction ring, or pathological uterine constriction rings, and causes and results of cervical dystocia including cervical rigidity, conglutination of the cervix, cervical stenosis, and annular detachment of the cervix. The midwifery student who is interested in these rare complications is encouraged to pursue this interest in medical obstetric textbooks and journals.

Previous Cesarean Section

The management of care of women who have had one or more previous cesarean sections has undergone more than one revolution in the past several

years. In the early 1970s the medical community eased away from an earlier "once a section, always a section" philosophy and toward cautious attempts at vaginal birth after cesarean section (VBAC) in carefully selected women [1]. By the early 1990s, all women with previous lower uterine segment (low transverse or low vertical incision) cesarean sections and no contraindications were encouraged to labor rather than plan a repeat cesarean section [2, 3]. It was thought that vaginal birth after cesarean section presented fewer risks than a repeat cesarean section and that VBAC would lower the rate of cesarean sections, which had increased to nearly 25 percent by 1988 from 5.5 percent in 1970 [4, 5]. By the late 1990s and into the early 2000s, however, studies were published that indicated an increased risk of uterine rupture in women electing to have a trial of labor rather than a repeat cesarean section [6, 7]. One study found a uterine rupture rate of 5.2/1000 women with spontaneous onset of labor and of 1.6/1000 women with repeat cesarean section without labor [7].

The risk to a woman of having a ruptured uterus while attempting to give birth vaginally after a prior cesarean section is related to the type of uterine incision and in some instances to the gestational age of the fetus at the time the cesarean section was performed. The risk of uterine rupture is also increased if a woman's labor is induced by any means other than prostaglandins (7.7/1000). Induction with a prostaglandin dramatically further increases the risk of uterine rupture to 24.5/1000 [7]. Increased risk of uterine rupture may also be related to whether the closure during the previous cesarean section was a single layer with a continuous running stitch or a double layer with interrupted sutures, with the latter obviously a stronger closure [8]. The crucial piece of information is whether the incision was in the lower uterine segment. Any incision that extends into the muscle mass of the uterine corpus or fundus increases the risk of uterine rupture. Since the lower uterine segment is poorly developed in early gestation, a cesarean section done before 28 weeks without labor necessarily involves the corpus muscle mass, even with a low transverse incision. Safety of a subsequent vaginal delivery in such a situation is thus questionable, especially if there had been no labor. With labor the lower uterine segment develops even in the second trimester.

There are two types of cesarean sections: (1) those in which the uterine incision involves the upper contractile uterine segment (corpus/fundus) and (2) those in which the uterine incision involves only the lower noncontractile uterine segment. The former is a vertical incision and is known as the classical incision or cesarean section. The latter may involve either a low transverse incision or a low vertical incision. The risk of subsequent uterine rupture is directly related to the type of uterine scar. The risk of uterine rupture for women who have had a previous low transverse uterine incision is between 0.19 and 0.8 percent [9, 10]. For women who have had a previous low vertical uterine incision the risk of uterine rupture is 1.1 percent [11]. Women with classical uterine scars have a risk of catastrophic uterine rupture of around 12 percent [2, 12].

There are two types of uterine ruptures when there is a scar from previous uterine surgery, the most common surgery being cesarean section. These types are differentiated by clinical findings and resulting morbidity and mortality. One type is catastrophic, in which there is separation of the old incision for most of its length, the fetal membranes also rupture, all or part of the fetus is extruded into the peritoneal cavity, and there is significant bleeding. The other type is atraumatic dehiscence in which the separation of the old incision does not involve the entire length, the fetal membranes do not rupture, the fetus remains within the uterus, and bleeding is minimal or absent. Rupture of a low transverse uterine incision, if it occurs, is not generally catastrophic or life threatening to either the mother or the baby. Such a rupture is usually no more than a dehiscence of the old scar and an incidental finding during uterine exploration following a vaginal birth or during an elected repeat cesarean section. To be life threatening, rupture of a uterine scar either extends into the rich blood supply found in the uterine corpus and fundus or disrupts the placenta, which is normally located in the uterine fundus. Because of these possibilities VBAC is not recommended for women with classical upper uterine segment vertical scars.

The risk to a woman of having a repeat cesarean section is the increased morbidity and mortality associated with cesarean section as major abdominal surgery. Causes of morbidity and mortality include anesthesia risks, inadvertent injury to the bladder or bowel, hemorrhage, wound infection, and increased newborn respiratory problems [13].

Factors that are associated with a higher success rate of VBAC include nonrepetitive indications

for the previous cesarean section (e.g., breech or malpresentation, fetal distress, preeclampsia), spontaneous labor with normal progression, and a history of previous VBAC. Factors that are associated with repeat cesarean section after a trial of labor include possible repetitive indications for the previous cesarean section (e.g., cephalopelvic disproportion, failure to progress, labor dystocia), use of induction or augmentation, more than one prior cesarean section, no prior vaginal delivery, and nonreassuring fetal heart tones when first seen in labor [14, 15].

The midwife should discuss management options for labor and delivery with the woman during the prenatal period. This discussion starts upon learning, during the initial visit, that the woman has undergone a previous cesarean section. The database obtained during the initial visit includes the following:

1. History
   a. weeks gestation at time of cesarean section
   b. type of cesarean section
   c. reason for cesarean section
   d. length of labor
   e. cervical dilatation at time of delivery
2. Physical examination
   a. abdominal scar (describe)
3. Pelvic examination
   a. clinical pelvimetry
   b. nonparous cervix and vaginal introitus if all previous babies have been delivered by cesarean section

It is critical that the midwife remember that the abdominal skin incision is not synonymous with the uterine incision. Only review of the operative report will give definitive information regarding the location of the uterine incision. You should obtain the operative report and record of the previous labor and surgery. Both are essential for determining the relative safety of VBAC for an individual and helpful in taking care of the woman during the subsequent labor. Look specifically both for type of incision into the uterus and for type of closure.

If the previous incision was low transverse or low vertical, the management options are (1) a scheduled, elective repeat cesarean section, (2) an elective repeat cesarean section after the onset of labor, or (3) a trial of labor for a vaginal delivery. If the previous uterine incision was classical, then a repeat cesarean section without labor is the appropriate management option. The available options should be reviewed with the woman and the risks and benefits of a repeat cesarean section versus a VBAC should be discussed. Documentation that this discussion has taken place should be recorded in the chart.

Although some women feel strongly that they should have the opportunity to deliver vaginally after a cesarean section, there are other women who would rather have another cesarean birth [16]. From a health perspective, all women who had an incision in the lower uterine segment and have no contraindications should be encouraged to attempt vaginal birth. However, part of informed consent is for the woman to know that morbidity has been found to be higher in those women who attempt VBAC and labor but deliver again by cesarean section than in either women who attempt VBAC and birth vaginally (lowest risk) or women who have an elective repeat cesarean birth [6].

If a woman chooses to have a scheduled elective repeat cesarean section without waiting for the onset of labor, she most likely will be scheduled at 39 weeks' gestation. Unless the woman has sure dates or an early dating ultrasound, it may be necessary to confirm fetal maturity by amniocentesis for fetal lung maturity in order to avoid iatrogenic prematurity. This intervention is avoided if the woman enters spontaneous labor prior to the repeat cesarean section.

If a woman chooses to have a vaginal birth, she will have some special needs for support in her decision. Referral to a special VBAC course or support group, if available, may help her overcome any negative feelings and fears she has from her previous experience. Support throughout the antepartal course is especially important when family members are skeptical about the woman's decision. The midwife should explore issues of body image, fear of failure, and self-image with the woman antepartally. The midwife should also compare the woman's recollection of the length of her labor and reason for the cesarean section with her medical records in order to discuss any lack of knowledge or misperception that would lead to unrealistic concerns on her part.

The midwife should be cautious in labeling a woman a poor candidate for vaginal delivery on the basis of a previous diagnosis of cephalopelvic disproportion (CPD). Many diagnoses of cephalopelvic disproportion do not reflect actual CPD but, rather, an unknown reason for failure to progress in labor. Approximately 60 to 70 percent of women with a previous cesarean section for CPD (or failure

to progress) will deliver vaginally in a subsequent pregnancy [3, 10], and often deliver babies larger than the one for which CPD was the diagnosis.

Discussion with your consulting physician regarding a woman with a previous cesarean section should include your findings, a review of your discussion with the woman, and her decision about birth, locale for labor and birth, and whether the physician needs to be present.

A candidate for VBAC should be allowed to labor normally. She may have a psychological milestone to overcome at the point in labor at which she experienced the difficulties that led to the previous cesarean section. Also, from this point she will subsequently progress like a primigravida if she has never delivered vaginally. Thus it is important to note the point in the previous labor at which arrest or difficulty occurred, as this is the point in the present labor where progress might be slow or nonexistent. Support and exploration of fear of failure is essential when the woman reaches that point in labor.

Management of care of the VBAC woman in labor and for birth is the same as for any woman in labor (see Chapters 26 and 28) with the exception of more frequent monitoring of the fetal heart (every 15 minutes during the first stage and every 5 minutes in second stage), if not using continuous electronic fetal monitoring, because the first indication of uterine rupture usually is fetal bradycardia.

Also, oxytocin for induction or augmentation should be used with great caution, weighing risks and benefits; prostaglandins should not be used for ripening the cervix and misoprostol (Cytotec) is contraindicated. There no longer is concern that epidurals might mask the symptoms of uterine dehiscence or rupture at the site of the scar because most of the symptoms have nothing to do with whether a woman feels pain. Fetal bradycardia, abrupt and persistent, may be the only indication that uterine rupture has occurred [9]. The woman should be closely monitored for the signs and symptoms of uterine rupture: abrupt change or cessation of uterine contractions, vaginal bleeding, and a loss of fetal station [3], as well as an abrupt change in the fetal heart rate. All interventions should be evaluated for safety and interference with normal labor progress and mechanisms.

In management of the third stage of labor, it is useful to remember that there is an increased incidence of the placenta's being implanted over the uterine scar. This leads to an increased incidence of placenta accreta. For this reason, in the event of a retained placenta you should transfer the woman to the hospital if you are at home or in a birth center and either ask your consulting physician to attempt the manual removal of the placenta rather than doing it yourself, or ask the physician to be present if you choose to do it.

Manual exploration of the uterine cavity immediately after birth to rule out scar dehiscence is a subject of controversy. The individual situation and events during labor should be considered and the absolute necessity of this painful procedure should be explored with your consulting physician. The management of asymptomatic scar dehiscence following vaginal birth is to do nothing, as the defect will heal itself by 6 weeks postpartum.

Preterm Labor/Birth

Preterm, or premature, labor is labor commencing any time after the start of the twentieth week of gestation up to completion of the thirty-seventh week of gestation. Preterm labor culminates in preterm birth in almost 12 percent of all births in the United States and is second only to birth defects as the leading cause of neonatal mortality. Despite all efforts during the 1980s to identify risk, develop preterm birth prevention programs, and intervene with tocolytic drugs, the research is inconclusive and the rate of preterm birth actually increased from 8.9 percent in 1980 to 10.2 percent in 1988 to 11.8 percent in 1999 [17].

Preterm birth accounts for 75 percent of all perinatal deaths and up to 50 percent of the neurological handicaps found in infancy. The incidence of preterm birth varies among different populations, with the lowest incidence in the socioeconomically more advantaged population and the highest incidence occurring in the medically indigent population. As the medically indigent population has a higher proportionate number of blacks than whites, the higher incidence of preterm birth in this population may account for the higher mortality rate among black infants than among white infants [18].

Management of preterm labor is predicated on first identifying the woman at risk for this complication. Risk-scoring tools have proved to have such low sensitivity, specificity, and positive-predictive value as to have limited usefulness except with upper socioeconomic women and with multigravidas [19]. However, a number of predisposing risk factors have been associated with preterm labor:

1. Low socioeconomic status
2. Nonwhite race: differences between the preterm birth rate for blacks and whites persist even when socioeconomic status is not a factor. This may reflect the fact that black women who are currently classified as middle-class are more likely than white women who are currently classified as middle-class to have been conceived and raised in poverty; the possible cumulative effect of poverty from generation to generation that stays in poverty; and the possible improvement in the rate of low birth weight in middle-class black women with each subsequent generation conceived and raised in the middle class [20].
3. Poor nutritional status: low prepregnancy weight; weight gain of less than 10 pounds by 20 weeks' gestation; weight loss; inadequate protein and calorie intake (see Chapter 22)
4. Previous history of a preterm labor or birth: any woman who had one preterm birth in a past pregnancy has a 20 to 40 percent risk of recurrence. The risk increases or decreases with each subsequent preterm or full-term birth, respectively. It is sometimes difficult to distinguish, from the history of birth weight and supposed months of gestation, whether a previous infant was preterm or growth-retarded. Therefore, an attempt should be made to obtain the medical records for any woman who had a previous infant weighing less than 2500 grams or who delivered prior to 36 weeks' gestation.
5. One or more spontaneous second trimester abortions
6. Short interval between pregnancies: one study found that for black women, an interval of fewer than 9 months between pregnancies was associated with a significantly greater prevalence of preterm delivery and lower birth weight, whereas for white women only an interval of fewer than 3 months between pregnancies was associated with a greater prevalence of preterm birth and lower birth weight [18].
7. Multiple gestation: ten percent of all preterm births are because of multiple gestation.
8. Substance abuse (cigarettes, alcohol, street drugs, particularly cocaine)
9. Inadequate prenatal care
10. Uterine anomalies
11. Incompetent cervix
12. DES exposure in utero
13. Urinary tract infection
14. Hemoglobinopathies (e.g., G_6PD)
15. Genital tract colonization and infection with Group B Streptococci, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Gardnerella vaginalis*, bacteroides species, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, or bacterial vaginosis [21].
16. Premature rupture of the membranes
17. Chorioamnionitis
18. Severe physical violence during pregnancy [22]
19. Abruptio placentae or placenta previa
20. Fetal death
21. Polyhydramnios

In addition to scrutinizing all the possible predisposing factors, intensive efforts have been made to identify biological markers for predicting and preventing preterm birth [17]. The results have been disappointing and the evidence is often inconsistent.

1. Use of home monitoring for frequency of contractions has been found to have a sensitivity and positive predictive value below 30 percent. Data are inconsistent on any difference in outcome. Further, although preterm delivery undoubtedly increases with increased frequency of contractions, measurement of contraction frequency was found to not be clinically useful for predicting preterm delivery [17, 23].
2. Measuring salivary estriol, which increases before the onset of spontaneous term or preterm labor, has a high number of false positives and too many confounding variables [17].
3. Making use of the known association of bacterial vaginosis and preterm labor [24] by screening and treatment protocols has been the focus of a number of studies. Results are inconsistent but largely without significant differences in the rate of preterm labor from unscreened and untreated control groups both in the United States and abroad [17, 25]. Certainly women who are symptomatic should be treated, but since 40 to 50 percent of women are asymptomatic, the evidence to date does not support screening and treatment of all pregnant women [17]. However, a significant reduction in the incidence of preterm delivery has been found in treating women with a previous preterm delivery and a diagnosis of bacterial vaginosis in the second trimester with oral metronidazole (Flagyl) for one week or more [21].
4. Fetal fibronectin (fFN) is a protein produced by the fetal membranes that serves as an adhesive binder of the membranes and placenta to the decidua and is normally present in cervical secretions until 20 to 22 weeks' gestation. After

that time, however, the presence of fFN is associated with preterm labor from 24 through 34 weeks. Screening for fFN has shown a positive test to have 61% sensitivity and 83% specificity for predicting preterm labor, however, a negative test is 95% predictive for *not* delivering within 14 days [17]. The problem is that even if fFN reliably predicted preterm labor, there is to date no related intervention that will decrease the risk of preterm delivery. Therefore, the test should not be used for routine screening of low-risk, asymptomatic women, and the following criteria should be met if used in specific high-risk groups [17]:

   a. membranes intact
   b. less than 3 centimeters cervical dilatation
   c. test used no earlier that the start of the 24th week of gestation and no later than the end of the 34th week of gestation

   A benefit of the high negative predictive value of the fFN test is that it can be used to rule out imminent preterm birth, avoid unnecessary intervention, and reassure expectant parents that their risk for the next two weeks is low. The test costs about $200 [26].

5. There is clearly an association between cervical shortening and preterm delivery [27], but the predictive value of using cervical ultrasonography has ranged from 68 to 100% sensitivity and 44 to 79% specificity [17]. The problem is the lack of a related effective treatment that would decrease the risk of preterm birth. Therefore, routine use of cervical length determination by ultrasonography is not recommended [17].

The same problem holds true for the strong predictive value of a combination of a positive fFN test and cervical ultrasonography of a cervical length of less than 25 millimeters as neither test alone has a related effective intervention. The negative predictive value is more useful at this time, especially with women with a number of predisposing risk factors.

Women with a history of incompetent cervix (see Chapter 24) and previous pregnancy loss, however, may benefit from weekly or biweekly monitoring of cervical length with vaginal ultrasound since they do not exhibit signs and symptoms of preterm labor until the membranes rupture, they have vaginal bleeding, or experience pelvic pressure and the cervix has already effaced and dilated. Although prophylactic cervical cerclage has not been found to be beneficial in the prevention of preterm labor [28, 29], once there are findings of the cervix becoming shorter or there is funneling (prolapse) of the membranes through the internal cervical os into the cervical canal, placement of a cerclage suture may be beneficial, although the evidence is inconsistent [28–31].

Screening for preterm labor, therefore, involves identifying both the predisposing factors for preterm labor during routine prenatal care and the signs and symptoms of preterm labor. The signs and symptoms of preterm labor are as follows:

1. Painful menstrual-like cramps—may be confused with round ligament pain
2. Dull low backache—different from the usual low backache a pregnant woman may have
3. Suprapubic pain or pressure—may be confused with urinary tract infection
4. Sensation of pelvic pressure or heaviness
5. Change in character or amount of vaginal discharge (thicker, thinner, watery, bloody, brown, colorless)
6. Diarrhea
7. Unpalpated uterine contractions (painful or painless) felt more often than every 10 minutes for 1 hour or more and not relieved by lying down
8. Premature rupture of the membranes

The signs and symptoms of preterm labor should be included as a routine part of the woman's prenatal education beginning around 20 to 24 weeks' gestation.

In addition to routine screening for complications, the midwife should provide the following care to a woman with a history of one previous preterm labor or birth and no signs and symptoms of preterm labor in this gestation:

1. Monthly screening for asymptomatic bacteriuria
2. Treatment of any vaginal and cervical infections
3. Diet history and appropriate nutritional counseling
4. Reinforcement of routine instructions about the signs and symptoms of preterm labor
5. Counseling, if necessary, regarding cigarette, drug, and alcohol use
6. Encouragement to communicate if she is having personal stress, so she can obtain appropriate help with stress reduction

If a woman has a history of two or more previous premature labors or births or has a multiple gestation and shows no signs and symptoms of preterm labor, then in addition to the above the midwife should do the following:

1. Conduct a vaginal examination every 2 weeks starting at 24 weeks' gestation for cervical

changes in position, consistency, effacement, and dilatation and for station of the presenting part. Research findings are inconsistent as to the predictive value of serial cervical examinations [19]. Findings from serial cervical examinations, however, may be used to make clinical management decisions [19].

2. Recommend a change and/or reduction in workload if the woman's job involves heavy lifting, pushing or pulling, long hours, rotating shifts, or a lengthy commute.
3. Recommend use of condoms during sexual intercourse to prevent sexually transmitted diseases that might predispose the woman to premature rupture of the membranes and to prevent prostaglandin in the semen from causing uterine irritability.
4. Advise the woman to avoid nipple/breast stimulation to prevent uterine contractions.

Research has not shown that the interventions of bed rest, home uterine activity monitoring (except for daily contact with a nurse), routine screening and treatment of asymptomatic pregnant women for bacterial vaginosis or for *Trichomonas vaginalis* [25, 32], prophylactic oral tocolytic therapy, or prophylactic cerclage are effective in the prevention of preterm labor [19, 29].

A woman with signs and symptoms of preterm labor, with or without any predisposing factors, should be seen immediately. You should make the following assessment and if the woman is indeed in preterm labor, notify your consulting physician.

1. History
   a. signs and symptoms of preterm labor
   b. signs and symptoms of urinary tract infection
   c. signs and symptoms of vaginitis/cervicitis/sexually transmitted diseases
   d. signs and symptoms of viral or bacterial infection
   e. signs and symptoms of premature rupture of membranes
2. Physical examination
   a. vital signs (especially temperature and pulse)
   b. evaluation of gestational age
   c. evaluation of contractions
   d. evaluation of fetal heart rate and pattern
   e. abdominal palpation for presentation, position, multiple gestation, estimated fetal weight, and assessment of abdominal pain
   f. costovertebral angle tenderness
   g. assessment of low back pain and suprapubic pain
3. Pelvic examination
   a. speculum examination for evaluation of any existing vaginitis or cervicitis, sexually transmitted diseases, premature rupture of the membranes, bloody show, meconium
   b. digital examination for evaluation of any existing cervical changes and of the station of the presenting part (a digital exam is not done if premature rupture of membranes is diagnosed upon speculum examination)
4. Laboratory tests
   a. microscopic urinalysis
   b. urine culture and sensitivity
   c. wet mount for bacterial vaginosis and for *Trichomonas vaginalis*
   d. cultures for Group B Streptococcus and any genital lesions
   e. specimen for gonorrhea and chlamydia diagnostic testing
   f. complete blood count (CBC) and differential (if the woman has signs and symptoms of infection)
   g. fern test (see pp. 743 and 864)
   h. nitrazine test (see pp. 743 and 864)

Multiple approaches are needed to provide the most accurate information when assessing preterm labor contractions. First is the woman's perception of the contractions: frequency, duration, where she feels the contractions, whether they have gotten any stronger, longer, or closer together, if they are regular or irregular, and if they feel like a previous preterm labor. Second is the midwife's palpation of the contractions for frequency, duration, and intensity. Third is the use of external electronic fetal monitoring. It is important to realize that a small uterus and mild contractions may not accurately trace on the monitor graph. Findings from fetal monitoring and the record of contractions should be correlated with the woman's perceptions and your findings from palpation.

Assessment of the fetus is done by external electronic fetal monitoring (see Chapter 27). Of particular consideration is that a very preterm fetus is very mobile in utero and may be difficult to monitor. The baseline fetal heart rate is higher in earlier gestation and should be ascertained before any tocolytic agents are given because tachycardia is a frequent side effect of the commonly used beta-adrenergic agonists (ritodrine; terbutaline). The very preterm fetus prior to 28 weeks will usually not have accelerations of the heart rate great enough to meet criteria for reactivity on a nonstress

test due to their immaturity (see Chapters 23 and 27).

An accurate diagnosis of preterm labor is critical to determining the appropriate treatment. Contractions alone are not enough to diagnose preterm labor. A diagnosis of preterm labor is made between 20 and 37 weeks' gestation when the woman is having uterine contractions (frequency of 5 to 8 minutes apart or four contractions in 20 minutes or eight in 60 minutes) *and* she exhibits (1) ruptured membranes *or* (2) intact membranes *and* (a) progressive cervical change, *or* (b) 2 centimeters dilatation, *or* (c) a positive fFn test [33].

Women with signs and symptoms possibly indicative of preterm labor should be collaboratively managed with your consulting physician in the hospital. The midwife's initial evaluation of preterm labor should include the level of care immediately available to the woman and the length of time needed to transport the woman safely to a tertiary hospital for access to a neonatal intensive care unit.

Management of care of women with signs and symptoms possibly indicative of preterm labor includes bed rest in a lateral, or side-lying, position, external fetal heart and uterine contractility monitoring, and, if the membranes are intact, monitoring with vaginal examinations (preferably by the same examiner) for cervical change. Hydration has not been shown to be effective in stopping labor but it may increase the risk of pulmonary edema if tocolytic therapy is subsequently used [29], and delay prompt initiation of intravenous tocolysis when immediately needed. If the woman is given intravenous fluid, the risk of pulmonary edema is reduced if the fluid used is a hypotonic solution (i.e., 5% dextrose in water or 5% dextrose in 0.25% normal saline).

If on evaluation the woman does not meet criteria for the diagnosis of preterm labor, she may be sent home with the following instructions:

1. Limit activity—curtail working hours in a nonstrenuous and nonstressful job or take a leave of absence from a strenuous or stressful job; do no heavy housework.
2. Arrange for someone to help with household and child care responsibilities.
3. Engage in no sexual activity until reevaluation in 1 week. Resumption of sexual activity depends on uterine activity and the presence of any predisposing factors to preterm labor. If sexual activity is subsequently resumed, use condoms. If resumption of sexual activity causes an increase or recurrence of uterine contractions, the couple should be advised to abstain from sexual intercourse or other sexual activity that leads to orgasm in the woman.
4. Return for routine prenatal care and reevaluation for preterm labor in 1 week. Routine prenatal care should continue every other week until 36 weeks and then weekly. In the event of a recurrence of the signs and symptoms of preterm labor, she should be reevaluated immediately.
5. Continue to follow previous instructions on nutrition, recognizing signs and symptoms of preterm labor, stress reduction, and use of cigarettes, drugs, and alcohol.

Midwifery management of women who are in preterm labor is conducted in collaboration with the consulting physician. Decisions have the goal of a viable baby with the least amount of morbidity. Women who meet the definition of preterm labor who are less than 4 centimeters dilated and less than 34 weeks' gestation are potential candidates for tocolysis. The value of tocolysis for women who are between 34 and 37 weeks' gestation is debatable, given the minimal improvement in neonatal outcome over 34 weeks and a questionable cost-benefit ratio. There may be individual circumstances, however, that would warrant tocolysis between 34 and 37 weeks' gestation.

Tocolysis is the use of medication that will inhibit uterine contractions. An accurate early diagnosis is critical to the use of any of the various tocolytic agents that are available to attempt to stop uterine contractions. The midwife needs to be acutely aware, however, that these drugs are extremely toxic and may produce dangerous side effects in both the mother and the fetus (see Table 29-1). The drugs that have been most commonly used are the beta-adrenergic agonists (betamimetics) ritodrine and terbutaline, and magnesium sulfate.

Studies of the various tocolytic agents show that at best tocolysis prolongs a pregnancy for the short term—24 to 48 hours and in some instances 3 to 7 days. The largest study of ritodrine, however, found that "the use of ritodrine in the treatment of preterm labor had no significant beneficial effect on perinatal mortality, the frequency of prolongation of pregnancy to term, or birth weight" [34], which led others to call on the FDA to reconsider its approval of ritodrine as a treatment for preterm labor in light of its lack of efficacy for this purpose and the serious maternal risks involved with use of this drug [35].

The beta-adrenergic agonists are well known for their maternal side effects of tachycardia and pul-

TABLE 29-1 Side Effects of Tocolytic Agents

	Beta-adrenergic Agonists (ritodrine, terbutaline)	Magnesium Sulfate	Prostaglandin Inhibitor (indomethacin)	Calcium Channel Blockers (nifedipine, nicardipine)

monary edema, marked increased in cardiac output, effect on blood pressure, increase in blood sugar levels and in insulin secretion, and the fetal side effects of tachycardia, hypoglycemia, and hyperinsulinism after birth [29] (see Table 29-1). Magnesium sulfate lacks adequate evaluation, has serious side effects that can lead to maternal cardiac arrest and death, and may increase perinatal morbidity and mortality [29, 36]. Indomethacin is the most widely used of the prostaglandin synthesis inhibitors and is more

effective at inhibiting uterine contractions than any of the betamimetic drugs [29]. Although the prostaglandin synthesis inhibitors are not without their side effects, especially on the gastrointestinal tract (see Table 29-1), they are clearly preferable to betamimetics for women with heart disease, hyperthyroidism, or diabetes [29]; however, routine use should not be encouraged [37].

The calcium channel blockers (nifedipine, nicardipine) have been more recently studied and research indicates that they have fewer maternal side effects, no adverse effect on fetal outcome, postpone birth longer, are as effective as the betamimetics and magnesium sulfate in stopping uterine contractions and in delaying birth, and are preferable to betamimetics for tocolytic use [29, 38–40]. The use of oxytocin antagonists (e.g., atosiban) are comparatively new with fewer studies. They may have fewer maternal side effects and equal efficacy as a tocolytic [29, 37], but greater fetal risk [41].

The risk-benefit ratio must be carefully weighed in considering the use of tocolytic agents. Their limited effectiveness raises the question of whether labor should be allowed to proceed or whether a potentially unsafe and possibly ineffective effort should be made to stop it. Risk-benefit analysis should include the uterine environment and whether the fetus will have a better chance outside rather than inside; maternal risk from the side effects and complications of specific tocolytic drugs; fetal risk from the side effects and complications of specific tocolytic drugs; the need to provide time to transport the mother to a hospital with neonatal intensive care facilities and personnel; and the need to provide time for the fetus to benefit from administration of corticosteroids for fetal maturation.

Antenatal corticosteroid therapy has been shown to reduce the incidence and severity of respiratory distress syndrome, intraventricular hemorrhage, and neonatal mortality when administered between 24 and 34 weeks' gestation to women at risk for preterm birth within 7 days [33, 42]. Optimal benefits begin 24 hours after initiation of therapy and last 7 days. The 24 hours needed for optimal benefit from the administration of corticosteroids may be provided by the 24 hours that may be obtained from tocolytic therapy. The corticosteroids used most often and their dosages for therapy are as follows:

betamethasone 12 mg IM given in two doses 24 hours apart, *or*
dexamethasone 6 mg IM given in four doses 12 hours apart

Higher or more frequent doses or repeated weekly courses of corticosteroids do not increase the benefits of antenatal therapy or reduce composite morbidity compared to a single course but does increase the risk of adverse short- and long-term neurologic damage, including risk factors for cerebral palsy [42, 43].

Women receiving tocolytics for preterm labor require intensive support to help them overcome the physical side effects of the drugs. Continuous monitoring and support by the midwife to help alleviate the anxiety produced by these side effects contribute to the success of the tocolysis.

The follow-up for women whose preterm labor is stopped is weekly prenatal visits and vaginal examinations, preferably by the same examiner, to evaluate her for any cervical change. She should abstain from sexual intercourse or other sexual activity that leads to orgasm and continue to follow all previous instructions regarding work; nutrition; signs and symptoms of preterm labor; stress reduction; use of cigarettes, drugs, and alcohol; and household and child care responsibilities. The woman's partner and family should be included in the review of these instructions at each prenatal visit. Efforts to maintain pregnancy with maintenance doses of oral beta-adrenergic agonists have proven not to be efficacious and this therapy is not recommended [44].

With any woman at risk for premature labor, the midwife must be careful to help her avoid becoming anxious, as this in and of itself has been implicated as a causative factor. Certainly, for a woman who has delivered prematurely in the past, the subsequent pregnancy will be fraught with anxiety. Your screening and instructions to the woman, if done appropriately, may decrease this anxiety. You should attempt to make her feel that she has some degree of control over and contribution to make to the situation. You can do this by trusting her suspicions and her reports of her observations of any important changes. Your being available by telephone to allay fears or review her uneasiness about what she is feeling will help her to feel that she is a valued participant in her care.

Midwifery management of progressive preterm labor to birth is conducted in collaboration with the consulting physician. Every decision should have the goal of avoiding fetal asphyxia and trauma. Management involves the following:

1. Deciding on the route of birth. This decision is based on the fetal presentation and gestational age.

2. Deciding on the type of analgesia and anesthesia. Narcotics, ataractics, and sedatives should not be used prior to delivery. Pudendal block or local infiltration should be used for episiotomy and repair; or, *if necessary*, a woman may have an epidural for comfort and control. Maternal hypotension from epidural anesthesia can be lessened by adequate preloading with crystalloid intravenous fluids. However, if the woman received one of the betamimetic drugs for tocolysis, the increased risk for pulmonary edema must be kept in mind.
3. Monitoring the fetus. A preterm baby has less reserve with which to tolerate the stresses of labor. Careful monitoring is also necessary for picking up tachycardia as a sign of intrauterine infection, especially if the membranes are ruptured or if still under the effect of a betamimetic drug.
4. Carefully weighing the usefulness of internal electronic fetal monitoring against the dangers involved in the application of the scalp electrode. The preterm fetus has wider fontanels and a different skull bone density and consistency than a term fetus. The decision to use internal fetal monitoring must be based on a real need for internal electronic fetal monitoring and on gestational age.
5. Deciding whether an episiotomy is needed. The need for an episiotomy depends on the estimated fetal weight and the relaxation of the woman's perineum.
6. Arranging for the pediatrician/neonatologist to be notified and present for the birth.
7. Consideration of the benefit of delayed cord clamping versus the need to hand the baby over to neonatal specialists. A workable compromise is to hold the baby in a warm blanket below the level of the introitus (this speeds the transfer of fetal blood from the placenta to the infant) for 30 to 45 seconds before cutting the cord [45, 46].
8. Making provisions for keeping the baby warm and for transporting the baby if necessary if the birth did not take place in a Level III hospital. Neonatal mortality is reduced if birth takes place in a tertiary hospital. If at all possible, it is better to transport the mother if this can be done safely prior to birth than to transport the baby after birth.

Premature Rupture of the Membranes

Premature rupture of the membranes (PROM) may be technically defined as rupture of the membranes prior to the onset of labor, regardless of gestational age. In practice and in research, however, premature rupture of the membranes is defined in accord with the number of hours that elapse from the time of rupture until the onset of labor. This interval is called the latent period and may last anywhere from 1 to 12 or more hours. The absence of a uniformly accepted method of establishing the diagnosis of premature rupture of the membranes makes comparison of studies difficult and results in the lack of a standard operational definition. The incidence of premature rupture of the membranes is 2.7 percent to 17 percent, depending on the length of the latent period used in making the diagnosis. Premature rupture of the membranes prior to term is called preterm premature rupture of the membranes (PPROM). Rupture of the membranes more than 24 hours before delivery is called prolonged rupture of the membranes.

The incidence of premature rupture of the membranes is higher in women with incompetent cervix, polyhydramnios, fetal malpresentation, multiple gestation, or vaginal/cervical infection (e.g., bacterial vaginosis, trichomonas, chlamydia, gonorrhea, Group B Streptococcus). A significant relationship also has been found between occupational fatigue and an increased risk of *preterm* premature rupture of membranes among nulliparous women (but not multiparous women) [47]. Possible complications resulting from premature rupture of the membranes include preterm labor and delivery, intrauterine infection, and umbilical cord compression secondary to prolapsed umbilical cord or oligohydramnios.

Since the risk of intrauterine infection (chorioamnionitis) is increased with rupture of the membranes, it is important for the midwife to make an accurate diagnosis without increasing the risk of infection. Leakage of amniotic fluid has to be differentiated from urinary incontinence, vaginal or cervical discharge, semen, or (rarely) rupture of the chorion. The following data are used to make a diagnosis:

1. History
   a. Amount of fluid loss: rupture of the membranes may initially cause a large gush of fluid followed by a continuous discharge. In some instances of ruptured membranes, however, the only symptoms the woman notices may be a small, continuous discharge (clear, cloudy, yellow, or green) and a feeling of moistness on her panties.
   b. Inability to control leakage with Kegel exercises: differentiates PROM from urinary incontinence.

   c. Time of rupture.
   d. Color of fluid: amniotic fluid can be clear or cloudy; if meconium stained the fluid will be yellow or green.
   e. Odor of fluid: amniotic fluid has a distinct musty odor, which differentiates it from urine.
   f. Last sexual intercourse: semen expelled from the vagina can sometimes be mistaken for amniotic fluid.
2. Physical examination: do an abdominal palpation to ascertain amniotic fluid volume. When there is a frank rupture of the membranes, it is possible to detect the decrease in fluid because there is increased molding of the uterus and abdominal wall around the fetus and decreased ballottability compared to examination findings before rupture of the membranes. Leaking membranes do not give these same changes in abdominal findings.
3. Sterile speculum examination
   a. Inspect the external genitalia for signs of fluid.
   b. Visualize the cervix for a flow of fluid from the os
   c. Visualize pooling of amniotic fluid in the vaginal vault
   d. If you do not see any fluid, have the woman bear down (Valsalva maneuver). Alternatively, exert gentle fundal pressure or gently elevate the presenting part abdominally to allow fluid to pass by the presenting part in the event of a high leak so you can observe any leaking fluid.
   e. Observe any fluid for the presence of lanugo or vernix caseosa if the pregnancy is greater than 32 weeks' gestation.
   f. Visualize the cervix to estimate dilatation if vaginal examination is not going to be done.
   g. Visualize the cervix for prolapsed cord or fetal extremities.
4. Laboratory tests
   a. Positive fern test: ferning, also called arborization, on a microscope slide is caused by the presence of sodium chloride and protein in amniotic fluid. (During the sterile speculum examination, use a sterile cotton swab to obtain a specimen either of the fluid from the posterior vaginal fornix or of the fluid exuding from the cervical os, but be careful not to get into or touch the os itself as cervical mucus will also fern, although with a slightly different pattern. Smear the specimen on a microscope slide and allow to dry thoroughly for at least 10 minutes [48]. Inspect the slide under a microscope for a fern pattern. See Figure 29-1.)
   b. Positive nitrazine paper test: this mustard-gold pH-sensitive paper will turn dark blue in the presence of alkaline material. The normal pH of the vagina is ≤4.5. During pregnancy there is an increased amount of vaginal secretion from exfoliated epithelium and bacteria, mostly *Lactobacillus*, which makes the pH of the vagina even more acidic. The pH of amniotic fluid is 7.0 to 7.5. (Place a piece of nitrazine paper against the blade of the speculum after withdrawing the speculum from the vagina.)

      The fern test is more reliable than the nitrazine paper test. This is because a number of materials besides amniotic fluid have a more alkaline pH, including cervical mucus, vaginal discharge caused by bacterial vaginosis or trichomonal infection [49, p. 25], blood, urine, semen, and glove powder. Thus, a specimen taken directly from the cervical os and then smeared on nitrazine paper may produce a false-positive color change.

      Ultrasound for oligohydramnios may be helpful if the preceding measures do not give a clear picture of ruptured membranes. Other causes of oligohydramnios, however, need to be ruled out and you need to remember that a woman can have ruptured membranes and still have a normal amount of amniotic fluid, especially if the membranes are only leaking.
   c. Specimens for Group B Streptococcus (GBS) culture: if the woman was screened for GBS between 35 and 37 weeks and a negative culture result within the previous 5 weeks is on record, then another set of specimens for culture do not need to be obtained and antibi-

FIGURE 29-1 Fern pattern of amniotic fluid.

Source: Reproduced with permission by the College of American Pathologists.

otic prophylaxis is not indicated [50]. If GBS culture was not done or the results are not known and the woman is at term, then collection of specimens for GBS culture is not indicated but antibiotic prophylaxis is given if rupture of the membranes lasts 18 hours or more before delivery or the woman has a temperature of ≥100.4°F [50]. If the woman is less than 37 weeks' gestation and GBS culture either has not yet been done or the results are not yet known, then vaginal and rectal specimens should be taken for GBS culture and, unless it is obvious that preterm labor and delivery will be averted, antibiotics started until results are known [50]. (See section on GBS later in this chapter.)

The earlier an examination is performed after the rupture occurs, the easier it is to diagnose ruptured membranes. When more than 6 to 12 hours pass, many of the diagnostic observations become unreliable because of lack of fluid. Observation of fluid coming from the cervical os is diagnostic of ruptured membranes. In the absence of direct visualization of fluid from the os, a history strongly suggestive of rupture, with a positive fern test, is diagnostic.

The incidence of chorioamnionitis (see next section in this chapter) increases in direct relationship to the number of pelvic examinations performed. Therefore, the fewer examinations performed, the less risk there is of chorioamnionitis developing. For example, the palpation of forewaters does not preclude the existence of ruptured membranes with a high leak. A digital examination during the initial examination, therefore, only exposes the woman to an unnecessary increase in risk of infection. In preparing your plan of management, remember that 80 to 85 percent of women of all gestations with premature rupture of the membranes will be in labor within 24 hours. Another 10 percent will be in labor within 72 hours. This leaves 5 percent whose latent period will be longer than 72 hours. The infection rate in the first 24 hours for pregnancies of 37 to 42 weeks' gestation has been reported variously from 1.6 percent to 29 percent depending on race, socioeconomic factors, receipt of prenatal care, and gestational age. In term pregnancies, there is an increase in the incidence of intrapartal fever if the latent period from rupture of membranes to onset of labor is more than 24 hours. If this latent period is in excess of 72 hours, there is a significant increase in perinatal mortality. In pregnancies of less than 37 weeks' gestation, however, the rates vary according to gestational age, and the risks associated with prematurity are much greater than the risk of infection following premature rupture of the membranes.

The ongoing debate over management options [51] emanates from this information. One management option is to accomplish delivery within 24 hours of rupture of the membranes, since after this is the time of greater risk. The cesarean section rate for women at term who are induced in order to effect delivery in 24 hours is between 30 and 50 percent. Since most women at term will go into spontaneous labor within the first 24 hours after rupture of the membranes, another management option is to await the onset of spontaneous labor while observing the woman closely for signs and symptoms of chorioamnionitis (expectant management).

With either management option, an initial digital examination to determine cervical dilatation is unnecessary, since knowledge of the cervical findings is superfluous to the management. If the plan is to induce labor in order to effect delivery within the first 24 hours after rupture, the digital examination can be done at the time of induction. The presenting part can be determined by ultrasound if you are unsure of your findings from abdominal palpation. In the presence of a breech presentation, the importance of digital examination for prolapsed umbilical cord is probably greater than the risk of infection. If the fetal heart rate pattern is abnormal, a vaginal examination to rule out cord prolapse is warranted.

When the management plan is to deliver the woman within 24 hours of rupture of the membranes, a 12-hour leeway is usually given for the woman to enter spontaneous labor before oxytocin induction is started. During these 12 hours, other methods of inducing labor are used (see Chapter 25), such as having the woman drink castor oil (2 oz), nipple stimulation, rupture of forewaters, or all of these. Sexual intercourse is contraindicated because of the premature rupture of membranes. If the cervix is not ripe, preinduction cervical ripening may be indicated. Discuss the situation with your consulting physician.

In either management option the management of labor care is the same as any other labor, with the following additions:

1. Assess temperature and pulse every 2 hours. Maternal chills often precede an elevated temperature.
2. Conduct fetal heart rate monitoring. Checking the fetal heart rate every hour prior to the onset of labor is adequate as long as the heart rate is normal. Closer monitoring of the fetal heart

rate with continuous electronic fetal monitoring is done during oxytocin induction for evidence of fetal distress due to cord compression or the induction. Tachycardia may be indicative of intrauterine infection.

3. Avoid unnecessary vaginal examinations.
4. When doing an absolutely necessary vaginal examination, also note the following:
   a. whether the vaginal walls are unusually warm (hot) to touch
   b. the odor of the discharge or fluid on your gloves
   c. the color of the discharge or fluid on your gloves
5. Pay even more scrupulous attention to hydration in order to have a clear picture of any developing infection. There is often a temperature elevation with dehydration.

If the woman is at least 36 weeks and not in labor and the chosen management option is to await the onset of spontaneous labor regardless of the number of hours that have elapsed since rupture of the membranes, expectant management of the woman at home may be appropriate. To be managed at home, a woman should have no compounding medical or obstetrical risk factors, including malpresentation or unengaged cephalic presentation. She must be able to take her own temperature and read a thermometer; understand and be able to implement the restrictions regarding pelvic rest; have a telephone and access to transportation; and have someone with her for support, to do the cleaning, and to run errands outside the house.

Regardless of the management option, monitoring for signs and symptoms of chorioamnionitis is imperative. A presumptive diagnosis of chorioamnionitis is made when the woman has premature rupture of membranes and a temperature of 38°C (100.4°F) or greater with no obvious cause for the temperature. Foul-smelling purulent amniotic fluid gives a definitive diagnosis of chorioamnionitis.

Maternal temperature and pulse are taken every 4 hours (including at night). Although the definition of febrile morbidity is a temperature elevation to 38°C (100.4°F), a woman with a slowly rising temperature should be carefully observed and the midwife should initiate active management geared toward getting her delivered before she reaches true febrile morbidity.

After an initial extensive continuous electronic fetal heart monitoring, the fetal heart tones should be taken every 4 hours when the woman is in the hospital. Fetal tachycardia (160 beats per minute or greater) is a relatively good indication of possible chorioamnionitis. Nonstress tests and/or biophysical profiles are done every 2 days to weekly (varies with clinicians) to assess fetal well-being, oligohydramnios, and cord compression from oligohydramnios and to predict possible or subclinical chorioamnionitis. For example, a biophysical profile that includes a nonstress test might be done weekly with a nonstress test done midweek. If a woman has a biophysical profile score greater than 6 (Manning criteria), it is unlikely that she has an intrauterine infection.

The woman should be evaluated daily for uterine tenderness; she can do this herself. Uterine tenderness prior to delivery, however, is a difficult sign to rely on, because it is so variable and unpredictable and mimicks uterine contractions.

A white blood cell count with differential should be done daily or every other day. An elevated maternal white blood cell count, especially when accompanied by a shift to the left in bands, indicates an infectious process. An elevated white blood cell count is a late sign of chorioamnionitis because it is possible to have an early infectious process without an elevation in white blood cells.

It must be emphasized again that you should *not* do a vaginal examination, as the risk of chorioamnionitis drastically multiplies with vaginal examination. For this same reason the woman should be advised to observe pelvic precautions—no vaginal therapeutics, no douches, no sexual intercourse.

When a pregnancy less than 36 weeks' gestation is complicated by premature rupture of the membranes, the risk of sepsis is outweighed by the risks of prematurity, which is the primary cause of perinatal morbidity and mortality in this gestational age group. Management of care has the primary purpose of prolonging the pregnancy as long as the woman is not in labor, does not have chorioamnionitis, and there is no fetal distress. Administration of antibiotics to women with preterm premature rupture of the membranes for a week or more has been associated with prolonging pregnancy and a reduction in the rate of clinical chorioamnionitis and neonatal sepsis. These benefits do not occur if the membranes are intact [21, 52]. In preterm premature rupture of the membranes, especially if it occurs at less than 26 weeks of gestation, fetal lung hypoplasia and fetal deformities may occur secondary to oligohydramnios.

The management of women with preterm premature rupture of the membranes is to await the onset of spontaneous labor while observing for signs and symptoms of chorioamnionitis. Vaginal and rectal specimens for GBS culture should be obtained during the initial examination if not already done in this pregnancy. Cervical os specimens for gonorrhea and chlamydia should be obtained with sterile supplies during the initial sterile speculum examination. Specimens for GBS culture are obtained again in four weeks if birth has not yet occurred [50]. These women are usually admitted to the hospital and restricted to bed rest. Prophylactic amnioinfusion in the presence of oligohydramnios may be considered to prevent cord compression (see Chapter 64). In the event that there is no further leakage of amniotic fluid, the presentation is vertex, and there are no signs or symptoms of chorioamnionitis, the woman may be followed at home. She should be placed on pelvic precautions and bed rest, instructed in the principles of good hygiene, and instructed about return visits for the necessary screening tests for chorioamnionitis. She will need to return to the hospital at least weekly for a biophysical profile. She will also need to be seen for routine prenatal care. Arrangements can be made to have her blood drawn at home for the more frequent blood tests.

Preterm rupture of the membranes can create anxiety for the woman and her family. The midwife should help the woman explore fears accompanying the anticipated birth of a premature infant as well as the added risk of chorioamnionitis. The plan of management involving a possible prolonged period of bed rest and hospitalization should be discussed with the woman and her family. Their understanding and cooperation are important to the continuation of the pregnancy.

A digital vaginal examination increases the risk of infection and is not necessary for women with preterm rupture of the membranes, since these women will be managed expectantly until labor ensues or there are signs or symptoms of chorioamnionitis. If the woman develops signs or symptoms of chorioamnionitis, immediate consultation with your consulting physician is indicated for induction of labor and delivery. The choice of delivery method (vaginal or cesarean section) depends on the gestational age, presentation, and the severity of the chorioamnionitis.

At the time of birth appropriate cultures should be obtained, including cultures of the uterus, both maternal and fetal sides of the placenta, the umbilical cord, and a gastric aspirate from the newborn. Some pediatricians also culture the baby's skin or ears or both. Whether the pediatrician should be present at delivery depends on the length of time the membranes have been ruptured, the absence or presence of infection, the gestational length of pregnancy, and the protocol of the department of pediatrics at the particular institution. The perinatal mortality rate for all gestational ages when there is premature rupture of the membranes is 2.6 to 11 percent.

Amnionitis and Chorioamnionitis

Amnionitis is inflammation of the amniotic sac and amnion. Chorioamnionitis is inflammation of the chorion in addition to the amnion and amniotic sac. These conditions almost always coexist.

Amnionitis and chorioamnionitis most often result when there has been prolonged rupture of the membranes (over 24 hours), with or without prolonged labor, with repeated vaginal examinations or manipulative vaginal or intrauterine procedures. Amnionitis and chorioamnionitis may also infrequently occur in women with intact membranes, for unknown reasons. The organisms most often associated with chorioamnionitis and subsequent infection of the fetus after rupture of the membranes are Group B Streptococci, *Escherichia coli*, *Ureaplasma urealyticum*, *Fusobacterium species*, and *Mycoplasma hominis* [21, 52].

Both the mother and the baby will be infected, and each will suffer further resulting complications. The mother's uterine contractility is adversely affected—the uterus does not contract as well, which may lead to labor dystocia from uterine dysfunction and abnormal cervical dilatation; nor does the uterus respond as well to oxytocin. The infected woman has the potential for being very sick both intrapartally and postpartally (see Chapter 44). The infant may develop life-threatening intrauterine pneumonia and acidosis. Chorioamnionitis has also been identified as a risk factor for both cerebral palsy and cystic periventricular leukomalacia [53].

Signs and symptoms of amnionitis and chorioamnionitis are as follows:

1. Maternal fever
2. Maternal tachycardia
3. Fetal tachycardia
4. Tender uterus

5. Vaginal walls unusually warm (hot) to touch
6. Foul-smelling, purulent amniotic fluid
7. Elevated white blood cell count

After the birth the following additional information is available that is indicative of infection: steamy translucence of the umbilical cord and fetal membranes and the presence of polymorphonuclear leukocytes in smears of gastric aspirate from the baby and of the chorionic surface of the amnion. The infant most likely will have an Apgar score below 7 and may have hypothermia. On the other hand the baby may have high Apgar scores and then crash 10 to 25 minutes after birth. Continued close observation of the baby during the first hour after birth is imperative.

Intrapartal management of the woman with amnionitis or chorioamnionitis has the primary goals of birth of the baby and treatment of the infection. These goals are achieved through collaboration with your consulting physician. Labor management of a term pregnancy complicated with chorioamnionitis may include the following:

1. Facilitation of birth: Induced vaginal delivery or cesarean section should take place within 24 hours of diagnosis. Cesarean section may be indicated if the maternal or fetal condition is worsening, or if labor dystocia is not helped by oxytocin. A cesarean section is not done just because of chorioamnionitis.
2. Oxytocin induction or augmentation to shorten the latent phase of labor.
3. Rupture of forewaters if present.
4. Internal electronic fetal monitoring.
5. Hydration with intravenous fluids (e.g., 5% dextrose in Ringer's lactate).
6. Monitoring of maternal vital signs every hour.
7. Notification of the pediatrician.

If birth is expected within 1 or 2 hours, intravenous antibiotic therapy for the mother may be delayed until immediately after delivery. This delay is advisable because the antibiotics given the mother will interfere with the pediatrician's ability to identify the causative infecting agent in the newborn. Otherwise, the mother should be treated with antibiotics during labor to initiate treatment to both the mother and the baby and decrease the neonatal sepsis rate [54, 55]. Choice of antibiotics and dosage varies according to protocol and whether GBS is identified. In this event, the broad spectrum antibiotic regimen for chorioamnionitis needs to include a drug known to be active against GBS [50].

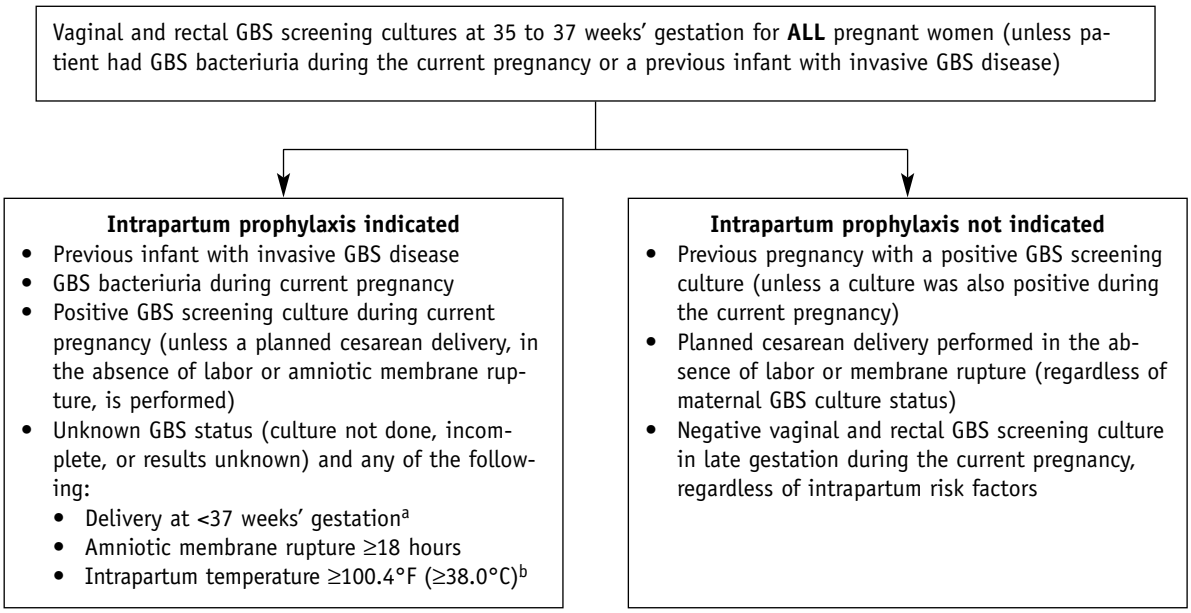
Birth may be accomplished in bed in a delivery room fully equipped for neonatal resuscitation and regulation of hypothermia. The pediatrician should be present for the birth, and appropriate cultures of the baby (gastric aspirate, skin, ears) and a cord pH should be obtained. Cultures may also be taken from the uterus, both maternal and fetal sides of the placenta, and the umbilical cord. Intravenous antibiotic therapy is continued for the mother until her symptoms of infection subside and her temperature is normal for more than 24 to 48 hours, after which she may be given oral antibiotics.

Group B Streptococcus

Group B streptococcus (GBS) is a beta-hemolytic gram-positive bacteria that is commonly found in the intestinal tract [56]. Approximately 10 to 30 percent of pregnant women have vaginal or rectal colonization of GBS. Intrauterine infection is the result of an ascending infection from vaginal colonization of GBS in the pregnant woman. GBS can cause chorioamnionitis, endometritis, urinary tract infections, and wound infections, and it has been implicated in preterm labor/delivery and in premature rupture of the membranes. In the newborn, early-onset disease with GBS is the leading cause of neonatal morbidity and mortality including sepsis, meningitis, and pneumonia. Early-onset disease is defined as within the first week of life. The newborn can become infected in utero or during passage through the birth canal. Vertical transmission from mother to baby primarily occurs after the onset of labor or after the membranes rupture [50]. A positive fetal fibronectin (fFN) test not only is the best predictor of spontaneous preterm labor but also has a strong association with subsequent chorioamnionitis and neonatal sepsis [21].

Prevention of early-onset GBS disease is through universal screening and intrapartum antibiotic prophylaxis. Universal screening at 35 to 37 weeks' gestation and collection of specimens for GBS testing for vaginal and rectal colonization was discussed in Chapter 22, pages 583–584. Figure 29-2 outlines which pregnant women are and are not indicated to receive intrapartum antibiotic prophylaxis. Note the following:

1. A previous pregnancy with a positive GBS screening culture does not automatically mean that a woman should receive intrapartum an-



[a] If onset of labor or rupture of amniotic membrances occurs at <37 weeks' gestation and there is a significant risk for preterm delivery (as assessed by the clinician), a suggested algorithm for GBS prophylaxis management is provided (Figure 29-3).

[b] If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

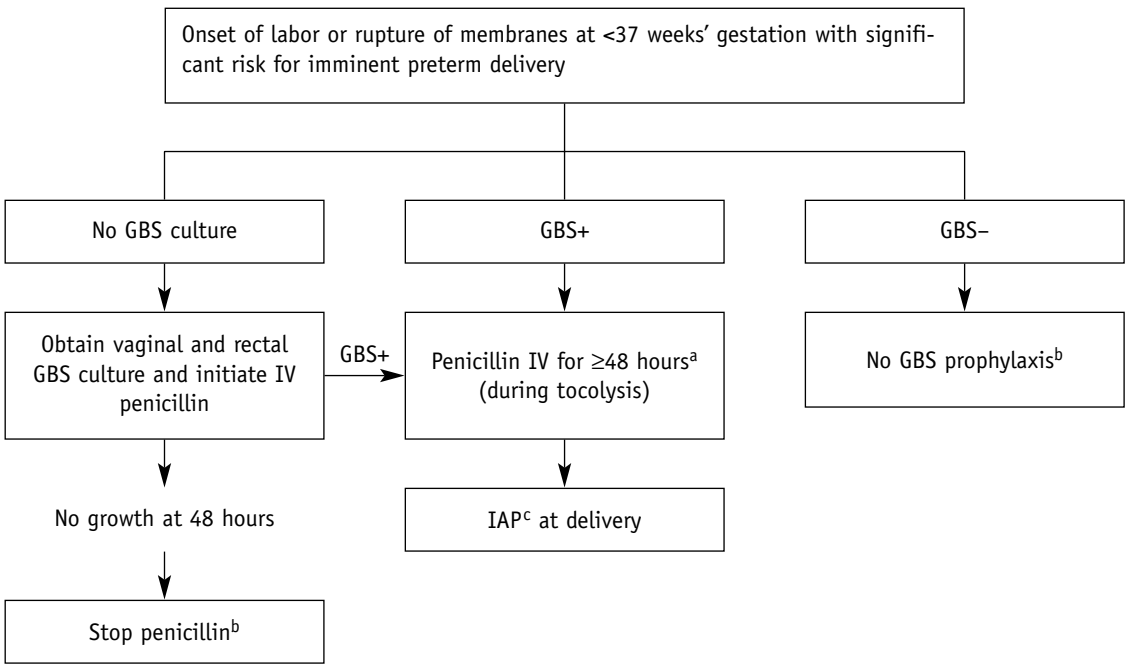
FIGURE 29-2 Indications for intrapartum antibiotic prophylaxis to prevent prenatal GBS disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35 to 37 weeks' gestation from all pregnant women.

Source: From Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease. *MMWR* (No. RR-11) 4:8 (August 16) 2002.

tibiotic prophylaxis with this pregnancy unless she again has a positive screening test [50].

2. A woman who had a previous baby with GBS disease should, however, automatically receive intrapartum antibiotic prophylaxis with this pregnancy and does not need to be screened at 35 to 37 weeks' gestation [50].
3. There are three risk factors that effect decisions about intrapartal antibiotic prophylaxis. These are: (1) delivery at less than 37 weeks' gestation, (2) rupture of the membranes for 18 hours or more, and (3) maternal temperature of 100.4°F (38.0°C) [50].
   a. If any one of these risk factors exist and the woman's GBS status is not known, she should receive intrapartal antibiotic prophylaxis [50].
   b. If the woman's GBS screening test was within the past 5 weeks and is negative, intrapartal antibiotic prophylaxis is not indicated [50].
   c. If the onset of labor or rupture of membranes occurs at less than 37 weeks' gestation and preterm delivery of less than 37 weeks is likely, the midwife should determine whether or not to administer intrapartal antibiotic prophylaxis. Figure 29-3 provides a possible algorithm that can be used [50].
4. A woman with GBS bacteriuria during this pregnancy should receive intrapartal antibiotic prophylaxis. She does not need to be screened at 35 to 37 weeks' gestation [50].
5. A woman who is having a planned cesarean section still needs to be screened at 35 to 37 weeks so her GBS status will be known and she can be treated accordingly in the event she starts labor or her membranes rupture prior to the cesarean birth. If her GBS test is positive but the cesarean section is performed before either starting labor or her membranes rupture, she is at low risk for having a baby with early-onset GBS disease and does not need intrapartal antibiotic prophylaxis [50].

The regimens for intrapartal antibiotic prophylaxis are given in Table 29-2. As penicillin is the drug of choice, alternate regimens are also given for women who are allergic to penicillin.



[a] Penicillin should be continued for a total of at least 48 hours, unless delivery occurs sooner. At the physician's discretion, antibiotic prophylaxis may be continued beyond 48 hours in a GBS culture-positive woman if delivery has not yet occurred. For women who are GBS culture positive, antibiotic prophylaxis should be reinitiated when labor likely to proceed to delivery occurs or recurs.

[b] If delivery has not occurred within 4 weeks, a vaginal and rectal GBS screening culture should be repeated and the patient should be managed as described, based on the result of the repeat culture.

[c] Intrapartum antibiotic prophylaxis.

FIGURE 29-3 Sample algorithm for GBS prophylaxis for women with threatened preterm delivery. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate.

Umbilical Cord Prolapse

Prolapse of the umbilical cord is a disaster requiring prompt and knowledgeable diagnosis and action on the part of the midwife while awaiting the arrival of the physician for final resolution of the problem by cesarean section.

There are two types of umbilical cord prolapse: frank and occult. In frank cord prolapse the cord slips through the cervix. In occult cord prolapse the cord slips down alongside the presenting part but does not protrude through the cervix. The danger in either type of cord prolapse is fetal hypoxia resulting from compression of the cord between the presenting part and the pelvis. Frank prolapse of the cord can occur without threatening life when there is a transverse lie or footling breech, because there is no compression of the cord. The route of delivery, however, is the same (cesarean section).

The precipitating causes of cord prolapse include the following:

1. Ruptured membranes and a breech presentation, compound presentation, transverse lie, small fetus (less than 2000 grams), or second-born twin [57]. Multiple gestation, preterm labor, and an excessively long umbilical cord are predisposing factors.
2. Adminstration of an enema if the membranes are ruptured and the presenting part is an unengaged head, a compound presentation, an unengaged breech or footling breech, or a shoulder
3. Amniotomy if there is an unengaged head, a compound presentation, a noncephalic presentation, or a small fetus whose presenting part (either cephalic or breech) does not fill the pelvis
4. Vaginal examination causing inadvertent rupture of the membranes in the presence of tense, bulging membranes and an unengaged head, a compound presentation, or noncephalic presentation
5. Spontaneous rupture of the membranes with an unengaged head, compound presentation, or noncephalic presentation
6. Displacement of the vertex during fetal assessment or obstetric manipulation (e.g., manual rotation of the head; placement of forceps other

TABLE 29-2 Recommended Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease Prevention[a]

Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 million units IV every 4 hours until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hours until delivery
If penicillin allergic[b]	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery
Patients at high risk for anaphylaxis[c]	
GBS susceptible to clindamycin and erythromycin[d]	Clindamycin, 900 mg IV every 8 hours until delivery OR Erythromycin, 500 mg IV every 6 hours until delivery
GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin,[e] 1 g IV every 12 hours until delivery

[a] Broader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis.

[b] History of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with beta-adrenergic-blocking agents.

[c] If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis.

[d] Resistance to erythromycin is often but not always associated with clindamycin resistance. If a strain is resistant to erythromycin but appears susceptible to clindamycin, it may still have inducible resistance to clindamycin.

[e] Cefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intra-amniotic concentrations. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

than outlet forceps; fetal scalp electrode application; attempted external cephalic version; intrauterine pressure catheter insertion) [58]

Any time the membranes rupture, your first action should be to check the fetal heart and then to perform a vaginal examination to feel for a prolapsed cord. A thorough vaginal examination includes not only feeling around the presenting part, the cervical edge at the juncture of the presenting part and the external cervical os, and in the vagina for a frank cord but also completely checking each of the vaginal fornices and feeling around and through the thinned-out lower uterine segment to palpate for an occult cord. Sometimes you will feel the cord in the vagina. At other times you may be summoned by auxiliary personnel or signicant others because "something came out between her legs." Vaginal examination will differentiate a cord from a mucus plug, a prolapsed foot, or a prolapsed arm.

The following actions are taken in the presence of a prolapsed cord:

1. Place your entire hand into the woman's vagina and hold the presenting part up off the umbilical cord at the pelvic inlet
2. Do not under any circumstances attempt to replace the cord—you won't be able to replace it, manipulation may cause cord spasm, and you may accidentally cause further cord compression.
3. Inform the woman of what has happened and elicit her cooperation.
4. Summon help. Warn the woman and, if necessary, yell to get attention and bring people to help.
5. Have your consulting physician be given a *STAT* call.
6. Direct others to get the woman into a position in which gravity will aid in keeping the baby away from the pelvic inlet and pressing on the cord: knee-chest or Trendelenburg position.
7. If the cord is protruding from the vagina, direct others to wrap it loosely with gauze soaked with warm normal saline.
8. Do not palpate for or rely on cord pulsations as an indicator of fetal life or well-being.
9. Ultrasound can be used to detect fetal heart movement if fetal heart tones cannot be heard.
10. Direct others to prepare for an emergency cesarean section.
11. Do not under any circumstances remove your hand from the woman's vagina or from the presenting part until the baby is delivered (probably by cesarean section).

Your first action is the one that will save the baby's life. Thereafter, you are inextricably joined to the mother until the baby is delivered and you can

safely remove your hand from the woman's vagina. This will call for some gymnastics, physical discomfort, and unusual positions on your part as you accompany the woman from wherever she is to the operating room, is prepared for surgery (you are under the drapes now), and the baby is born. Then you can remove your hand from the mother's vagina.

An alternative method can be used with an *unengaged* presenting part. This method is to insert a #16 Foley catheter, fill the bladder with 500 cc of sterile water or normal saline, and clamp the catheter while your hand is in the vagina displacing the fetal head off the umbilical cord. The full bladder then displaces the presenting part and alleviates the cord compression. This technique can also be used when the presenting part is engaged if the woman is a multipara. It will be necessary, however, for you to displace the presenting part out of the pelvis with your hand before filling the bladder. Pressure on the presenting part should be evenly distributed during this maneuver. Once the bladder is filled you should again check the woman vaginally to determine that the presenting part is indeed displaced. The fetal heart should be continually electronically monitored. If bradycardia recurs, reinsert your hand into the vagina to ensure that the fetal head is off the cord. Some physicians combine filling the bladder with an intravenous infusion of 50 mg ritodrine in 500 mL of D_5W [59] or 0.25 mg terbutaline sulfate subcutaneously [60] to stop the uterine contractions. The ritodrine is then discontinued before induction of anesthesia and the bladder is emptied prior to opening the peritoneal cavity during the cesarean section.

Cephalopelvic Disproportion

Cephalopelvic disproportion (CPD), or fetopelvic disproportion, is a disproportion between the size of the fetus and the size of the pelvis, in which a particular pelvis is not large enough to accommodate passage of a particular fetus through it to vaginal birth. The determination of CPD is relative. A pelvis that is adequate for passage of a 5-pound baby may not be large enough for passage of a 7-pound baby, or a pelvis large enough for a 7-pound baby may not be large enough for an 8-pound baby. Therefore, the adequacy of the pelvis must be evaluated in relation to the particular fetus that is to pass through it.

Evaluation of the bony pelvis and the types of pelves are discussed in Chapter 61. The discussion includes the findings that indicate pelvic adequacy as well as the normal average lengths of the diameters of the pelvis. No single finding determines adequacy or inadequacy. Rather, the total pelvis (its measurements, architecture, shape, and various dimensions) should be taken into account in relation to the fetus (its size, presentation, position, variety, and normality).

The following may indicate the possibility of cephalopelvic disproportion:

1. Excessively large fetus
2. The woman's general body type and specific characteristics [61]:
   a. shoulders wider than hips, regardless of height
   b. short, square stature
   c. short, broad hands and feet (shoe size is informative)
3. History of pelvic fracture
4. Spinal deformity, for example, scoliosis or kyphosis (note posture)
5. Unilateral or bilateral lameness (observe for limp and for marked lordosis)
6. Other orthopedic deformities—for example, rickets, pinned hip
7. Platypelloid pelvis
8. Malpresentation or malposition
9. Dysfunctional labor, such as failure to progress and uterine dysfunction

The midwife initially evaluates a woman's pelvis during her first antepartal visit and again on entry into labor. Any question the midwife has of the possibility of cephalopelvic disproportion is noted on the woman's chart for reevaluation on entry into labor. Clinical pelvimetry should again be performed when you first see the woman in labor to detect a truly contracted pelvis in relation to the actual size of this baby, and to anticipate where delay in descent and rotation might occur. Therapeutic measures, such as changes in maternal position, can then be initiated early enough to facilitate the mechanisms of labor.

Engagement and descent usually occur predominantly in the posterior pelvis and are associated with normal progressive labor and vaginal birth. The cervix is usually felt posteriorly in the vagina. There is a higher incidence of abnormal labor and operative delivery when engagement and descent is predominantly in the forepelvis and the cervix is in an anterior or forward position in the vagina [62, p. 542].

It is quite unusual to find a pelvis so severely contracted that labor is absolutely contraindicated.

The only true test for cephalopelvic disproportion is a trial of labor. If the pelvis is obviously contracted to the point that it is only adequate for delivery of an extremely small fetus, discuss planning a possible cesarean section with your consulting physician.

All women who have failure to progress or an arrest of labor should be evaluated for cephalopelvic disproportion. This evaluation includes the following:

1. Abdominal palpation to determine fetal lie, presentation, position, flexion, engagement and station of the presenting part, and estimated fetal weight. (A common clinical phenomenon occurs in estimating the fetal weight in an arrested labor: the longer the arrest, the larger the baby seems to become when the clinician is estimating the fetal weight. Usually, your initial estimation before the arrest is the most accurate, since it carries the least situational bias.)
2. Assessment of uterine contractions for frequency, duration, intensity, and changes in uterine activity from what was previously noted. A dysfunctional labor pattern is often seen in a labor complicated by CPD.
3. Pelvic examination to evaluate position of the presenting part, engagement, station, degree of flexion, synclitism/asynclitism, formation and degree of caput, molding, and progress or lack thereof in cervical dilatation and descent of the presenting part.
4. Clinical pelvimetry to determine where in the pelvis the disproportion is occurring

Cephalopelvic disproportion may be evidenced by a dysfunctional labor pattern, failure to progress, poorly flexed head, or an arrest of internal rotation and descent (i.e., deep transverse arrest [see next section]). Cephalopelvic disproportion may or may not be accompanied by the formation of caput and molding. Dysfunctional labor caused by cephalopelvic disproportion may result in the following tragedies:

1. Fetal damage—for example, brain damage
2. Fetal or neonatal death
3. Intrauterine infection
4. Uterine rupture
5. Maternal death

Suspected CPD should be discussed with your consulting physician. The primary management plan when CPD is a possibility is careful evaluation of the woman's pelvis and contractions and her fetus as detailed above, a trial of labor, efforts to maximize maternal pelvic space with positioning that matches this particular pelvic architecture with the way this particular fetus is coming through the pelvis [63], avoiding maternal exhaustion (see section later in this chapter), careful monitoring of fetal well-being, and calling for the cesarean section if there is evidence that the baby is poorly tolerating the effort to get through the pelvis or there is a combination of failure to progress, arrested labor, and hypotonic uterine dysfunction along with suspected CPD before deep transverse arrest occurs. Remember that the goal is a healthy baby and a healthy mother—not a damaged baby and a grief-stricken traumatized mother. There are times when obstetric heroics with forceps or a vacuum extractor to satisfy the goal of a vaginal birth is not worth the price paid. Midwives should be just as well known for calling for a cesarean section when it is truly indicated as we are for promoting and facilitating vaginal birth.

Deep Transverse Arrest

Deep transverse arrest is associated with platypelloid and android pelvic types because of flat posterior pelvic configuration throughout the depth of these pelves. Additionally, platypelloid pelves are also flat in the forepelvis and android pelves have convergent side walls and prominent ischial spines. These factors inhibit the mechanism of labor of internal rotation which brings the sagittal suture from being in the transverse diameter to being in the anteroposterior diameter of the mother's pelvis. Careful clinical pelvimetry during the initial examination enables you to anticipate a potential problem.

A deep transverse arrest should be considered when there is a prolonged second stage. Signs and symptoms include the following:

1. Sagittal suture of the fetal head is in the transverse diameter of the mother's pelvis
2. Development of second stage hypotonic uterine dysfunction
3. Extensive molding of the fetal head
4. Formation of considerable caput succedaneum
5. Lack of descent of the fetal head

The above signs and symptoms are late indicators of deep transverse arrest. If you have identified the potential for deep transverse arrest from your initial clinical pelvimetry, you need to pay particular attention to facilitating the woman's efforts during second stage. Facilitation includes helping the

woman assume positions that promote pushing (e.g., squatting, kneeling) and making sure she enters second stage in a well-hydrated state. In order to prevent exhaustion from pushing, encourage the woman to push only with the peak of the contraction and when she feels like pushing.

It is also important to evaluate the woman's progress accurately. Extensive molding and caput formation may be misleading when evaluating station and descent. Ascertain engagement abdominally with Leopold's fourth maneuver. By vaginal examination, evaluate the degree of molding and caput, locate the parietal bones by palpating past the caput, and note whether the biparietal diameter has passed through the pelvic inlet. Also estimate the amount (depth) of caput by palpating past it to skull bone and ascertain the station of the actual lowermost part of the presenting part.

The primary management plan for deep transverse arrest is prevention when you suspect from your original evaluation of the mother's pelvis that this may be a possibility. Since deep transverse arrest and subsequent obstructed labor are manifestations of cephalopelvic disproportion, prevention of deep transverse arrest, attentive monitoring, careful evaluation, and alert management is the same as for CPD. Delay may be costly. Cesarean section at full dilatation with little amniotic fluid (most likely the membranes have ruptured either spontaneously or artificially) and an engaged head also has serious potential morbidity to both mother and baby as does augmenting labor and using forceps or a vacuum extractor [64]. A timely cesarean section before morbidity by any route of birth becomes inevitable is a far better management plan in the presence of a baby having difficulty maneuvering through a contracted pelvis.

Uterine Dysfunction

Uterine dysfunction is a diagnosis made by observing a prolongation of any phase or stage of labor beyond its expected length. It is identified by a lack of progress in cervical effacement or dilatation or in descent of the presenting part.

Uterine activity can be measured in two ways:

1. *By abdominal palpation and vaginal examination:* This is done by palpation of the contractions and determination during vaginal examination of the progress of labor as defined by progressive effacement, dilatation, and descent of the presenting part.
2. *Biophysically:* This is done by inserting an intrauterine pressure catheter to measure the frequency and pressure of each contraction at each phase and stage of labor (see Chapter 64).

Measurement of progress in effacement, dilatation, and descent—the result of effective uterine contractions—is still the most accurate way to recognize uterine dysfunction.

Uterine dysfunction may reflect a biochemical problem in the woman caused, for example, by stress, which results in alterations of endorphins and catecholamine production, which in turn affect uterine activity. Uterine dysfunction may also reflect the presence of another complication, in effect being a symptom of either cephalopelvic disproportion (e.g., pelvic contracture, hydrocephaly), fetal malpresentations and malpositions (e.g., shoulder, face), or soft-tissue dystocias such as myomata or vaginal or uterine septa. There is also some thought that a gradual and continuous aging process of the myometrium begins around age 25 and may contribute to a slower and more complicated labor process in women over the age of 35 [65].

There are two types of uterine dysfunction: hypotonic and hypertonic. They are differentiated from each other by signs and symptoms, underlying contraction physiology, when they occur in labor, and the effect of each on the mother and the fetus. The two things they have in common are that the contractions are ineffective and cervical dilatation and fetal descent are arrested.

Hypotonic Uterine Dysfunction

In hypotonic uterine dysfunction, contractions have a normal gradient pattern (greatest in the fundus and decreasing to weakest in the lower uterine segment and cervix [see Figure 26-2]) but a very poor tone or intensity (less than 15 mm Hg of pressure), which is too little pressure to dilate the cervix. In this situation the woman feels great because she has no pain and is able to rest. However, labor is prolonged, which increases the risk of maternal distress, hemorrhage, and, if the membranes are ruptured, intrauterine infection. The fetus usually experiences no distress unless the condition is allowed to go on over a long period of time and intrauterine infection develops.

The signs and symptoms of hypotonic uterine dysfunction are as follows:

1. History: contractions not currently painful; labor progressed well into the active phase of the first stage of labor or the second stage and then stopped.

2. Physical examination: contractions infrequent, of short duration and mild intensity
3. Pelvic examination: lack of progress in cervical dilatation or fetal descent (station) because the contractions are ineffective

If a problem is suspected or evident, you should do a complete assessment and discuss the situation with your consulting physician. A complete assessment consists of the following:

1. Assessment of contractions: frequency, length, interval, intensity, and changes from what was previously observed
2. Assessment for maternal exhaustion (see section later in this chapter)
3. Assessment of fetal well-being
4. Assessment of maternal environment; note any stress factors
5. Assessment of presentation, position, engagement, and station
6. Assessment for cephalopelvic disproportion: molding, caput formation, flexion, synclitism/asynclitism, and pelvic adequacy
7. Assessment of progress of labor: effacement, dilatation, and descent of the presenting part

There are various management options for a woman whose labor is complicated by hypotonic uterine dysfunction. The use of these options depends on whether other parameters are within the range of normal. These parameters, which should be evaluated before implementing a management plan, include the following:

1. Reassuring fetal heart rate pattern/absence of fetal distress
2. Clear amniotic fluid if the membranes are ruptured
3. Membranes intact or recently ruptured and absence of signs and symptoms of chorioamnionitis
4. No signs and symptoms of maternal exhaustion
5. Adequate pelvis

The management options are as follows and can be used singly or in combination:

1. Modification of the environment to decrease maternal stress.
2. Correction of maternal exhaustion and dehydration through rest and fluid intake.
3. Discussion with the woman to detect any underlying fears or concerns either for herself or as they relate to the baby or delivery. Epidural anesthesia will sometimes produce positive results if the woman's fear of pain of the birth process cannot be overcome by education, support, and communication.
4. Ambulation.
5. Hydrotherapy: shower, tub, or time in a jacuzzi; but no more than 1 to 2 hours in the tub or jacuzzi if there is no progress [66].
6. Enema: the purpose of the enema must be weighed against the following factors in making a decision about using an enema:
   a. Station/location of the presenting part: if the presenting part is unengaged or above the ischial spines, there is a risk of prolapse of the umbilical cord accompanying expulsion of the enema. The risk is less (though still present) if the membranes are intact.
   b. Whether the membranes are ruptured: if the membranes are ruptured, there is an increased risk of possible intrauterine infection. Extreme care should be taken in cleansing the perineal area following expulsion of the enema.
   c. Presence of any complications that would contraindicate an enema: examples include vaginal bleeding with suspected abruptio placentae or placenta previa (avoid bringing either of these conditions to a life-threatening crisis), preterm labor (avoid stimulating labor), breech presentation (danger of a prolapsed cord), severe preeclampsia (need for the woman to be as quiet and undisturbed as possible).

   Soapsuds enemas, because they are irritating, are thought to be more effective for stimulating labor than just warm tap water or a Fleet enema. The old "3H" enema (high, hot, and a hell of a lot) should be avoided. The water should be body temperature for comfort, the tube should be inserted the usual distance for giving an enema, and the fluid should be given gently and slowly with the tubing pinched off during any contractions. The amount can vary, with 500 to 1000 cc used for stimulating contractions, depending on the woman's tolerance.

   Someone should be with or near the woman while she is expelling the enema in case of strong expulsive contractions, rupture of the membranes, prolapse of the umbilical cord, or birth of the baby. The fetal heart tones should be checked after the enema is expelled. If this measure is effective, improved uterine activity should occur within an hour or so.
7. Rupture of membranes (see Chapter 26, p. 778). If this measure is effective, improved uterine activity should occur within 2 hours.
8. Nipple stimulation (see Chapters 23 and 25).
9. Pitocin stimulation if the above management is

unsuccessful in accomplishing progress in labor (see Chapter 25). One study showed that a high-dose oxytocin regimen—an initial 4 mU/min increased by 4 mU/min every 15 minutes until adequate uterine contractility is achieved—was more effective with fewer operative deliveries than a low-dose regimen [67].

In incorporating the above options into a management plan, you should establish an estimated time period for anticipated correction of the uterine dysfunction and communicate the plan to your consulting physician. If any of the clinical parameters are abnormal (e.g., presence of fetal distress, meconium, prolonged rupture of membranes, maternal exhaustion, malposition) immediate collaboration with your consulting physician and a more aggressive management approach is appropriate.

Hypertonic Uterine Dysfunction

In hypertonic uterine dysfunction, contractions have a distorted gradient pattern, with the midportion of the uterus contracting more forcefully than the fundus and with portions of hypertonicity throughout the uterus (see Figure 26-2). In this situation, the mother becomes literally exhausted, with an increased likelihood of maternal distress and an increased risk of infection if the membranes are ruptured and the woman has undergone repeated vaginal examinations. Fetal intolerance of labor may quickly develop from uteroplacental insufficiency caused by hypertonicity of the uterus and may result in increased perinatal and infant morbidity and mortality. As hypertonic uterine dysfunction occurs primarily during the latent phase of labor, and because a prolonged latent phase is at times difficult to distinguish from false labor, there is some thought that hypertonic uterine dysfunction may be a form of false labor. These fine delineations have not yet been clearly determined.

The signs and symptoms of hypertonic uterine dysfunction are as follows:

1. History: usually occurs in primigravidas; contractions feel excessively painful for the period of labor and the severity of the contractions by palpation; occurs early in labor during the latent phase
2. Physical examination: contractions are frequent and irregular in tonicity
3. Pelvic examination: there is a lack of progress in cervical effacement and dilatation and in fetal descent (station) because the contractions are ineffective and labor never really commences

The midwife collaborates with the consulting physician when the condition is first suspected. Management usually begins with stopping this discoordinate labor and inducing rest with a combination of morphine and a barbiturate. Most women will awaken in normal, coordinated labor.

Maternal Exhaustion (Maternal Distress; Ketoacidosis)

Maternal exhaustion (maternal distress) should be guarded against because deterioration in the woman's condition is dangerous both to her and to her unborn baby. Checking her urine for ketones, maintaining hydration from the start of labor, and being prompt about seeking physician help if labor is not progressing should prevent the development of maternal exhaustion. In other words, if the midwife is providing good management, severe maternal distress should not occur.

The signs and symptoms of maternal exhaustion/distress are as follows:

1. History: the woman feels weak, apathetic, sick, and anxious; labor is prolonged; she complains of dehydration (dry lips, dry mouth, parched throat).
2. Physical examination: the woman looks distressed and is restless; she has a rising pulse, elevated temperature, circumoral pallor, vomiting.
3. Laboratory tests: observe urine for concentration and examine it for ketones.

The midwife should already have collaborated with the consulting physician regarding abnormal length of any phase or stage of labor. Management should include correction of the fluid and electrolyte imbalance.

Uterine Rupture

Uterine rupture, fortunately, is a rare event. Etiological factors in uterine rupture encompass a number of injuries to or defects of the uterus occurring either before or during the present pregnancy. The most common causes are previous surgery to the fundus or corpus of the uterus, such as a classical cesarean section; previous removal of intrauterine myomata that invaded the myometrium; injudicious use

of oxytocin induction or augmentation of labor, especially for women of high parity; induction of labor in women with a previous cesarean section using any method but especially the use of prostaglandins [7]; and a single-layer closure of a previous lower segment incision for cesarean section [8]. Spontaneous rupture can also occur as a result of abnormal presentations, especially in the thinned-out lower uterine segment of a grand multipara.

Given the approximately 5 percent maternal mortality and the approximately 50 percent fetal mortality resulting from uterine rupture, the life of the mother and the baby may depend on the speed with which the rupture is recognized and action is taken. Therefore, everyone responsible for care of the woman during labor should be familiar with the signs and symptoms of uterine rupture and the immediate emergency steps to take.

Signs and symptoms of uterine rupture may be either dramatic or quiet. Regardless, change in the fetal heart rate pattern, especially recurrent late decelerations, may be an early sign of impending uterine rupture [68]. Late decelerations reflect uteroplacental insufficiency and can have causes other than uterine rupture. However, the fetal heart rate pattern of late decelerations due to uterine rupture are not relieved by repositioning, stopping administration of any oxytoxic, and administration of oxygen. The most ominous pattern is that of recurrent late decelerations followed by prolonged decelerations and terminal bradycardia [68, 69].

In dramatic rupture of the uterus, the woman experiences a sharp, shooting pain in her lower abdomen at the height of a severe contraction. She feels that something has given way inside of her and may cry out that "something tore." Contrary to previous teaching, uterine contractions usually do not stop [41, p. 650]. Vaginal bleeding may be observed either as a slight amount or as a hemorrhage. Findings on abdominal palpation are changed from previous findings, as follows:

1. The presenting part is now movable above the pelvic inlet.
2. There may be dramatic repositioning or relocation of the fetus in the mother's abdomen with corresponding loss of station.
3. The fetal parts are more easily palpated than before.
4. The fetal movements may become violent and then reduce to no fetal movements.
5. A round, firm (contracted) uterus may be felt beside the fetus (the fetus is felt outside of the uterus).

The woman may exhibit the signs and symptoms of shock—elevated pulse (rapid and thready); decreased blood pressure; pallor; cold, clammy skin; apprehensiveness, feeling of impending doom or death; air hunger (shortness of breath); restlessness; and visual disturbances.

In a quiet uterine rupture in which the uterus ruptures silently (without the dramatic clinical picture), the woman may or may not have some vomiting; other manifestations include increased tenderness over the abdomen, severe suprapubic pain, hypotonic uterine contractions, lack of further progress in labor, and a feeling of faintness. Eventually she will evidence hematuria, vaginal bleeding, some pain, and the signs of progressive shock from blood loss with a rising and rapid pulse rate, and pallor. The contractions may continue but they have no effect on the cervix; or no contractions may be felt. The fetal heart tones may be lost.

Signs and symptoms of uterine rupture may mimic the signs and symptoms of other catastrophes. Bleeding into the peritoneum may irritate the diaphragm and cause referred pain to the chest thus mimicking the signs and symptoms of an amniotic fluid or pulmonary embolus. Another confounding possible diagnosis is abruptio placentae. Pain medication, especially epidural block, may mask any pain related to uterine rupture [41].

The midwife should have the consulting physician and pediatrics notified immediately and initiate the following measures:

1. Start two intravenous infusion routes with 16-gauge intracatheters: one for electrolyte solutions (e.g., lactated Ringer's solution) and the other for the blood transfusion (keep the infusion line open with normal saline until the blood is obtained).
2. Notify the blood bank of your need for a *STAT* blood transfusion. Estimate the number of units needed as well as the probable need for fresh frozen plasma.
3. Administer oxygen.
4. Make all preparations for immediate abdominal surgery (laparotomy and most likely hysterectomy).

Blood Transfusion Reaction

The midwife may become involved with blood transfusions as a result of obstetric complications such as postpartal hemorrhage, placenta accreta,

placenta previa, or abruptio placentae. The following steps should be taken when administering blood in order to minimize the risk of a blood transfusion reaction:

1. When initially drawing a specimen for blood typing and crossmatch, make sure the specimen is properly labeled with the correct name and chart number.
2. When you receive a unit of blood, check the name and unit number against the name and unit number of the woman to whom it is to be given. They should be the same.
3. Compare the woman's blood type with that on the unit of blood to be administered. They should be the same except in an extreme emergency, when it may be necessary to administer O-negative blood to a woman who is Rh positive.
4. Compare the unit number with the number on the vial of blood that is taped to the bag of blood. Both numbers should be the same.
5. Avoid giving blood that is ice cold unless the situation is life threatening. The resulting chills may be mistaken as a sign of a blood transfusion reaction.

A blood transfusion reaction can arise from a variety of possible complications during receipt of a blood transfusion: air embolism, anaphylactic shock, circulatory overload, febrile reactions, hemolytic reactions, hyperkalemia, hypocalcemia, hypothermia, and septic shock.

This presentation identifies all the possible signs and symptoms of all the possible complications, since it is the midwife's responsibility to recognize that a reaction is taking place and to so inform the physician. It is the physician's responsibility to diagnose which blood transfusion complication it is and determine the appropriate management.

Subjective signs and symptoms of a blood transfusion reaction include the following:

Lumbar and leg pain
A feeling of fullness in the head
Vertigo
Headache
A feeling of chest constriction
Feeling cold
Vague muscle weakness extending from extremities into trunk
Nausea
Apprehensiveness
Muscle cramps
Paresthesia of hands, feet, and tongue; also of fingers and around the mouth

Objective signs and symptoms of a blood transfusion reaction include the following:

Fever
Chills
Shortness of breath
Tachycardia
Hypotension
Decreased urine output
Skin rash (urticaria)
Edema
Diarrhea
Slow, irregular pulse
Convulsions
Respiratory stridor, rales
Spasms of the hands and feet
Hyperactive reflexes
Neck vein distention

The woman may also have bronchospasm, shock, and paralysis of the respiratory muscles and myocardium, leading to cardiac arrest.

In the presence of a blood transfusion reaction the appropriate immediate actions are as follows:

1. Stop the transfusion.
2. Flush the IV tubing and keep the IV route open with normal saline.
3. Notify the consulting physician of the reaction so the physician can diagnose which complication has occurred and determine its management.
4. Notify the blood bank and save the unit of blood that caused the reaction for further analysis. Most blood banks have clearly outlined procedures to take when there is a transfusion reaction. They may also want to obtain blood and urine samples from the woman.

CHAPTER

30

Management of Selected Obstetric Complications and Deviations from Normal

Every midwife will inevitably be confronted with complications or deviations from normal that demand immediate action. The midwife must know how to manage the following obstetric complications and deviations from normal until they are resolved or until a collaborating physician can take over:

1. Shoulder dystocia
2. Face presentation
3. Breech presentations
4. Multiple gestation
5. Third stage hemorrhage
6. Immediate postpartal hemorrhage
7. A newborn that needs resuscitation

Management of the first four conditions is described in this chapter; management of third stage hemorrhage, immediate postpartum hemorrhage, and resuscitation of the newborn are described in Chapters 32, 34, and 38, respectively.

Midwives may be confronted with emergencies in any setting. Theoretically and ideally, all of these complications and deviations from normal should have been diagnosed or anticipated before delivery and before they actually occur. Situational circumstances, however, dictate that this will not always be the case. Rarely is a midwife confronted with any of these because of failure to have properly diagnosed or anticipated the problem.

Management of Shoulder Dystocia

The definition of shoulder dystocia is critical to determining the most effective sequence of management steps and maneuvers. The diagnostic entity known as shoulder dystocia refers to cephalic presentations in which the anterior shoulder is wedged above the symphysis pubis instead of entering the true pelvis. This occurs when the shoulders attempt to enter the true pelvis with the bisacromial diameter in the anteroposterior diameter of the pelvic inlet instead of in either the more roomy right or left oblique diameter of the pelvic inlet, which is the method of pelvic entry during the normal mechanisms of labor (see Chapter 28). The oblique diameter of 12.75 centimeters is larger than the anteroposterior diameter of 10.6 centimeters for the obstetric conjugate of the pelvic inlet (see Figures 61-3 and 61-4). The posterior shoulder usually has descended past the sacral promontory and entered the true pelvis. Very rarely, the posterior shoulder is also jammed above the sacral promontory along with the anterior shoulder. Thus the key to the definition of shoulder dystocia, and to the resolution of the problem, is the location of the anterior shoulder wedged above the symphysis pubis.

However, while this definition is anatomically correct, the diagnosis of shoulder dystocia in the clinical situation is subjectively and simultaneously

or retrospectively based on what can be observed at the time of occurrence. Some authors have suggested defining shoulder dystocia by the length of time from delivery of the head to delivery of the body or by which and how many maneuvers have to be used to free the shoulders and deliver the baby [1, 2]. Others look for some combination of "turtle sign," head-to-body delivery length of time, maneuvers needed, and predisposing factors. Complicating the diagnostic picture are two other closely related types of dystocia: snug shoulders and bed dystocia. The midwife needs to make a differential diagnosis between shoulder dystocia (the real thing), snug shoulders, and bed dystocia.

The clinical picture of shoulder dystocia has been vividly described by Morris as follows:

> The delivery of the head with or without forceps may have been quite easy, but more commonly there has been a little difficulty in completing the extension of the head. The hairy scalp slides out with reluctance. When the forehead has appeared it is necessary to press back the perineum to deliver the face. Fat cheeks eventually emerge. A double chin has to be hooked over the posterior vulval commissure, to which it remains tightly opposed. Restitution seldom occurs spontaneously, for the head seems incapable of movement as a result of friction with the girdle of contact of the vulva. On the other hand, gentle manipulation of the head sometimes results in a sudden 90 degree restitution as the head adjusts itself *without descent* [italics added] to the anteroposterior position of the shoulders.
>
> Time passes. The child's head becomes suffused. It endeavors unsuccessfully to breathe. Abdominal efforts by the mother or by her attendants produce no advance; gentle head traction is equally unavailing.
>
> Usually equanimity forsakes the attendants. They push, they pull. Alarm increases. Eventually
>
> > By greater strength of muscle
> > Or by some infernal juggle
>
> the difficulty appears to be overcome, and the shoulders and trunk of a goodly child are delivered. The pallor of its body contrasts with the plum-colored cyanosis of the face, and the small quantity of freshly expelled meconium about the buttocks. It dawns upon the attendants that their anxiety was not ill-founded, the baby lies limp and voiceless, and too often remains so despite all efforts at resuscitation. [3]

The retraction of the head against the perineum, and seemingly back into the vagina if it were possible, is called the *turtle sign*.

Snug shoulders are often given the misnomer "mild" shoulder dystocia and most likely do not meet the definition of the impingement (or impaction) of the anterior shoulder or both shoulders above the pelvic brim. Snug shoulders can occur with a large baby, an adequately shaped pelvis, and a somewhat obese mother, which together comprise a soft tissue dystocia. The head is born very slowly but the midwife does not need to push the perineum back manually in order for the head to be born. The baby's face is fat but the baby does not really exhibit the turtle sign as the head goes through both restitution and external rotation. The shoulders are tight and take more effort to deliver, but making sure the shoulders are in the oblique diameter of the pelvis, a little suprapubic pressure, and an exaggerated lithotomy position readily take care of the problem, as does having the mother get into the hands-knees position. The 1-minute Apgar score is rarely less than 4 and usually not less than 6. It's enough to scare you but it's not the real thing.

Bed dystocia occurs when the woman is in a semi-Fowler's or similar propped-up position and the baby is being born downward into the bed. Bed dystocia is especially common with a soft bed that sags under the woman's buttocks. In such a situation there is no room for delivery of the shoulders. This, however, is not shoulder dystocia. The problem is readily rectified by slipping something under the woman's hips that elevates them and by reducing the upright angle of her position in the bed; or by bringing her buttocks to the edge of the bed; or by turning her on her side or into the hands-knees position. It is an error to record such an event as an incidence of shoulder dystocia.

The incidence of shoulder dystocia is generally reported as being less than 1 percent but may occur from 0.2 to 2 percent of vaginal cephalic deliveries [4]. An accurate figure, however, probably does not exist. The problem in accurately establishing the incidence of shoulder dystocia is threefold:

1. Some reports are not clear if the incidence they cite is based on all deliveries or if their denominator excludes those babies who weighed less than 2500 grams. If babies weighing less than 2500 grams are included in the denominator, the incidence, and thus risk, of shoulder dystocia would appear lower than it actually is.
2. Some reports are not clear if the incidence they cite is based on all deliveries, including cesarean

sections, or just on vaginal deliveries, or just on vaginal cephalic deliveries. If cesarean sections are included in the denominator, the incidence and risk of shoulder dystocia are not accurately reflected.

3. Many practitioners have a problem in making a differential diagnosis of shoulder dystocia from snug shoulders and from bed dystocia.

The incidence of morbidity and mortality resulting from shoulder dystocia and its management (or mismanagement) is approximately 15 percent and increases with the severity of the shoulder dystocia and the number of maneuvers used to deliver the shoulders to approximately 40 percent [5]. Fetal and newborn complications include death (intrapartal death between delivery of the head and delivery of the shoulders, resulting from anoxia; or neonatal death resulting from injuries sustained during delivery of the shoulders), brain damage, fractured clavicle(s), and brachial plexus (Erb's) palsy. It should be noted that brachial plexus injuries may occur without antecedent shoulder dystocia [2, 6]. Maternal complications include extensive perineal and vaginal lacerations, emotional distress resulting from a traumatic delivery, and emotional shock and grief if the baby is either damaged or dead.

The amount of time you have between delivery of the head and delivery of the shoulders before infant morbidity or mortality is likely to occur depends on how much the baby has already been compromised. The amount of compromise may or may not have been evaluated by the time of delivery, and the evaluation may be more or less complete and accurate. Some practitioners claim a margin of safety up to 5 minutes, or even 10 minutes if there has been no previous compromise. A more conservative time frame, which is to be through the steps of management of shoulder dystocia with delivery of the baby within 3 minutes, gives the baby its best chance for both survival and a minimum of brain damage due to hypoxia. This time frame requires instant recognition of the problem, preferably having anticipated it, and unhesitating swift action.

The best preparation for management of shoulder dystocia is to have anticipated it. The possibility of shoulder dystocia should be anticipated whenever you note any of the following findings or conditions:

1. Large fetus, as determined by palpation or ultrasound diagnosis of macrosomia. In macrosomia ("large body") the bisacromial diameter of the shoulders may become larger than the critical diameters of the head and the chest and shoulder circumference is larger than the head circumference. It should be noted, however, that birth weight alone is not predictive for shoulder dystocia [7]. There is a 50 to 60 percent occurrence of shoulder dystocia in infants who weigh *less* than 4000 grams [2].
2. Maternal diabetes, particularly gestational or Type I class A diabetes, because of the possibility of macrosomia. Infants of diabetic mothers have a greater shoulder-head circumference ratio than do infants of nondiabetic mothers even though the birth weight is the same [4].
3. Postdates, because the baby continues to grow and get larger with an increase in macrosomia between 40 and 42 weeks' gestation. There is a greater shoulder-head circumference ratio as growth of the biparietal diameter slows but not of the shoulders and chest [4].
4. Obstetric history of large babies.
5. Family history of large siblings.
6. Maternal obesity. A large baby combined with the extra tissue found in an obese mother cuts down on the space in the passageway. This is probably more frequently the problem in the diagnosis of "snug shoulders."
7. Varney's predictive factor of an estimated fetal weight 1 pound or more greater than the woman's largest previous baby [8]. This situation is one in which you can have the worst shoulder dystocia, because frequently it is not anticipated, especially if the woman's first baby was 5 or 6 pounds and this baby is estimated at the average 7 to $7^1/_2$ pounds.
8. Obstetric history of a difficult delivery or previous shoulder dystocia.
9. Cephalopelvic disproportion:
   a. pelvic shape that shortens the anterior-posterior diameters
   b. deformed pelvis (e.g., the result of an accident or ricketts)
10. Desultory active phase of the first stage of labor. The active phase just squeaks along, the woman barely dilating another centimeter within reasonable time limits for evidence of progress. Such a labor pattern could reflect cephalopelvic disproportion which, in the event of a vaginal delivery, would portend shoulder dystocia.
11. Prolonged second stage of labor, which includes both excruciatingly slow descent of the head and the failure to descend seen in deep transverse arrest.

12. Indication of the need for midpelvic rotation and/or delivery with either forceps or vacuum extractor. This is the predictive factor that most likely will be combined with a large fetus, prolonged second stage of labor, and cephalopelvic disproportion, and that most strongly indicates consideration of a cesarean section. The incidence of shoulder dystocia increases dramatically when increased birth weight is combined with prolonged second stage labor and midpelvic delivery [9].

When confronted with a shoulder dystocia you can take unhesitating swift action only if you have learned and drilled a set of steps to follow and become confident both that they will work and that you are able to do them. In addition you must develop a mind-set that is contrary to normal practice for midwives. This mind-set includes recognizing that you are going to hurt the woman. This is not the time for the gentle approach, delicacy in handling maternal tissues, and lengthy explanations. You need to be aggressive with your hands and with your mind. You also need to recognize that you are no longer facilitating natural, normal processes but facilitating a birth in a process that is no longer normal. This is *not* the time to be waiting for the next contraction before doing something. You must implement your set of steps instantly.

The danger of shoulder dystocia is in large part attributable to clinicians' not knowing how to manage the emergency properly. It is important that the midwife know how to manage this situation because, even if you anticipate it, you cannot make a diagnosis until after the fetal head is born. This gives little time to resolve the problem before the baby is either damaged or dead. If you learn, drill, and review the following protocol en route to each labor and birth situation, you need not fear shoulder dystocia because you will know precisely what to do. You also need to ensure that the nurses in the hospital setting know what to do in the event of a shoulder dystocia and offer in-service education if needed. If birth is in the home or birth center, it is equally essential that the birth assistant also know, frequently drill, and review these steps en route to a birth.

The following steps should be taken to manage this emergency situation of shoulder dystocia. The first six steps occur concurrently; the rest occur in sequence.

1. *Stay calm.* You know what to do and will effectively manage this situation.
2. *Request that your consulting physician be called immediately.* If you anticipated the possibility of a shoulder dystocia, you should have previously alerted the physician of your potential need for him or her. Most likely you will have delivered the baby by the time the physician arrives. If you don't need the physician's help in delivering the baby, you still want the physician to be present because there is a good chance that the baby will need resuscitation and that the mother will have an immediate postpartum hemorrhage.
3. *Request readiness for a full-scale newborn resuscitation effort.*
4. *Request readiness for an immediate postpartum hemorrhage.* Many of the causes of shoulder dystocia also overdistend the uterus and predispose the woman to immediate postpartum hemorrhage. See Chapter 34 for management. Include a request for a straight catheter.
5. *Briefly tell the mother that there is a problem with delivery of the baby's shoulders, that you and the baby need her cooperation, and that you will be doing things that will hurt her.* Tell her that she must *not* push now.
6. *Place the woman in an exaggerated lithotomy position (McRoberts maneuver).* The McRoberts maneuver is the most effective first maneuver to make for the alleviation of shoulder dystocia with the least amount of injury to the baby [2, 4, 10].

   Gonik et al. explain the effectiveness of the McRoberts maneuver as follows (see Figure 30-1):

   > The exaggerated flexion of the patient's legs results in a straightening of the sacrum relative to the lumbar spine with consequent rotation of the symphysis pubis cephalad and a decrease in the angle of inclination. . . . Although this maneuver does not change the dimensions of the true pelvis, rotation of the symphysis superiorly frees the impacted anterior shoulder without manipulation of the fetus. [11]

   The knee-chest position is the same as the exaggerated lithotomy position, only upside down. The McRoberts maneuver also gives you more room for manipulations. If the woman is in lithotomy position or you have brought her to the edge of a bed, position her so her buttocks overhang the edge of the table or bed. Alternatively, if the woman is in the middle of a bed, then place an inverted bedpan (or a delivery pan, or a softball or baseball base—which some midwives carry with them to home births—or anything firm and several inches

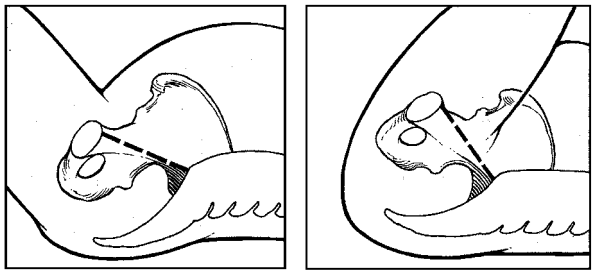

FIGURE 30-1 Angle of the pelvis with the woman's legs down and with her legs in exaggerated lithotomy position.

Source: From Gabbe, S. G., Nieble, J., and Simpson, J. L. *Obstetrics: Normal and Problem Pregnancies*, 2nd ed. New York: Churchill Livingstone, 1991, p. 568. Reproduced by permission.

thick) underneath her buttocks. Either way, have her bring her legs up, back, and out and have her hang on to them with her hands on her knees or behind her thighs (as she did when pushing) if there are no extra hands to help keep her legs flexed.

7. *Check the position of the shoulders. Rotate them into one of the oblique diameters of the pelvis* if they are in either the transverse or anteroposterior diameter of the mother's pelvis.

   Again, instruct the mother not to push. To rotate the shoulders, place all of the fingers of one of your hands on one side of the baby's chest (e.g., right side) and all of the fingers of your other hand on the baby's back on the opposite side (left side) and then press with the amount of force necessary to move the baby. It is important that your entire hand be used rather than just two fingers of each hand because you most likely won't have the necessary strength in two fingers to move the baby. Using all of your fingers on both sides gives you maximum strength. It also gives you a wider area on which to exert and equalize pressure, thereby decreasing the risk of injury to the baby, which is possible when all the force is concentrated on a smaller area.

   Under no circumstances make the mistake of thinking that moving the head will move the shoulders. All you will do is twist the baby's neck; this may result in injury of the brachial or cervical nerve plexus or fracture of the cervical vertebrae.

8. *Have someone else apply suprapubic pressure while you exert your usual downward and outward pressure on the side of the baby's head* (see Chapters 70 and 71). Pressure on the baby's head should be firm but not excessive. Excessive force or traction on the baby's head may result in nerve palsy.

   Suprapubic pressure is most effective if the person applying it stands on a footstool in order to get greater force behind the downward push. This person places both hands palm down, one on top of the other, in the abdominal midline just above the symphysis pubis and then pushes straight downward into the lower abdomen. Suprapubic pressure can be directed to adduct the shoulders to a lesser bisacromial diameter and help them move from their anteroposterior position above the symphysis pubis to an oblique diameter. You need to instruct the person applying suprapubic pressure as to the position of the baby and which way to direct the pressure so that it is applied against the back of the shoulder and then laterally and downward. The baby will have delivered after this step if the condition was a mild shoulder dystocia.

   Under no circumstances should you allow fundal pressure to be given. Fundal pressure will only further impact the shoulders, waste time, possibly cause injury to the fetus, and possibly rupture the uterus with disastrous consequences for both mother and baby.

9. If the baby has not delivered, take the time (approximately 40 to 45 seconds) to give yourself every piece of knowledge, advantage, and bit of room to deliver the shoulders:
   - **a.** *Catheterize the woman to empty her bladder* if you don't know if she entered delivery with an empty bladder. It takes very little urine for the bladder to become an obstruction and impede descent of the anterior shoulder. To save precious time it is better to ensure that a woman's bladder is empty at the start of delivery if there is any anticipation of a possible shoulder dystocia.
   - **b.** *Ascertain the need to cut or enlarge the episiotomy.* This decision requires clinical judgment and depends on the tightness or laxity of the woman's perineum and the ease with which you can insert your hands for necessary manipulations [12].
   - **c.** *Do a vaginal examination to rule out other causes of labor dystocia after the head is born.* This requires the insertion of your entire examining hand as far as you can. Other causes of labor dystocia to be ruled out at this time are
     - **(1)** short umbilical cord (relative or absolute)
     - **(2)** enlargement of the thorax or abdomen of the fetus such as might be caused by tumors, gross deformities, or severe edema

(3) locked twins
(4) conjoined twins
(5) Bandl's retraction ring

A midwife should never confront the last three causes of labor dystocia. Locked or conjoined twins should be diagnosed prior to the start of labor and delivery and Bandl's retraction ring is the hallmark of neglected labor.

10. *If the labor dystocia is diagnosed as resulting from shoulder dystocia, attempt again to deliver the baby with McRoberts and directed suprapubic pressure* while you exert firm, but not excessive, downward and outward pressure on the side of the baby's head. The baby will have delivered after this step if the condition was a moderate shoulder dystocia.

11. (Steps 11 and 12 are reversible.) *If the baby has not delivered, do the corkscrew maneuver, utilizing the screw principle of Woods* (Figure 30-2). To do this maneuver, place your hands in the same manner as you did for rotation of the shoulders in Step 7. Rotate the baby 180°, thereby substituting the posterior shoulder for the anterior shoulder. Always rotate the body of the baby so that the back is rotated anteriorly (back up). This means that you alternately rotate the baby 180° clockwise and then 180° counterclockwise (or vice versa) until the baby is screwed out, but without being twisted upon itself. It also means that as you begin the maneuver your hand on the baby's back will be on the anterior shoulder pushing forward and down and your hand on the baby's chest will be pushing backward toward the posterior shoulder and up.

In order to make the best use of natural forces you will need to switch the placement of your hands after the baby has rotated 90° before continuing on through the last 90°. For example, if the baby is positioned with its back to the mother's right in an ROT position, then initially your right hand will be pressing against the baby's chest for the posterior shoulder and your left hand will be pressing against the baby's back for the anterior shoulder. After 90° rotation, which places the bisacromial diameter in the transverse diameter of the mother's pelvis, reposition your hands by exchanging their positions. This means that your left hand will now be pressing upward against the chest on the right side of the baby, and your right hand will now be pressing downward against the back on the left side of the baby for the final 90° rotation of the baby's body. The baby's body has now been rotated 180° in a clockwise direction and the posterior shoulder substituted for the anterior shoulder.

If the baby is still undeliverable, rotate the baby another 180°, again substituting the present posterior shoulder for the anterior shoulder. The direction of this rotation will now be counterclockwise, in effect rotating the baby back the way it originally came, only further down and out of the pelvis. This is accomplished by placing your hands so that your left hand is pressing against the baby's chest for the posterior shoulder and your right hand is pressing against the baby's back for the anterior shoulder for the first 90° of the rotation. You then switch your hands so that your left hand is now pressing downward against the right side of the baby's back and your

FIGURE 30-2 Woods screw principle. A = anterior shoulder; P = posterior shoulder; X = symphysis pubis; Y = sacral promontory; Z = coccyx.

Source: From Woods, C. E. A principle of physics as applicable to shoulder dystocia. *Am. J. Obstet. Gynecol.* 45:798, 1943. Reproduced with permission.

right hand is now pressing upward against the left side of the baby's chest for the final 90° rotation of the baby's body. Continue rotating the baby's body at least three to four times.

12. *If the baby still has not delivered, deliver the posterior arm* (see Figure 30-3). Delivery of the posterior arm is accomplished by placing your entire hand deep into the vagina behind the posterior shoulder. Following the arm down from the shoulder, find the elbow and lower arm. If the arm is extended, press in the antecubital space to cause the arm to flex (Figure 30-3, top), or if the arm is jammed, splint the lower arm down from the elbow and sweep it up and across the baby's abdomen and chest in its normal range of motion until you can grasp the baby's hand and deliver the entire arm.

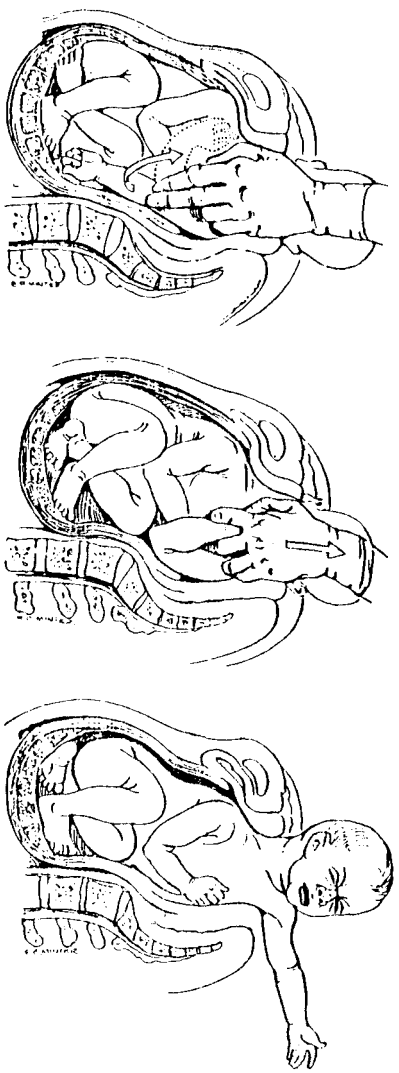

FIGURE 30-3 Delivery of the posterior shoulder.

Source: From Mazzanti, G. A. Delivery of the anterior shoulder: A neglected art. *Obstet. Gynecol.* 13(5):606, 1959. Reproduced by permission.

In doing this maneuver, resist any temptation to hook your fingers under the baby's axilla or into the armpit. This will not help you deliver the posterior shoulder as readily as the maneuver described and most likely will cause nerve plexus injury.

13. *Attempt to deliver the baby now by the combination of McRoberts, suprapubic pressure, and downward and outward pressure on the side of the baby's head* (see Step 8).

14. *If the baby has not delivered, rotate the baby's body 180°* (as described in Step 11). This will substitute the now delivered posterior shoulder for the anterior shoulder.

If the baby did not deliver after either Step 8 or Step 10, it will have delivered after Steps 11, 12 and 13, or 14 if the condition was a severe shoulder dystocia. In an exceptionally rare situation (which the majority of midwives will not see in an entire career), the baby will not have delivered and you then proceed to the next step.

15. *Traditionally the next step was to break the baby's clavicle*, and for some it may still be the next step. The danger, however, in breaking the clavicle is the possibility of puncturing the underlying lung with the broken ends of the bone and causing pneumothorax or of injuring the subclavian vessels. The anterior clavicle is broken first in order to collapse the anterior shoulder and dislodge it from behind the symphysis pubis.

16. *For other practitioners the next step is to use the Zavanelli maneuver to replace the head back into the vagina followed by delivery of the baby by cesarean section* (see Figure 30-4). To

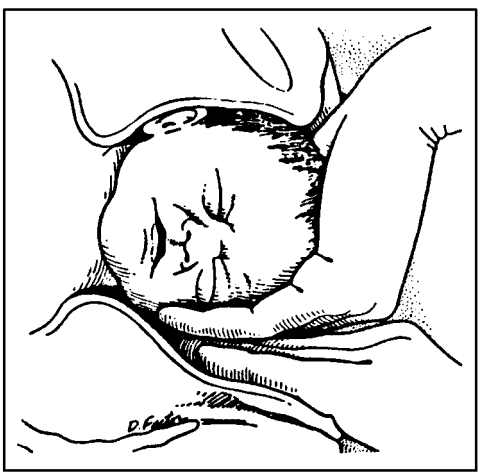

FIGURE 30-4 Zavanelli maneuver.

Source: From O'Leary, J. A., and Gunn, D. L. Option for shoulder dystocia—cephalic replacement. *Contemp. OB/GYN* 157–159 (January) 1986. Reproduced by permission.

replace the head, reverse the mechanisms of labor and depress the posterior vaginal wall while supporting the head [13]. While the Zavanelli maneuver has been successful in a number of desperate cases [14], it is not always easy to perform and there have been cases in which the maneuver failed and symphysiotomy was necessary [15, 16].

The Zavanelli maneuver is a final option, unless you found an obstructive tumor on vaginal examination in Step 9c. In such a situation you would go directly to the Zavanelli maneuver, as it is not possible to deliver the baby vaginally.

For snug shoulders, an alternative management method has been used with success [17, 18]. With this approach, you first turn the woman completely over on her side with her back at a right angle toward you. If delivery does not readily occur in the side-lying position, help the woman into a hands-knees position. The posterior shoulder, which is now uppermost, should deliver readily.

However, it is difficult to ascertain at the beginning of a shoulder dystocia situation just how severe the problem is or even if it is a case of shoulder dystocia or of snug shoulders. The hands-knees methodology will often work for cases of snug shoulders, but it will not always work for a case of real shoulder dystocia. Problems with the hands-knees position in the presence of shoulder dystocia include the following:

1. You are unable to use suprapubic pressure. If you try suprapubic pressure when the woman is in the hands-knees position you lose force and power as you try to exert pressure upward.
2. Gravity works against you with the hands-knees position. Remember the anterior shoulder is wedged above the symphysis pubis; thus, having the woman adopt a hands-knees position causes the contents of the abdomen to hang down above the symphysis pubis, which only exaggerates the situation.
3. Unless the woman is already in the hands-knees position, you may waste precious time if you go through the process of getting her into the hands-knees position only to be unable to deliver the baby when she is in that position and have to reposition her in order to do the steps listed above for management of shoulder dystocia. It is easier to get a woman into the hands-knees position when she is on a large bed or on the floor. It is more difficult and time consuming to get a woman into the hands-knees position if she has had an epidural. Since the methodology presented for management of shoulder dystocia (Steps 1 through 16) will work for both snug shoulders and shoulder dystocia, it should be the method used in all cases unless the woman is already in the hands-knees position for giving birth. In such an event the hands-knees position for delivery of the shoulders can be tried first.

Delivery of an Infant with a Face Presentation

Many babies with face presentations begin labor in a brow presentation and convert to a face presentation during descent. The diagnosis of a face presentation is based on the following:

1. *Abdominal palpation (Leopold's third and fourth maneuvers)*: With hyperextension of the head, the occiput becomes the cephalic prominence, is easily palpable, and is located on the same side of the mother's abdomen as the hyperextended "hollowed" or arched back; the head may feel larger than you would anticipate as compared to a well-flexed head.
2. *Pelvic examination:* You may be unable to identify both fontanels clearly or may feel only the anterior fontanel if the baby is in a hyperextended presentation. With a brow presentation, you will feel the brow and possibly the anterior fontanel, but no other common identifying landmarks. In a face presentation, you will be able to feel the baby's eyes, nose, mouth, and chin, although initially the presenting part may feel soft and lumpy, similar to a breech presentation, rather than firm and smooth. On further examination and palpation, the landmarks of the face become evident. If the membranes are ruptured, the baby may even suck your finger as you approach the mouth.

Once you have diagnosed a face presentation, do not apply an internal electrode, as this device will damage the baby's face or may be inadvertently applied to an eyelid. You also need to be very careful with your vaginal examinations so as not to injure the baby's eyes.

In order to appropriately manage the delivery of a baby in a face presentation, you need to know the mechanisms of labor for this malpresentation, especially the mechanisms that vary from normal and the implications these have for the outcome. The mechanisms of labor for a face presentation are as follows:

1. *Extension:* The arbitrarily chosen point on the fetus used to determine the position in a face

presentation is the chin (mentum), which is palpable because the head is extended rather than flexed. Why some form of interference occurs in approximately 0.5 percent of all deliveries that causes the head to deflex is not understood. Whatever the reason, a fetus that was LOP or ROP, for example, converts, respectively, to RMA or LMA at the start of labor and enters the pelvis face first.

2. *Engagement:* Engagement takes place when the trachelobregmatic (submentalbregmatic) diameter (9.5 cm) has passed through the pelvic inlet. Approximately 70 percent of all face presentations engage as either mentum anterior or mentum transverse varieties. The remaining 30 percent engage as a posterior variety. The axis of the face (midchin to midbrow, bisecting the nose) is used as the fetal diameter in relation to the mother's pelvis in determining in which oblique diameter of the pelvis engagement takes place.
3. *Descent occurs throughout:* Further extension occurs when resistance is encountered and the brow and occiput are forced toward the back of the baby while the chin becomes the lowermost part of the presenting part and leads the way in descent through the mother's pelvis.
4. *Internal rotation:* Internal rotation usually occurs late in labor when descent enables the entire face to be well applied to the pelvic floor. Rotation of the chin is either anterior or posterior as follows:
   a. rotation of the chin anteriorly (Figure 30-5):
      45° for RMA and LMA to MA
      90° for RMT and LMT to MA
      135° for RMP and LMP to MA
   b. rotation of the chin posteriorly:
      45° for RMP and LMP to MP

   If the chin rotates posteriorly into a mentum posterior position, the mechanisms of labor cease at this point because the baby cannot deliver vaginally from this position (Figure 30-6). This is because the length of the neck of the fetus is only about half as long as the length of the sacrum. Therefore it is not possible for the chin to escape from the vaginal floor over the perineum, thereby allowing the remainder of the head to be born by flexion. The midwife must recognize this condition immediately before impaction of the head takes place with its extremely poor prognosis for the fetus. Delivery is by cesarean section by the physician.
5. *Birth of the head:* When the chin rotates to mentum anterior, birth of the head is by a double mechanism of extension followed by flexion. Extension is maintained until the chin is born by escaping beneath the symphysis pubis. The submental area beneath the chin impinges beneath the symphysis pubis and becomes the

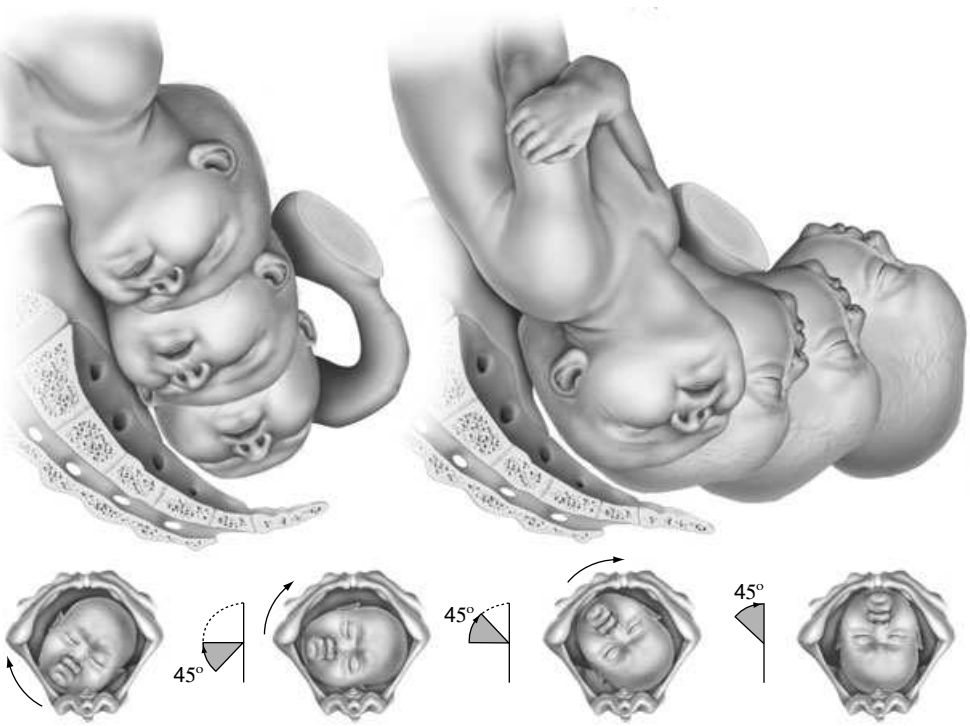

FIGURE 30-5 Mechanisms of labor for a baby in right mentoposterior position. Note engagement in ROP, descent throughout, internal rotation 135° to mentum anterior, and birth of the head first by extension and then by flexion.

FIGURE 30-6 Face presentation with chin directly posterior (MP). Unless rotation to mentum anterior (MA) occurs, vaginal birth is not possible.

pivotal point for the delivery of the rest of the head by flexion. The rest of the head is born sequentially starting with the mouth, then the nose, eyes, brow, anterior fontanel, and posterior fontanel, and ending with the occiput as the head flexes.

6. *Restitution:* Restitution takes place 45° in the direction from which the head rotated during internal rotation. For example, if internal rotation was from RMT to MA, then restitution is 45° to the RMA (or LOP) position.
7. *External rotation:* External rotation takes place another 45° in the same direction as restitution, for example, to the RMT (or LOT) position.
8. *Birth of the shoulders and body:* This occurs by lateral flexion via the curve of Carus.

Management of a face presentation includes the following:

1. Recognize that the position is a face presentation and notify the consulting physician of this malpresentation.
2. Reevaluate the adequacy of the pelvis and consult with the physician if there is a question of possible cephalopelvic disproportion to rule out this condition.
3. Closely monitor the mechanism of labor of internal rotation. The midwife must immediately inform the physician if rotation is to a direct mentum posterior position.
4. For delivery of the head:
   a. It may be necessary to apply pressure on the fetal brow to maintain extension until the chin is born. This is done by pressing on the posterior end of the perineal body as the vulvovaginal orifice distends. You need to protect your gloved hand from contamination from the rectum during this maneuver by covering it with a towel.
   b. Control the head, thereby allowing the gradual flexion and birth of the remainder of the head. Most face presentations deliver spontaneously with little need for extensive hand maneuvers.
5. Delivery of the shoulders and body is the same as for other cephalic presentations.
6. Request that the pediatrician/neonatal nurse practitioner attend the delivery. If there is extensive edema of the neck (trachea), nose, and mouth, respiratory function may be compromised.
7. Reassure parents, family, and significant others that the position of the head and neck of the baby (neck extended, head fallen backwards), the long molded head, and the extensive swelling and distortion of the features of the face normally improve noticeably in a day or two and completely disappear in a few days.

Delivery of an Infant with a Breech Presentation

The findings of an international study comparing planned vaginal delivery with planned cesarean section for breech presentation reported in 2000 [19, 20] led the American College of Obstetricians and Gynecologists to issue a Committee Report stating that: "Patients with persistent breech presentation at term in a singleton gestation should undergo planned cesarean delivery" [21]. The multicenter randomized controlled trial demonstrated a significant reduction in perinatal mortality, neonatal mortality, or serious neonatal morbidity with the planned cesarean section group and no difference between the two groups in maternal mortality or serious maternal morbidity. A 2001 Cochrane Review of randomized trials comparing planned cesarean section with planned vaginal delivery for breech presentation affirmed "greatly reduced" perinatal and neonatal mortality and neonatal morbidity but found a modestly increased maternal morbidity [22]. Emphasis is now being placed on the reduction of breech presentation in term singleton gestations by external cephalic version with research focusing on how to improve the success rate, primarily with tocolytic agents [20, 23, 24].

Although there will inevitably be a reduction in the numbers of women at term with breech presentation and a reduction in the number of vaginal deliveries of those who have a breech presentation at term, there are still times when a midwife might be

confronted with delivery of a breech presentation. These times include those women with no prenatal care who present in late active labor, those women who make an informed choice for vaginal delivery, and those women for whom the second twin is in a nonvertex presentation [21].

The midwife must know how to manage the delivery of a baby with a breech presentation because chances are that someday an unexpected or emergency situation will arise, even in a medical center, where a woman with a breech presentation may be an object of competition among obstetric residents for teaching and learning purposes.

An emergency breech delivery should not be caused by lack of a diagnosis by a midwife caring for the woman during the antepartal period or during labor. Expected and planned for delivery of a breech presentation by a midwife should always involve close collaboration with, and immediate availability of, the consulting physician. This is essential because of the potential problems in breech delivery: difficulty in delivery of the aftercoming head and need for extensive resuscitation measures for the newborn.

The midwife facilitates the mechanisms of labor of a breech presentation, follows the principle of nonintervention as long as progress is visible, and does manual extraction manipulations as indicated. Inasmuch as there is a direct relationship between the mechanisms of labor and the hand maneuvers for delivery of a breech, these are presented side by side in Table 30-1. The table presents

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation

Mechanism of Labor	Hand Maneuvers
1. Descent occurs throughout. **2.** Engagement of the hips takes place in an RSA position with the sacrum in the left anterior portion of the mother's pelvis and the bitrochanteric diameter in the right oblique diameter of the mother's pelvis.	**1, 2, 3.** Normally you will not need to intervene in the first three mechanisms of labor. In the event that the breech does not descend, cephalopelvic disproportion and hydrocephalus must be ruled out. It is possible, however, that failure to descend may be due to a splinting effect caused when it is a frank breech and the extension of the legs across the baby's abdomen prevents the fetus from maneuvering and arrests progress. In such an event, use of the Pinard maneuver will break up the breech and enable you to bring down the feet and legs, thereby changing a frank breech presentation to a footling breech presentation. This is done as follows (see Figure 30-7):

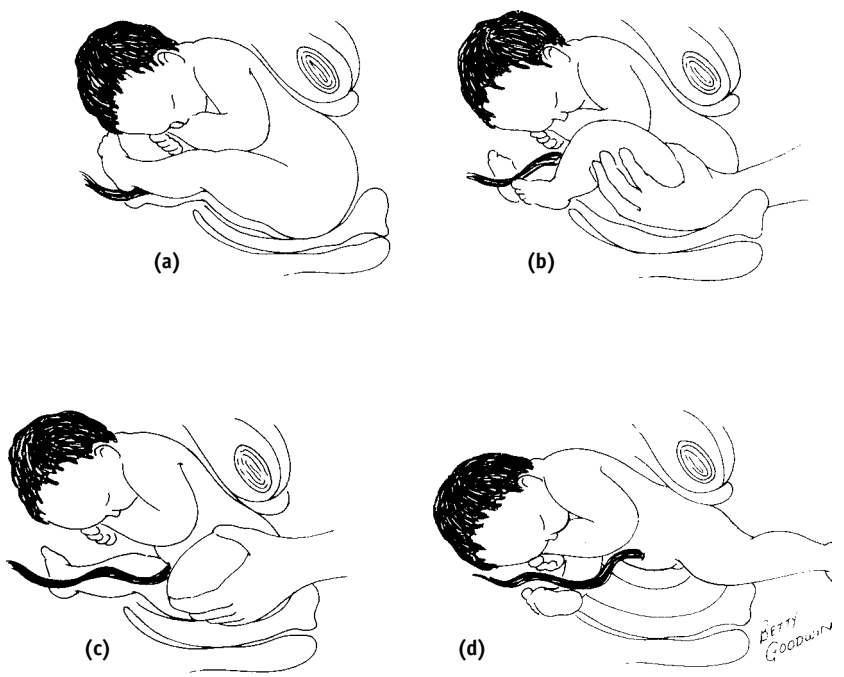

FIGURE 30-7 Pinard maneuver. (a) frank breech; (b) leg abducted and flexed at knee by pressing in popliteal fossa; (c) foot and leg are brought down and delivered; (d) procedure is repeated for other leg and foot.

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation (*continued*)

Mechanism of Labor	Hand Maneuvers
3. Internal rotation of the buttocks 45° from RSA to RST. This brings the anterior hip, which descended more rapidly than the posterior hip and initiated internal rotation when it encountered resistance from the pelvic floor, 45° forward (anterior) to underneath the pubic arch. The bitrochanteric diameter is now in the anteroposterior diameter of the mother's pelvis.	**a.** With your vaginal hand (left hand if the baby is in a left sacrum position, right hand if the baby is in a right sacrum position) follow the posterior side of a thigh up from the buttocks to the popliteal fossa behind the knee. Your thumb will be on the anterior side of the thigh. **b.** Move the leg laterally away from the midline and the baby's body while pressing in the popliteal fossa. This will cause the leg to flex at the knee, thereby bringing the foot, which was at the level of the baby's face and out of reach, down to where you can grasp it. **c.** Bring the leg down by drawing it across the baby's abdomen in its natural range of motion and down for its delivery. **d.** Repeat for the other thigh, leg, and foot.
4. Birth of the buttocks by lateral flexion. When born spontaneously, the posterior hip is born first; the anterior hip impinges beneath the symphysis pubis and serves as the pivoting point for the lateral flexion necessary for the posterior hip to follow the curve of Carus to birth. The baby's body then straightens out as the anterior hip is born. The legs and feet usually follow the birth of the breech and are also born spontaneously.	**4.** You should deliberately avoid using any hand maneuvers at this point—keep your hands off the baby. The one exception is if the baby is in a frank breech presentation and the extended legs prevent the necessary lateral flexion for birth of the buttocks. In such an event, the Pinard maneuver is used for delivery of the feet and legs and then the buttocks. The legs and feet may not be born spontaneously if it is a frank breech presentation. In such an event, the Pinard maneuver will cause delivery of the legs and feet. Because 70 percent of breech deliveries are frank breech presentations, it is important to know how to do Pinard's maneuver inasmuch as it is the solution for three possible times of arrest during descent and delivery of the buttocks. However, prior to using this maneuver to deliver the buttocks, legs, and feet (i.e., during descent), you must clearly rule out cephalopelvic disproportion.
5. (a) External rotation of the buttocks 45° from RST to RSA and (b) engagement of the shoulders with the bisacromial diameter in the right oblique diameter of the mother's pelvis (the same as for engagement of the buttocks). These two mechanisms occur simultaneously, with the external rotation of the buttocks being visible evidence of the entry of the shoulders into the true pelvis as the body untwists and aligns itself with the descending shoulders. Descent of the shoulders after their engagement is rapid.	**5.** Continue a hands-off approach. The rationale for this management is as follows: **a.** There is no need to facilitate the progress of the mechanisms of labor until the baby is born up to the umbilicus. After that, the remainder of the baby needs to be born in 3 to 5 minutes to avoid any anoxia from compression of the umbilical cord against the pelvic brim with resulting possible brain damage. **b.** Traction exerted on the baby prior to birth up to the umbilicus may cause (1) the arms to fly up in a reflex action, thereby extending them above, over, or behind the head and causing later difficulties in the delivery, and/or (2) the head to deflex, which may cause dangerous problems with birth of the head. **c.** Natural progress using the bulk of the breech maintains cervical dilatation and lessens the possibility that the cervix may clamp around the baby's head or neck. It is a good time to request a warm towel to use next. When the baby is born up to the umbilicus you do two things: **d.** Pull down a good-sized loop of umbilical cord to prevent stress on its insertion in the umbilicus during the rest of the delivery. **e.** Place the warm towel around the baby from just below the umbilicus down. This helps keep the baby warm and gives you a nonslippery hold on the baby, which is essential both for safety and to allow you to exert the traction now needed.

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation (*continued*)

Mechanism of Labor	Hand Maneuvers
6. Internal rotation of the shoulders 45°, bringing the bisacromial diameter of the fetus from the right oblique diameter to the anteroposterior diameter of the mother's pelvis. This is evidenced externally when the delivered body also rotates and the sacrum returns to an RST position from an RSA position.	**6.** After birth of the umbilicus, you exert downward and outward traction while facilitating internal rotation of the shoulders by rotating the body so the sacrum again rotates from RSA to RST. To do this safely without injury to internal organs or structures (e.g., kidneys, adrenal glands) resulting from the pressure you apply in order to exert traction, the placement of your hands on bone is vitally important. **a.** Grasp the baby on its hips with your thumbs on either sacroiliac region and your fingers on the corresponding iliac crests (see Figure 30-8). **b.** Continue this traction until you can see not only the lower half of the scapula of the anterior shoulder but *also its corresponding axilla*.
7. Birth of the shoulders by lateral flexion. When born spontaneously, the anterior shoulder impinges beneath the symphysis pubis and serves as the pivotal point for the lateral flexion necessary for delivery of the posterior shoulder via the curve of Carus. Birth of the anterior shoulder then follows as the body straightens out.	**7.** It does not matter which shoulder is delivered first. The following methodology is in accord with the mechanisms of labor: **a.** Grasp the feet of the baby in one hand with your index finger between the legs and your middle finger and thumb each encircling a leg (see Figure 30-9[a]). **b.** Holding the baby by its feet, exert upward traction for the entire body and draw the baby's abdomen toward the mother's inner thigh. Be careful to keep the back from turning upward so that the head will enter the pelvis in the transverse diameter.

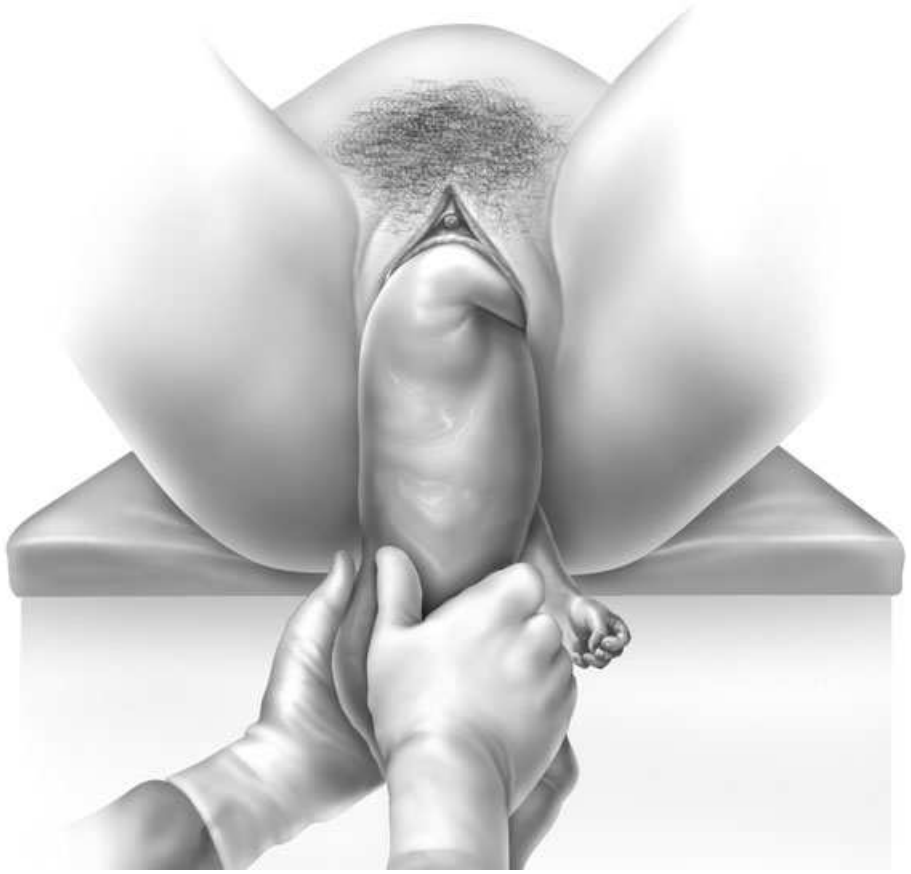

FIGURE 30-8 Breech presentation. Birth of the anterior shoulder by downward traction. Note placement of hands on the baby's hips (Step 6).

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation (*continued*)

Mechanism of Labor	Hand Maneuvers
	c. This draws the posterior shoulder over the perineum to birth, followed by the arm and hand of the same side. **d.** If necessary, such as when the arm has become extended, deliver the arm first, as follows: **(1)** Insert the fingers of your vaginal hand (in this instance of the baby's sacrum being to the right, you would be holding the baby's feet with your right hand and your left hand would be the vaginal hand) and follow the humerus of the posterior arm until you feel the elbow. **(2)** Use these fingers now as a splint for the arm and sweep it across the baby's chest downward to delivery. (See Figure 30-9[b].) **e.** Now exert downward traction on the baby for delivery of the anterior shoulder, arm, and hand. To exert this downward traction, again place your hands on the baby's hips as you did in Step 6 (see Figure 30-8). **f.** Again, if necessary, such as when the arm has become extended, deliver the arm first, as described in Step 7d. **g.** If there is a nuchal arm (the arm is entended from the shoulder but flexed at the elbow so that the lower arm is wedged behind the head), attempts to deliver it the same way as for extended arms as in Steps 7d and 7f will not work. Delivery of a nuchal arm is as follows: **(1)** Grasp the baby by placing your hands on the baby's hips as you did for Step 6.

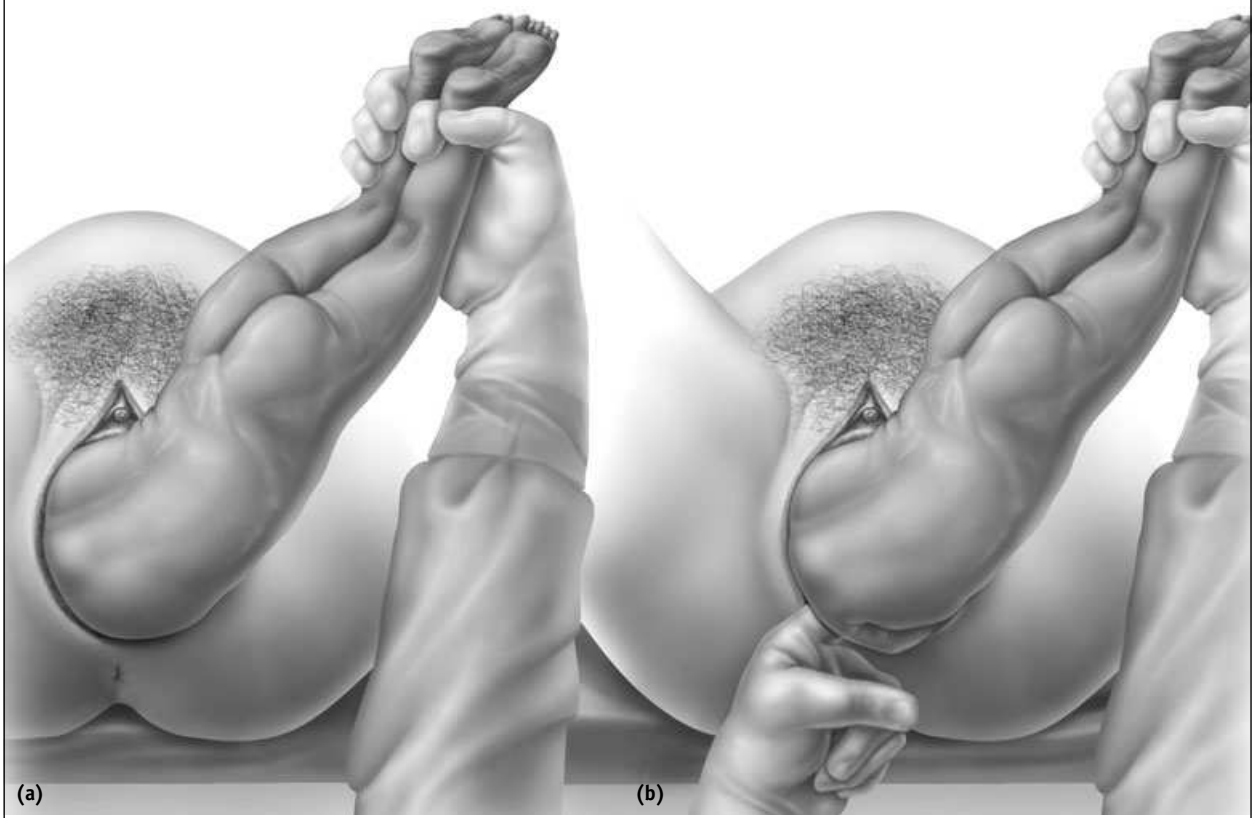

FIGURE 30-9 Breech presentation: (a) birth of the posterior shoulder by upward traction; (b) freeing the posterior arm.

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation (*continued*)

Mechanism of Labor	Hand Maneuvers
	(2) Rotate the baby's body 90–180° in the direction in which the hand behind the head is pointing until the arm is dislodged from behind the head. This is accomplished by the friction of the body rotating against the vaginal outlet in a direction that forces the elbow toward the face and places the arm in a position from which it can now be delivered. **(3)** Deliver the arm as for an extended arm as described in Step 7d. **(4)** If both arms are nuchal arms, then repeat this process for the other arm, rotating the baby in the direction indicated, after delivery of the first arm. **h.** If all else fails (a rare circumstance), break the arm by hooking a finger over it and pulling on it. Such trauma is indicated when weighed against the baby's life. Such a fracture usually heals well without deformity.
8. Engagement of the head takes place with the sagittal suture in either the transverse or left oblique diameter of the mother's pelvis and the occiput in the right side of the pelvis. The head enters the pelvis as the shoulders near the outlet and may engage prior to or after internal rotation of the shoulders—which explains why engagement is in either the transverse or oblique diameter of the pelvic inlet.	**8.** Suprapubic pressure should be applied to maintain the normal flexion of the baby's head. You need to request that someone else apply the pressure because your hands are well occupied with delivery of the shoulders. Suprapubic pressure is continued until the head is born.
9. Internal rotation of the head 45° or 90°, bringing the sagittal suture from the left oblique or transverse diameter, respectively, into the anteroposterior diameter of the mother's pelvis with the occiput directly anterior and the brow in the hollow of the sacrum of the mother's pelvis. This rotation is evidenced externally because the delivered body also rotates, thereby bringing the bisacromial diameter of the shoulders into the horizontal plane of the mother and the sacrum into a direct anterior position (i.e., the back of the baby is upward and the baby is facing down).	**9.** Facilitate rotation of the head to an occiput anterior position: **a.** Grasp the baby by placing your hands on the baby's hips as you did for Step 6. **b.** Monitor the rotation of the head by observing the external rotation of the body. **c.** *Do not allow the head to rotate to an occiput posterior position* as evidenced by rotation of the back posteriorly. If this rare event should begin to occur, counteract by rotating the baby so its back is anterior. Rotation of the head posteriorly so that the occiput is posterior and the chin is facing the symphysis pubis makes delivery of the head extremely difficult and dangerous. Fortunately this posterior rotation is quite rare.
10. Birth of the head by flexion.	**10.** It is vital to keep the head flexed at this time by continuing suprapubic pressure and by using the Mauriceau-Smellie-Veit maneuver. This maneuver is performed as follows (see Figure 30-10): **a.** One hand is introduced into the vagina palmar side up beneath the baby's face. **(1)** Place the index finger of this hand in the baby's mouth and press the back of the finger against the maxilla (upper jaw bone), i.e., against the roof of the mouth. **(2)** This finger is used to help keep the head in flexion and should never be used for traction.

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation (*continued*)

Mechanism of Labor	Hand Maneuvers
	(3) Take care not to allow the finger to slip and apply pressure and/or traction against the mandible (lower jaw bone) and the base of the tongue, as this could cause serious injury. **(4)** Use the rest of this hand to support the body of the baby, which is positioned astride your arm. **b.** Your other hand is placed on the baby's upper back with your index finger hooked over one shoulder on one side of the neck and your middle finger hooked over the other shoulder on the other side of the neck. **(1)** This hand will be used for exerting traction. **(2)** Place your hooking fingers as far as possible away from the neck to avoid pressure on the cervical or brachial nerve plexuses. **(3)** Grasp the shoulders with your thumb and remaining fingers. **c.** Modifications of the Mauriceau-Smellie-Veit maneuver include the following [25, 26]: **(1)** Placement of the index and fourth fingers of the lower hand on the upper jaw (malar bones) on either side of the nose with the middle finger in the baby's mouth. Another alternative is to put the index and fourth finger on the infraorbital ridge and the middle finger in the mouth, but you must be *extremely* careful not to misplace your fingers and damage the baby's eyes. These modifications allow you to exert traction with your lower hand.

FIGURE 30-10 Breech presentation. Birth of the head using the Mauriceau-Smellie-Veit maneuver and suprapubic pressure.

TABLE 30-1 Correlation of Mechanisms of Labor and Hand Maneuvers for Delivery of a Breech Presentation (*continued*)

Mechanism of Labor	Hand Maneuvers
	(2) Extension of one or two fingers (index or index and middle fingers) of the upper hand up the back of the baby's neck under the symphysis pubis and up the occiput, thereby splinting the baby's neck, keeping the head from extending, and facilitating flexion.
	d. Apply downward and outward traction with your hand on the baby's shoulders until you can see the suboccipital region (hair line) under the symphysis pubis.
	e. Now apply upward traction while elevating the body of the baby so that the chin, mouth, nose, eyes, brow, anterior fontanel, posterior fontanel, and occiput follow the curve of Carus and are born in sequence as the head remains flexed for birth.
	f. Birth of the head is controlled by the pressure of your hands. If this step proceeds too fast and the head pops out, intracranial damage may result; and if it is too slow, hypoxia becomes a concern.

maneuvers for a fetus in a specific position; that is, the position of the fetus upon entry of the buttocks into the pelvis is RSA (right sacrum anterior). The arbitrarily chosen point on the fetus for determining position in breech presentations is the sacrum. The fetal diameter used to determine the relationship of the baby to the diameter of the mother's pelvis is the bitrochanteric diameter at the upper ends of the femurs as measured at the level of the hip joint (acetabulum). It helps to visualize the mechanisms of labor if you remember that they *are in sequence for birth of the buttocks, birth of the shoulders, and birth of the head*, in that order.

Before the actual delivery begins, the following should have taken place:

1. Careful abdominal examination or, if necessary, sonography or x-ray to rule out hyperextension of the head, hydrocephalus, or a footling or kneeling breech.
2. Complete cervical dilatation.
3. Elimination of any question about the adequacy of the pelvis.
4. Emptying of the bladder.
5. Cutting of an episiotomy if you determine the need for one. Whether the woman needs an episiotomy depends on the estimated fetal weight and the relaxation of the perineum. If an episiotomy is to be performed, provide local anesthesia and choose the type of incision that will give you the most room for manipulative maneuvers. You can cut an episiotomy at any time during the delivery, even after the buttocks are delivered, if you determine the need for additional room to complete the birth.
6. Determination of an effective maternal pushing effort.
7. Preparations for a full-scale newborn resuscitation effort.
8. The woman should be positioned so there is plenty of room for lateral flexion and downward traction—that is, she should be in the lithotomy position either in stirrups or at the edge of a bed.
9. Your consulting physician should have been notified and should either be present or immediately available.

If this is an in-hospital emergency situation in which you are delivering a woman you have not seen before and have not previously had time to examine, your first action should be to inform the attending nursing staff of the situation and request that in addition to a *STAT* call being placed for the consulting physician, an anesthesiologist or nurse anesthetist and a pediatrician or neonatal clinical nurse specialist or practitioner should also be called to stand by in case they are needed.

Delivery of a Woman with Multiple Gestation

The midwife should manage the labor and delivery of a woman with multiple gestation only in the hospital in collaboration with a consulting obstetrician so that the midwife can be assured of the obstetrician's presence for help with the potential problems of neonatal resuscitation, prematurity (higher inci-

dence in multiple gestation), immediate postpartal hemorrhage (resulting from an overdistended uterus), malpresentation of the second twin (higher incidence of malpresentations in multiple gestation), delay in resumption of labor for delivery of the second twin, or the need for cesarean section such as with locked twins. Even if not in a practice where the midwife manages the birth of twins collaboratively with a consulting obstetrician, the midwife may at some point during her or his career be confronted with an emergency delivery of multiple-gestation infants. This situation should not arise because of the midwife's failure to diagnose multiple gestation while caring for the woman during the antepartal period. In the event of an emergency, the midwife must know what to do to effect safe delivery of all viable fetuses.

This discussion will be limited to the planned collaborative delivery of twins; the process is repeated for however many fetuses there are. Following are the cardinal rules and essential steps for assisting the labor and delivery of a woman with multiple gestation:

1. Medication during labor should be limited to ataractics (e.g., Vistaril) because of the gestation and size of the fetuses. They are often preterm or small-for-gestational-age. Either condition makes medication (analgesics and sedatives) hazardous for them.
2. The woman should have a patent IV, and a type, antibody screen, and crossmatch drawn.
3. The woman's bladder should be empty at the start of the actual delivery.
4. The consulting obstetrician should be notified and present at the start of the actual delivery.
5. Anesthesia personnel should be notified and on standby.
6. The pediatrician should be notified and present. There should be at least one person per baby present who is skilled in newborn resuscitation.
7. The woman should be in lithotomy position to allow plenty of room for manipulations.
8. Nursing personnel should be alerted as far in advance as possible because they must prepare multiples of equipment, supplies, forms, and so forth.
9. Preparation for full-scale resuscitation should be completed at the start of the actual delivery.
10. Nursing personnel should be alerted to the probability of an immediate postpartum hemorrhage.
11. Whether the woman requires an episiotomy depends on the estimated fetal weights, the anticipated need for manipulation if there are fetal malpresentations, and the relaxation of the perineum. If an episiotomy is to be performed, choose the type of incision that will give you the most room for manipulative maneuvers and, in the event of small size or prematurity, will reduce the possibility of intracranial damage. You can cut an episiotomy at any time during the delivery, for example, after the first twin is born and during the delivery of the second twin, if necessary.
12. The presentation and position of all babies should be known prior to the start of the actual delivery.
13. The first twin is delivered in accord with its presentation and position.
14. Have an assistant direct the second twin into position abdominally as you deliver the first twin.
15. Quickly and securely clamp and cut the cord. There must be no delay in this action because whether these are monozygotic twins most likely will not have been diagnosed prior to delivery. The second twin may exsanguinate by bleeding through the cord if they are. Monozygotic (single-ovum) twins usually have one placenta, one chorion, and two amnions (Figure 30-11).
16. Determine the presentation and position of the second twin and evaluate the size of this baby. Ultrasound guidance is helpful.
17. The fetal heart should be closely monitored and the vagina constantly scrutinized for any sign of bleeding (indicates placental separation) while waiting for labor to resume. As long as there is no bleeding or evidence of fetal distress, haste is not indicated. This does not mean, however, that you are not doing anything. The optimum time for the second twin to be born is between 3 and 15 minutes after delivery of the first twin, which allows the baby to come through the just fully dilated cervix before it starts to close again. Also, you wish to deliver the second twin before the placenta starts to separate, a condition that demands quick action in order to obtain a viable second baby.
18. Whether or not labor resumes within this period of time, the presenting part is guided into the true pelvis by a combination of abdominal pressure and vaginal manipulations. Care is first taken to rule out a presenting umbilical cord.
19. Once the presenting part is fixed into the pelvis, rupture the membranes. Leave your hand in the vagina to ascertain whether the cord has pro-

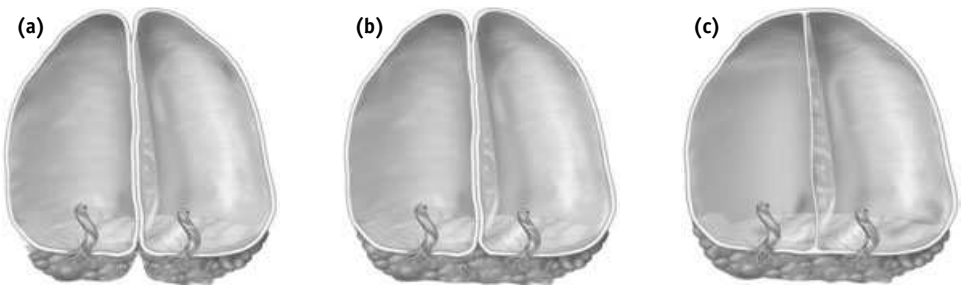

FIGURE 30-11 Membranes and placenta in twin pregnancies. (a) two amnions, two chorions, and two placentas: either dizygotic or monozygotic twins (zygotic division occurred within the first three days after fertilization); (b) same as (a) except the two placentas fused into one placenta; (c) two amnions, one chorion, and one placenta: monozygotic twins (zygotic division occurred between the fourth and eighth days after fertilization).

lapsed. There is less chance of a prolapsed cord if the membranes are ruptured with no pressure (contractions or fundal) behind them and if they are leaked rather than torn. If labor has not resumed up to this point, rupturing the membranes may stimulate contractions to resume.

20. If contractions still have not resumed, an intravenous solution of 1000 mL D_5W or D_5RL with 10 IU of Pitocin should be hung and started at a slow drip (approximately 30 mU/min).
21. Delivery is conducted as usual.
22. Third stage hemorrhage or immediate postpartum hemorrhage is likely. (See Chapters 32 and 34 for management of these emergencies.)

CHAPTER

31

The Normal Third Stage of Labor

The third stage of labor starts upon completion of the birth of the baby and ends with the birth of the placenta. It is known as the placental stage of labor. The third stage of labor lasts on average between 5 and 10 minutes. However, it is within the range of normal for the third stage to last up to 30 minutes. The risk of hemorrhage increases when third stage is longer than 30 minutes, especially between 30 and 60 minutes [1–3].

Database for the Third Stage of Labor

The components of the database for determining the well-being of the woman during the third stage of labor are as follows:

1. Continuing evaluation of any previous significant findings
2. Evaluation of the progress of labor
3. Continuing evaluation of the mother
4. Screening for signs and symptoms of third stage hemorrhage. (This topic is discussed in Chapter 32.)

The midwife must understand the processes of the third stage of labor and parameters of normal for this period in order to evaluate the database.

Although the midwife also conducts an initial evaluation and manages the care of the baby during the third stage of labor, for the sake of clarity these tasks are not covered in this chapter but are instead discussed in the chapters pertaining to the neonate. The Leboyer methodology is a continuum of actions taken during and immediately after birth that coincide with the third stage of labor. This methodology was detailed in Chapter 28.

Evaluation of the Progress of Labor

The third stage of labor consists of two sequential phases: (1) placental separation and (2) placental expulsion. Both separation and expulsion are brought about by contractions, which begin again after a brief pause following the birth of the baby. The contractions had been approximately every 2 to $2^{1}/_{2}$ minutes apart during the second stage of labor. After the birth of the baby, the next contraction may not occur for 3 to 5 minutes. Contractions then follow every 4 to 5 minutes until the placenta has separated and been expelled. After that, the empty uterus contracts down on itself and remains contracted if the muscle tone is good. If the muscle tone is not good, a woman will have increased lochial flow and recurrent uterine contractions as the uterus relaxes. This causes afterbirth pains.

Placental separation is the result of the abrupt decrease in size of the uterine cavity during and following the delivery of the baby, as the uterus contracts down on the reduced uterine contents. This decrease in uterine size necessarily means a concomitant decrease in the area of placental attachment. The placenta, however, remains the same size. The placenta first accommodates to this decrease in uterine size by becoming thicker, but at the site of attachment it is unable to withstand the stress and buckles. The result is separation of the placenta from the uterine wall, which takes place in the spongiosa layer of the decidua. As the placenta separates, a hematoma forms between the separating placenta and the remaining decidua as a result of bleeding into the intervillous space. This is known as the retroplacental hematoma and may vary considerably in size. Although this hematoma is the result rather than the cause of placental separation, it

does facilitate the completion of placental separation.

After the placenta has separated it descends into the lower uterine segment or into the upper vaginal vault, causing the following clinical signs of placental separation to become evident:

1. Sudden trickle or small gush of blood
2. Lengthening of the amount of umbilical cord visible at the vaginal introitus
3. Change in the shape of the uterus from discoid to globular as the uterus now contracts on itself
4. Change in the position of the uterus: It rises in the abdomen because the bulk of the placenta in the lower uterine segment or upper vaginal vault displaces the uterus upward

Placental expulsion begins with the descent of the placenta into the lower uterine segment. The placenta then passes through the cervix into the upper vaginal vault, from whence it is expelled. Expulsion of the placenta is by one of two mechanisms. The Schultz mechanism is by far the more common of the two, although both are considered normal.

The *Schultz mechanism* of placental expulsion is delivery of the placenta with the fetal side presenting. This presentation is thought to result when separation begins centrally with corresponding formation of a central retroplacental clot, which weights the placenta so the central portion descends first. This, in effect, inverts the placenta and amniotic sac and causes the membranes to peel off the remainder of the decidua and trail behind the placenta. The majority of bleeding occurring with this mechanism of labor is not visible until the placenta and membranes are delivered, since the inverted membranes catch and hold the blood.

The *Duncan mechanism* of placental expulsion is delivery of the placenta with the maternal side presenting. This presentation is thought to result when separation first takes place at the margin or periphery of the placenta. Blood escapes between the membranes and uterine wall and is visible externally. The placenta descends sideways and the amniotic sac, therefore, is not inverted but trails behind the placenta for delivery.

The memory aid for correctly identifying the mechanisms of placental expulsion is based on the appearance of the two different sides of the placenta. The fetal side is shiny and glistening because its covering is the fetal membranes, whereas the maternal side is rough and red-looking—hence the sayings "shiny Schultz" and "dirty Duncan."

Continuing Evaluation of the Mother

Many of the normal physiological changes occurring during the first and second stages of labor come to an end when the placenta is expelled, and the woman's vital signs return to prelabor levels during the third stage:

1. *Blood pressure:* Both systolic and diastolic pressures start to return to prelabor levels.
2. *Pulse:* The pulse rate gradually returns to prelabor level.
3. *Temperature:* Body temperature continues to be slightly elevated.
4. *Respirations:* Breathing returns to normal.
5. *Gastrointestinal activity:* If not affected by drugs, gastric motility and absorption begin to return to normal activity. It is unusual for a woman to experience any nausea and vomiting during the third stage.

During the third stage of labor the mother's interest in her baby is apparent if the baby is on her abdomen. In the event the baby is not with the mother, she will express her interest and concern with questions: "Is my baby all right?" "What is it?" "How much does she/he weigh?" She wants to see for herself that her baby is all right and usually is eager to touch and hold her baby (Figure 31-1). She is elated, proud of herself, relieved, and very tired. She also has concerns for herself and may ask if she needs stitches. Prepared mothers are also usually interested in the placenta.

Mothers or couples may want to use the Leboyer approach to childbirth and transition of the baby from intrauterine to extrauterine life. This approach was detailed in Chapter 28.

FIGURE 31-1 Midwife handing baby to mother immediately after birth.

Management Plan for the Third Stage of Labor

This part of the chapter strictly addresses the obstetric management of care of the mother during the third stage of labor. Although not alone in providing care, the midwife is responsible while managing third stage to also initiate or delegate care of the baby (i.e., drying the baby, providing for warmth, ensuring a clear airway) and early mother-baby-family bonding and relationships. This material is presented elsewhere.

How the placental stage of labor is managed can make considerable difference in the amount of blood the mother loses [1]. The Bristol third stage trial in England, where use of oxytocin with delivery of the anterior shoulder is common, showed that there is less blood loss with the active management of the third stage of labor than when third stage is managed physiologically [4]. Active management was defined as giving oxytocin immediately after delivery of the anterior shoulder, clamping the cord immediately after delivery of the baby, and using controlled cord traction for delivery of the placenta. Later studies confirmed a significantly lower blood loss with active management of third stage even in populations at low risk for postpartum hemorrhage [5, 6]. The midwife needs to be sure that there is only one baby to be delivered before administering oxytocin after delivery of the anterior shoulder [7].

Mismanagement of third stage is the largest single cause of third stage hemorrhage. Mismanagement of third stage can also be the cause of uterine inversion and its attendant life-threatening shock. Such disastrous complications can be readily avoided by strict adherence to the following rules:

1. Guard the uterus to keep yourself and anyone else from massaging it prior to placental separation.
2. Do not massage the uterus before placental separation except when partial separation has occurred by natural processes and excessive bleeding is evident (see Chapter 32).
3. Do not pull on the umbilical cord before the placenta separates; *never* pull on the cord with an *uncontracted* uterus.
4. Do not try to deliver the placenta prior to its complete separation except in the emergency situation of third stage hemorrhage (see Chapter 32).
5. Become expert in diagnosing placental separation.
6. If not using active management of third stage with administration of any oxytocin immediately after birth of the anterior shoulder, then discipline yourself in the art of patient waiting and in not feeling pressured into unwise interference with natural processes.

Placental Separation

During initial care of the baby, the midwife must keep one eye on the mother's perineum in order to watch for signs of placental separation and for excessive bleeding. (By the same token, when the midwife is managing third stage, she or he must keep one eye on the baby to continually evaluate the baby's well-being.)

The first step in managing third stage is to evaluate the progress of labor and the mother's condition. One hand is placed on the mother's abdomen to feel, without massaging, the shape and position of the uterus and determine whether it is contracted.

If cord blood is to be collected, now is the time to obtain the specimens. Blood for cord blood gases, if needed, has to be processed promptly. This is obtained by drawing blood directly from a cord artery and, separately, from the cord vein into heparinized syringes. Cord blood is then carefully drained into a small sterile bowl by holding onto the cord while releasing the clamp on the cord. After reclamping the cord, a syringe without a needle is filled with the blood in the basin and subsequently inserted into a blood tube. Blood for cord blood gases cannot be taken from the basin of cord blood as that contains a mixture of venous and arterial blood.

Some midwives fairly routinely "drain the placenta" by simply taking the clamp off the umbilical cord and catching the blood either in a foot basin or a placental pan. The rationale for this action is that draining the placenta decreases its volume, thereby facilitating its separation from the uterine wall. This rationale is of questionable validity but there are no known dangers to draining the placenta. It is worth trying if separation is slow and enough time has passed that you are beginning to be concerned. The only problem is that blood from the placenta can significantly inflate the estimation of the total blood loss unless it is collected separately.

After specimens of cord blood have been collected, the cord is wound around the clamp until the clamp is at the vaginal introitus so that traction can be effectively exerted on the cord when needed; or, if you have another clamp, you can place it on

the cord at the introitus. (Do not release your only clamp on the cord to move it to the introitus or you will have blood spraying everywhere—not a good idea in this day of HIV/AIDS.) This clamp is held with one hand while the other hand continues to guard the uterus.

"Guarding the uterus" means exactly what the words imply. While your hand is in a position to continually ascertain the shape, position, and consistency of the uterus it is also in a position to keep anyone else from massaging the uterus, thereby guarding it and the mother from the complications that can result from such an action. Normal placental separation from the uterine wall is accomplished by the effect of uterine contractions, as detailed earlier in this chapter. If the uterus is massaged before the placenta's separation from the uterine wall, the massage may cause partial separation of the placenta, resulting in hemorrhage. The danger of a partial separation is that a portion of the placenta is still attached to the uterus, and the uterus is unable to contract sufficiently to ligate and collapse the bleeding vessels interwoven through the muscle fibers in the area where separation has occurred. Hemorrhage results. Management of this complication is discussed in Chapter 32.

If you are unsure whether the placenta has separated, you can check by using a modification of the Brandt-Andrews maneuver. Hold the cord taut at the vaginal introitus with one hand, using the clamp for leverage. Bring the tips of your fingers on your abdominal hand, with your fingers close against each other, straight down into the lower abdomen just above the symphysis pubis and watch what happens to the umbilical cord (Figure 31-2). If the cord recedes into the vagina, then the placenta is not separated. If the cord has a feeling of give and remains the same length or extends beyond its position at the vaginal introitus, then the placenta has separated and you may proceed with facilitating placental expulsion. This modified procedure differs from the Brandt-Andrews maneuver in that you make no effort to press on the uterus to hold or push it anteriorly (up in the abdomen), as you would to facilitate expulsion after separation. The modification carries no risk of unintended massage of the uterus prior to separation.

If you are still unsure whether the placenta is separated, there is another method you can use to determine the location of the placenta. Again hold the cord tautly with one hand at the vaginal introitus, and with your other hand follow the cord into

FIGURE 31-2 Checking for placental separation.

the vagina with your examining fingers until you can feel either where the cord inserts into the placenta or where it extends through the cervix and into the uterus beyond your reach. In the latter instance you can assume that the placenta has not separated. In the former instance you will probably find the placenta in or at the cervical os or in the upper vaginal vault and obviously separated. This technique should not be used routinely, but reserved for when there is true doubt or concern, because of both the increased risk of introducing infection every time you put your fingers inside the vagina and the possible additional discomfort to the woman. Generally you do not need to use this technique, but it is handy to know. It is better, however, to sharpen your diagnostic ability by scrupulous attention to the signs of placental separation.

Placental Expulsion

Once you are sure the placenta has separated, you may facilitate the mother's efforts to expel it by using a combination of the Brandt-Andrews maneuver and controlled cord traction. Use your abdominal hand to ensure that the uterus is contracted and brace the body of the uterus by placing the palmar surface of your hand just above the symphysis pubis and pressing against the uterus, lifting it with a slight upward direction toward the umbilicus. At the same time the other hand exerts traction on the cord, using the clamp around which the excess cord is wrapped for leverage. At the same time you ask the woman to push. It is important to remember that the placenta follows the curve of Carus just as the fetus did. Therefore, you should first exert traction on the cord downward and then upward as the placenta comes into view for the actual delivery.

Never exert traction on the cord at any time unless the uterus is contracted. If the uterus is not contracted and the placenta or membranes are adhering to the uterine wall, inversion of the uterus is a potential danger. In such circumstances cord traction may bring not only the placenta but also the attached uterine wall. This is an obstetric disaster and is discussed in Chapter 32. Inversion is prevented by checking to make sure the uterus is contracted before exerting any degree of cord traction and by not attempting to deliver the placenta by pulling on the cord before being absolutely sure placental separation has occurred.

Likewise, pulling on the cord can cause the cord to detach from the placenta (evulsion), thereby requiring manual removal of the placenta and exposing the woman to unnecessary trauma and an increased risk of intrauterine infection.

Bracing of the uterus during the expulsion of the placenta and being scrupulously careful not to use the uterus as a piston to push the placenta through the vaginal canal has important gynecological implications. Using the uterus as a piston stretches the cardinal ligaments and may potentiate uterine prolapse in later life, especially if done vigorously or repeated with each childbearing experience. Not using the uterus as a piston thus becomes a preventive measure to uterine prolapse.

It should be noted that placental expulsion is not a problem requiring facilitative efforts by the midwife if the mother uses a natural position such as squatting. Positioning the woman in a flat or slightly elevated recumbent position negates both the down and outward direction of the vagina and the effect of gravity, which are the natural facilitative forces when the woman is in an upright position.

A basin is placed below the perineum to catch blood and to hold the placenta when it is delivered. If the woman is in a lithotomy position the pan is braced between the woman's buttocks and the midwife's body, leaving both hands free to manage the third stage of labor. Use of the placenta basin to catch the blood makes it possible to measure the majority of the blood loss and also minimizes mess.

As the placenta is delivered, it is either allowed to slide gently down the side of the placenta basin, which is positioned more on its side at the vaginal introitus for this purpose, or is delivered into the midwife's hands at the vaginal introitus. Either way the principle involved is not to let the placenta drop any distance from the level of the vaginal introitus since this might cause the after-coming membranes, which may still be peeling off the uterine wall as the placenta is delivered, to tear and break off and be retained (see Figure 31-3).

The third stage has ended if the membranes immediately follow the placenta and are delivered with the placenta. However, sometimes the membranes trail behind and threaten to break off if tension is applied to them. In such an instance, they may be teased out in one of two ways.

One way is to take a clamp (a large Kelly clamp is preferable; a large ring forceps will do) and place it on the membranes at the vaginal introitus. If the mother is not in bed in dorsal position, one hand continues to support the placenta, or the basin with the placenta in it, in order to prevent tension on the membranes. Otherwise your hand can be on the

FIGURE 31-3 Delivery of the placenta.
Source: Photograph by Artemis/Harriette Hartigan.

mother's abdomen stabilizing the uterus. Your other hand manipulates the clamped membranes by gently rocking them up and down and side to side while exerting the slightest bit of traction on them (see Figure 31-4). You will be able to judge the appropriate amount of traction because you will feel when the steady "give" of the membranes being teased out becomes a "tearing give" instead. As the membranes are gradually teased out, the clamp moves away from the vaginal introitus. You should, therefore, periodically reclamp the membranes at the introitus whenever the clamp moves an inch or two away from the introitus because you have better control manipulating the membranes the closer the clamp is to the vaginal introitus. The process is continued until the membranes are delivered.

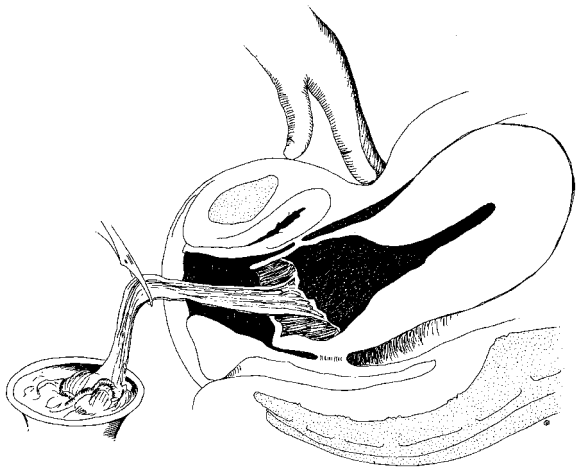

FIGURE 31-4 Teasing out the membranes.
Source: From *Oxorn-Foote Human Labor and Birth*, 5th ed. Norwalk, CT: Appleton-Century-Crofts, 1986, p. 143. Reproduced by permission.

The other way to tease out the membranes is to hold the placenta in your hands and turn it over and over. This causes the membranes to twist and gradually teases them out until they are delivered. This method may be more difficult for inexperienced hands because the placenta is slippery and it is not as easy to control the amount of tension on the membranes as it is with the first method.

If the membranes do break off while you are trying to tease them out, third stage is considered ended. Sometimes the torn end of the membranes may be visualized during the cervical inspection and more can be teased out. The generally accepted management if a portion of the membranes is retained is that uterine exploration to remove them is not warranted. Uterine exploration is traumatic to the woman and increases the risk of intrauterine infection. Retention of a portion of the membranes is not a cause of hemorrhage, as is retention of placental fragments. The retained portion of the membranes will eventually be expelled with the lochia; however they should be expelled as soon as possible as their retention does increase the risk of endometritis. To achieve this more rapid expulsion, a full methylergonovine (Methergine) series should be ordered for the woman: Methergine 0.2 mg every 4 hr for 6 doses. Some midwives follow this initial series with 0.2 mg Methergine t.i.d. for 3 days. If the estimated portion of membranes retained was a large amount, some midwives also give an immediate dose of Methergine 0.2 mg intramuscularly. Methergine is contraindicated if the woman is hypertensive.

Evaluation of the Mother

The mother's blood pressure and pulse should be taken at least once during the third stage and more often if the third stage is longer than average or the blood pressure and pulse are either bordering on or in abnormal ranges. This monitoring not only follows through on evaluation of any previous elevations but is necessary as a means of screening for shock in the event of hemorrhage.

CHAPTER

32

Third Stage Complications and Management

Third stage complications relate to the placenta and its attachment to the uterus. With the exception of a placenta that is retained for reasons other than placenta accreta, all are life-threatening. The midwife must know what to do to maintain the woman or resolve the problem while awaiting the physician. Third stage complications discussed in this chapter are retained placenta, third stage hemorrhage, placenta accreta, and uterine inversion.

Retained Placenta

A retained placenta is a placenta that has not separated and creates no visible hemorrhage. The definition of retained placenta is based on the length of time that elapses between the birth of the baby and the expected delivery of the placenta. Some clinicians intervene after 5 minutes. Most midwives will wait half an hour for the placenta to deliver before saying it is retained.

Gestational age is associated with length of third stage. Decreasing gestational age is associated with a longer third stage. The frequency of manual removal of the placenta is also associated with preterm delivery. Hemorrhage is increased with both decreasing gestational age and increased manual removal [1].

Natural interventions the midwife may initiate when there is a retained placenta include putting the baby to breast, nipple stimulation, having the woman assume a squatting position, and providing privacy for the couple for noncoital lovemaking. Other actions include ensuring an empty bladder (by means of catheterization if the woman has a full bladder and is unable to void) and administering an intraumbilical oxytocin injection with a solution of 10 IU of Pitocin diluted with 20 cc of normal saline into the umbilical vein [2, 3].

During the period of time it takes to implement these interventions, the midwife monitors the woman's vital signs; checks for other signs of shock, visible external bleeding, and hidden internal bleeding (increased fundal height); and notifies the consulting physician of the situation.

If the placenta still has not delivered, the next step is manual removal. This should be done in-hospital, necessitating transfer of the woman if she is in an out-of-hospital setting. The in-hospital setting is the proper setting for nonemergency manual removal of the placenta, both for reasons of safety and to enable the woman to receive anesthesia or deep analgesia for a painful procedure. The procedure for manual removal of the placenta is discussed in Chapter 76. In the nonemergency situation, the midwife can manually remove the placenta in consultation with the physician. Placenta accreta should be in the back of the midwife's mind when the placenta does not spontaneously deliver within a reasonable period of time or when a plane of cleavage is not evident upon attempted manual removal.

Third Stage Hemorrhage

Third stage hemorrhage is due to partial separation of the placenta. The most common reason for partial separation is mismanagement of the third stage, usually involving uterine massage prior to placental separation. Partial separation may occur naturally during the physiological separation of the placenta but this condition is usually quickly transient. Partial separation resulting from massage of the uterus before the placenta's separation from the uterine wall is not physiological and carries with it the almost guaranteed result of third stage hemorrhage.

Normally there is some blood loss during the third stage, insofar as a sudden trickle or small gush of blood is a sign of placental separation. However, when there is a steady flow of blood and you have located the placenta within the uterus and determined that it has not fully separated, you need to institute measures for managing third stage hemorrhage immediately. These measures are as follows:

1. Have the nursing staff (in-hospital), a nurse or your assistant (birth center), or your assistant or a family member (home) give your consulting physician a *STAT* call. Also call an ambulance if you are in an out-of-hospital setting. Your consulting physician most likely will meet you at the hospital.
2. Thoroughly massage the uterus. Although this should never be done prior to placental separation in a normal situation, it is the first action to take when faced with a partially separated placenta and third stage hemorrhage. This is because a thorough massage at this time may complete placental separation. This action, with a well-contracted uterus, is combined with controlled cord traction so as separation is completed delivery of the placenta occurs immediately.
3. While doing Step 2, have the nursing staff or your assistant take the following steps:
   a. Make sure that the IV is patent or start one with a 16-gauge needle and Ringer's lactate solution if the woman does not have an IV.
   b. If the woman already has a patent IV, change the solution to Ringer's lactate for infusion.
   c. Draw a type and crossmatch if one has not already been drawn.
   d. Watch for signs and symptoms of shock and start monitoring the woman's blood pressure and pulse; lower the woman's head to flat on the bed if indicated.
4. If the placenta has not yet delivered, manually remove it (see Chapter 76). Catheterize the woman first unless you are sure that her bladder is empty.
5. If the placenta has not yet delivered and you do not know how to remove it manually, bleeding is steady and continuing, and the physician (in-hospital) or ambulance (out-of-hospital) has not yet arrived, then the addition of oxytocin to the IV infusion is in order. The purpose of oxytocin is to contract the uterus in an effort to cause completion of placental separation. Usually this action is delayed unless absolutely necessary. Oxytocin causes the cervix to close, thereby making manual removal of the placenta difficult as well as increasing the incidence of placental retention after its separation. However, an oxytocin preparation that causes intermittent contractions (Pitocin, Oxytocin, Syntocinon) is preferred over a preparation that causes a sustained contraction (Methergine). The former is less likely to cause the cervix to clamp down.

The incidence of third stage hemorrhage is rare *if* third stage is *not* mismanaged. Nevertheless, it can happen, even with the best third stage management. An infectious process with a high temperature during pregnancy increases placental adherence, as does any intrauterine infection, disease processes of the fetal membranes, or previous cesarean section. History of a previous third stage hemorrhage should make you anticipatory, alert, and wary. Third stage hemorrhage will occur when there is a partial placenta accreta.

Placenta Accreta

Placenta accreta is an abnormal partial or total adherence of the placenta to the uterine wall. In placenta accreta the placenta adheres directly to the myometrium with either defective decidua or no decidua in between. When the chorionic villi extend further than contact with the myometrium and actually penetrate the uterine wall, the condition is called *placenta increta*. *Placenta percreta* occurs when the chorionic villi invade through the entire uterine wall to the serosa layer. These conditions are rare complications, although there is an increased incidence of placenta accreta when the woman has placenta previa, previous cesarean section, or an unexplained elevated MSAFP [4].

A partial placenta accreta is first seen as an acute third stage hemorrhage resulting from a par-

tially separated placenta. Clinical diagnosis is made when the placenta's adherence is discovered during attempted manual removal. Definitive diagnosis of placenta accreta is made by microscopic examination. A complete placenta accreta has no signs and symptoms since there is no partial separation and, therefore, no hemorrhage. It is discovered during attempted manual removal of the retained placenta.

Placenta accreta is an obstetric disaster. Any suspicion that a retained placenta is due to placenta accreta requires that the midwife immediately place an emergency call for the consulting physician. If the woman is in an out-of-hospital setting, she should be transferred to the hospital in an ambulance immediately. While waiting, the midwife does all she or he can do to maintain the woman and prepare her for immediate surgery. Under no circumstances should any further attempt be made to remove the placenta, as this will only cause greater hemorrhage and possible rupture or inversion of the uterus. The physician probably will manage the care of the woman by performing an emergency hysterectomy.

Uterine Inversion

Uterine inversion is the situation in which the uterus literally turns inside out so that the inside of the fundus either (1) protrudes through the cervical os (incomplete), (2) descends to immediately within the vaginal introitus (complete), or (3) extrudes beyond the vulva (prolapsed). In the first two positions, the fundus, on vaginal examination, feels like a soft tumor filling the cervical or vaginal orifice. Abdominally, a funnel-like depression may be felt instead of the fundus (see Figure 32-1).

Basically there are three conditions that combine to create a situation favorable to uterine inversion. These are (1) uterine atony, or uncontracted uterus, (2) a patulous, dilated cervix, and (3) fundal pressure or traction caused by pulling on the umbilical cord or placenta.

Although it is possible for uterine inversion to occur spontaneously, it is more likely to be the result of mismanagement of the third stage of labor. In considering the three conditions just mentioned, it becomes obvious that it is the third condition over which the midwife has the most control. Uterine inversion can take place as a result of fundal pressure caused by a sudden increase in intra-abdominal pressure, such as with coughing. However, it is more apt to occur from any or a combination of the following, each of which is an act of mismanagement:

1. Applying fundal pressure with a hand on an uncontracted uterus, such as might be done in facilitating expulsion of the placenta if the uterus were wrongly being used as a piston
2. Having the mother push to help expel the placenta without first checking to see that the uterus is contracted
3. Exerting cord traction prior to placental separation
4. Pulling on the placenta during manual removal prior to total placental separation

In approximately three-quarters of the cases of uterine inversion, the placenta is completely or partially attached to the uterine fundus. Spontaneous uterine inversion fortunately is an extremely rare obstetric accident.

The major result of uterine inversion is shock. Excessive bleeding and severe uterine pain may or may not be present. Diagnosis is made by observation of the uterine lining outside the vulva or on the basis of findings from vaginal and abdominal examination. Uterine inversion should be suspected and a diagnostic vaginal examination performed if the woman goes into shock after giving birth without obvious reason.

In the event of uterine inversion, the consulting physician should be notified immediately. If the woman is in an out-of-hospital setting, she should be transferred to the hospital in an ambulance immediately. While waiting for the ambulance, the midwife should start an IV and apply normal saline packs to the inverted uterus. The woman should be maintained and treated for shock until the physician arrives at the hospital. The physician probably will manage the care of the woman by treating for shock and by repositioning the uterus. Repositioning the uterus can be done manually if inversion is diagnosed and the manipulation is performed immediately after the inversion occurs. However, if there has been a time interval between inversion and diagnosis, which can happen in insidious cases during the postpartal period, then operative procedures will be required in order to reposition the uterus.

Repositioning of the uterus is done with the placenta still attached. Blood loss is usually related to the length of time the uterus is inverted but will be less if the placenta is removed *after* the uterus is replaced [5]. Manual repositioning is accomplished by placing one entire hand in the vagina with the

fingertips around the circumference of the junction where the uterus has turned on itself and the inverted fundus in the palm of the hand (see Figure 32-1). Pressure is then applied with the palm of the hand on the fundus and the fingertips on the uterine walls. The fingertips walk up the uterine walls as the fundus is repositioned. Care must be taken not to puncture or rupture the soft uterine wall. At the same time the entire uterus is lifted high out of the pelvis, above the level of the umbilicus, and held there for several minutes. This puts tension on the uterine ligaments, which keeps the uterus reinverted. This procedure is usually quite painful, and deep anesthesia or an intravenous uterine relaxant (e.g., magnesium sulfate, halogenated anesthetic agents, terbutaline) is desirable [6]. All of these drugs have hypotensive side effects and should be used with great caution in the event of excessive blood loss and a falling blood pressure. The midwife should know this technique and use it, with or without drug-induced uterine relaxation, in the event arrival of the physician is going to be delayed. Most midwives will never see this complication.

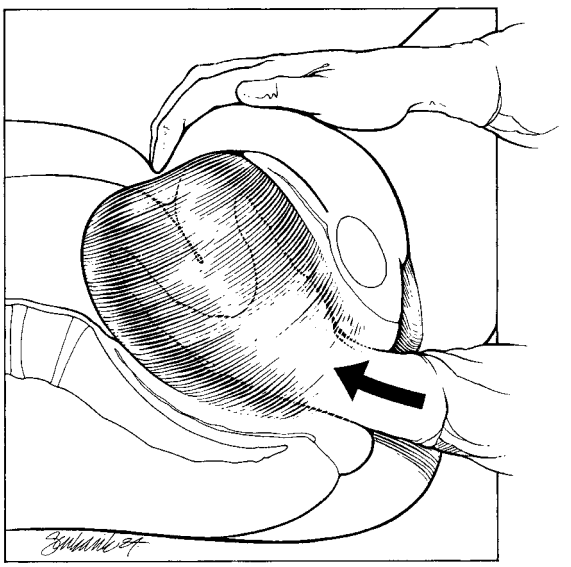

FIGURE 32-1 Repositioning the inverted uterus. Note that the abdominal hand feels a funnel-like depression instead of the fundus.

CHAPTER

33

The Normal Fourth Stage of Labor

Immediately following the birth of the placenta, a number of maternal changes occur as the physical and emotional stresses of labor and birth resolve into postpartum recovery and bonding. At the same time, the midwife has a series of evaluations and tasks to complete related to the intrapartum period. Although intrapartum is complete, the term *fourth stage of labor* identifies this first postpartum hour as one requiring close observation and assessment. The midwife has responsibility during this hour for the following:

1. Evaluation of uterine contractility and bleeding
2. Inspection and evaluation of the cervix, vagina, and perineum
3. Inspection and evaluation of the placenta, membranes, and umbilical cord
4. Assessment and repair of any lacerations or an episiotomy
5. Evaluation of vital signs and other physiological changes that indicate recovery

Throughout this period another activity of paramount importance is taking place: family relationships are being formed (Figure 33-1). Newborns are alert, able to see and hear those close by, and responsive to the touch of their mother's body against their own. Facilitation of this taking-in phase and ensuring the mother's ability to participate are vital steps in the process of bonding. Bonding is an ongoing process. Thus, urgent medical intervention for either the mother or baby takes precedence.

Just as the midwife must be aware of all assessments of the mother during this time, such as her vital signs, she also has responsibility for knowing about the baby's vital signs and physiologic indications of well-being. Evaluation of the baby is discussed in the chapters on the neonate.

Database for the Fourth Stage of Labor

The components of the database for the fourth stage of labor include information needed for the evaluation and management of the care of the mother during the first hour postpartum, and knowledge of the taking in phase of the newborn and the maternal child bonding process.

The Uterus

After delivery of the placenta, the uterus can be found in the middle of the abdomen approximately two-thirds to three-fourths of the way up between the symphysis pubis and the umbilicus (see Figure

FIGURE 33-1 New family relationships.

42-1). If the uterus is found centrally above the umbilicus, it suggests the presence of blood and clots in the uterus, which need to be expressed and expelled. A uterus above the umbilicus and displaced, most commonly to the right, is more likely to represent a full bladder. A full bladder displaces the uterus, preventing contraction and allowing increased bleeding to occur. If the mother is unable to void spontaneously at this time, the bladder should be emptied by catheter to prevent excessive bleeding.

The normally contracted uterus should be firm to the touch. If the upper uterine segment is hard but bleeding persists, assessment of the lower segment is essential. A soft, boggy, hypotonic uterus is not well contracted; uterine atony is the major cause of immediate postpartum hemorrhage. Effective uterine hemostasis is effected by the contraction of the intertwining muscle fibers of the myometrium. These fibers serve as ligatures for the open blood vessels at the placental site. In general, thrombi form in the distal blood vessels of the decidua, rather than in myometrial vessels. This mechanism—by which ligation occurs in the myometrium and thrombosis in the decidua—is important because it prevents the release of thrombi into the systemic circulation.

The Cervix, Vagina, and Perineum

The cervix, vagina, and perineum are inspected for lacerations, bruising, and early hematoma formation. Since inspection of the cervix may be painful for the mother, it is performed only when indicated, as discussed in the management plan later in this chapter. Immediately after the birth, the cervix is patulous, floppy, and thick. An anterior lip during labor, or any portion of the cervix trapped by the descent of the fetal head for a prolonged period, is reflected by increased edema and bruising in that area. Vaginal tone, as well as the appearance of the vaginal tissue itself, is affected by the stretching that has occurred during the second stage of labor. Edema or bruising at the introitus or throughout the perineal area should be noted.

The Placenta, Membranes, and Umbilical Cord

Inspection of the placental unit requires that the midwife be able to identify the different placental types and cord insertions. This information, along with the procedure for placental inspection, is discussed in Chapter 74. The midwife must be aware of whether the placenta and membranes are complete, and whether any abnormalities, such as a true knot or two-vessel cord, are present.

Repair of Episiotomy and Lacerations

Repair of episiotomies and lacerations entails knowledge of perineal anatomy, types of stitches, hemostasis, surgical asepsis, and wound healing. The relevant material is found in Chapter 79. The midwife should also be aware of suture and needle types, standard instruments, and equipment available in the setting.

Physiological Status

Many of the physiological changes that occur during labor and birth return to prelabor levels and stabilize during the first hour postpartum. Other physiological manifestations seen during this period result from or are the aftermath of the stresses of labor. Knowledge of normal findings is essential to accurate evaluation of the mother.

Vital Signs Blood pressure, pulse, and respiration should stabilize at prelabor levels during the first postpartum hour. Monitoring blood pressure and pulse regularly during this interval is one means of detecting shock from excessive blood loss. The mother's temperature continues to be slightly elevated but normally remains below 100.4°F (38.0°C).

Shaking It is not uncommon for a woman to experience a shaking tremor during the fourth stage of labor; such shaking is considered normal in the absence of fever >100.4°F (38.0°C) or other signs of infection. This response may result from release of tension and energy expenditure during birth; the physiologic response to the decrease in intra-abdominal volume and hematologic shift also play a role.

Gastrointestinal System Nausea and vomiting, if present during labor, should be resolved. Thirst is common, and many mothers report hunger shortly thereafter.

Renal System A hypotonic bladder with significant urinary retention and enlargement is not uncommon. Pressure and compression on the bladder and urethra during labor and birth are the cause. Keeping the woman's bladder empty during labor can reduce trauma. After birth, it is important for the bladder to stay empty to prevent uterine dis-

placement and atony. A poorly contracted uterus increases both bleeding and the severity of pain.

Management Plan for the Fourth Stage of Labor

Evaluation and Management of the Uterus

The midwife's first action following delivery of the placenta is to evaluate uterine consistency and to massage it as needed to bring it into a state of firm contraction. At the same time, the degree of cervical/uterine descent into the vagina can be assessed. Most of the time a healthy uterus can contract on its own. If the midwife determines that the uterus is relaxed, or atonic, the cause should be assessed and management to fully contract the uterus be initiated promptly. Failure to attend to the problem of atony can lead to an immediate postpartum hemorrhage (see Chapter 34). The following are factors to consider:

1. Uterine consistency; the uterus should be well contracted, feeling firm and hard to the touch.
2. Potential for uterine relaxation, including the following:
   a. history of uterine atony in a prior pregnancy
   b. maternal status as a grand multipara
   c. overdistension of the uterus, as with multiple gestation, polyhydramnios, or macrosomia
   d. induction or augmentation of labor
   e. precipitous labor
   f. prolonged labor
3. Completeness of placenta and membranes on inspection—i.e., evidence of possible retained placental fragments or membranes
4. Status of the urinary bladder
5. Availability of a second person to monitor uterine consistency and lochial flow, and assist with uterine massage
6. Ability of the mother-baby pair to initiate early breastfeeding (see Figure 33-2)

If the mother intends to breastfeed, placing the baby at breast may stimulate uterine contractions and promote maintenance of firm tone. If this is not possible, the use of oxytocics can be considered. Factors considered in using oxytocic drugs in the immediate postpartum period should include the woman's need for this therapy, and the action and effect of the different drugs available. The action, effect, dosage, and route of the different oxytocic drugs, and their use in control of immediate postpartum hemorrhage are discussed in Chapter 34.

FIGURE 33-2 Breastfeeding within the first hour of life.

Inspection and Evaluation of the Cervix, Vagina, and Perineum

Having assured that the uterus is well contracted and that any bleeding is from another source, the midwife inspects the perineum, lower vagina, and periurethral areas for bruising, hematoma formation, lacerations, or torn and bleeding blood vessels. If an episiotomy has been cut, it is evaluated for depth and for any extensions.

Next, consideration is given to inspection of the vaginal vault and cervix for lacerations or injury. In most normal spontaneous vaginal births, there will be no indication for this evaluation, and it need not be performed. Indications for such an examination include the following:

1. A steady flow or trickle of bright red vaginal bleeding, from above any observed lacerations, after uterine contraction is confirmed
2. Rapid or precipitous labor
3. Manipulation of the cervix during labor—e.g., to reduce an anterior lip
4. Maternal pushing prior to full cervical dilation
5. Operative vaginal delivery with forceps or vacuum
6. Traumatic delivery—e.g., shoulder dystocia

The presence of any of these factors indicates the need for cervical inspection and ascertainment of the need for repair. Some clinicians advocate routine inspection of the cervix, using the rationale that this eliminates cervical laceration as a cause of later hemorrhage. However, cervical inspection is not required in the presence of normal labor and birth without persistent bleeding. The midwife needs to master the thorough, rapid performance of this skill

for those occasions when it is necessary, since it is frequently uncomfortable or even painful for the mother. The technique of cervical inspection is discussed in Chapter 75.

Finally, the midwife should evaluate the perianal area for hemorrhoid formation and for any small skin tears. If an episiotomy has been cut or lacerations have occurred, assessment of extension into the rectal area is included in this inspection.

Inspection and Evaluation of the Placenta, Membranes, and Umbilical Cord

Even though the midwife may have performed a quick, cursory inspection of the placenta, membranes, and cord as they delivered, it is essential to completely examine them prior to repairing lacerations or an episiotomy. First, if the midwife finds evidence of retained placental fragments or membranes, the uterus must be explored; retained fragments can cause hemorrhage later as well as immediately after the birth. Second, delaying exploration until after any repair work is done will put tension on the suture line and may cause it to break down. Examination of the placenta, membrane, and cord is detailed in Chapter 74. Exploration of the uterus is described in Chapter 77.

Repair of Lacerations or Episiotomy

This step follows the evaluation of the placenta, as mentioned above. The uterus is checked for consistency once more prior to this step. The condition of the entire vaginal area should be considered before suturing begins. A plan should develop in the midwife's mind that facilitates hemostasis and the reestablishment of normal anatomy as the repair progresses; small, well-approximated first degree lacerations that are not bleeding may not require repair. Basic stitches used in the repair of lacerations, manipulation of the needle holder and suture, and step-by-step repair of a midline episiotomy, mediolateral episiotomy, and lacerations are detailed in Chapter 79.

Completing the Immediate Postpartum Evaluation

After all inspection, evaluation, and repair is complete, the midwife assesses the uterine fundus again. This provides an opportunity to assess tone, evaluate the effect of uterine massage on lochial flow, and express any accumulated clots. Next, a final vaginal examination is performed, to ensure that any gauze packing has been removed, evaluate the consistency of the lower uterine segment as needed, and check the status of any repairs. Finally, the midwife cleans the perineal area, vulva, inner thighs, buttocks, and perianal area, using the same principles observed when washing the area before delivery. Dried blood and secretions in this area can be sticky and irritating; this procedure will make the woman more comfortable. Clean absorbent bed pads and fresh linen are provided, and a perineal pad or ice pack may be placed against the perineum. Ice is used to decrease edema of the vulva, and to cool or comfort tissues bruised by the delivery process. Particularly if the woman has sustained significant lacerations, or smaller tears in particularly sensitive areas such as around the clitoris, ice may offer relief. Chemical ice packs, or crushed ice in a glove or small plastic bag, can be used; in either case, an insulating layer, such as a washcloth or pad should be between the ice and the woman's skin.

If women deliver or have vaginal repairs in lithotomy position, both legs are lifted down from the stirrups at the same time to reduce back strain, potential nerve compression, and physical discomfort, which may occur if one leg is down and the other is still up in a stirrup. The preferred technique is to bring her legs together and support her legs as she lowers them simultaneously to a resting position.

After completion of all tasks related to the mother's well-being, the midwife removes any sharps from her sterile field and straightens her work area, minimizing risk of an injury or exposure to blood and body fluids for others.

Monitoring Physiological Well-Being

Throughout the first hour after birth, the mother's vital signs, uterus, lochia, perineum, and bladder are regularly monitored and evaluated until all are stabilized in the normal range.

Vital Signs Monitoring the mother's blood pressure, pulse, and respirations begins immediately following the delivery of the placenta and continues every 15 minutes until the vital signs are stable at prelabor levels, or until a determination is made that a problem requiring more intensive monitoring exists.

In addition, the temperature is taken at least once during this period. New mothers are often thirsty, and all healthy mothers should be encouraged to drink liberally, particularly non-caffeine beverages such as water or juice. As soon as food is available, she can eat if she is hungry. However,

what she eats may be limited by what food is available or can be prepared at the site of birth.

Maternal shakiness or tremor not associated with infection can be relieved with warm blankets, reassurance, and the use of the same progressive relaxation and controlled breathing techniques she learned to use for labor relief.

Uterine Consistency and Lochia Uterine tone and amount of lochial flow are assessed simultaneously by regular massage of the uterine fundus. A well-contracted uterus will not demonstrate increased bleeding when massaged. In contrast, if the uterus has a tendency to relax and become boggy, the lochial flow will be moderate or large. This is assessed most easily by directly observing for an increase in lochia or expressed clots while massaging the fundus. Persistent heavy lochia when the fundus is well contracted will require further assessment.

Support to the lower uterus during massage prevents stretching the cardinal ligaments. To perform uterine massage correctly, grasp the lower uterus abdominally just above the symphysis pubis and hold it in place with one hand while massaging with the other. Effective uterine massage involves more than the anterior slope of the fundus. The entire fundus—anterior, lateral, and posterior—must be reached. This procedure is done quickly with a firm, gentle touch. As you begin, warn the mother that the procedure may be painful and explain why this is necessary. Such thorough massage can be avoided if the uterus is never allowed to become soft. Breastfeeding is an effective method of improving uterine tone, but few infants stay at the breast for a substantial portion of the first hour of life. Maintaining frequent light massage is also effective; if the nurse or birth assistant is unable to remain at the bedside throughout this time, the mother herself can be shown how to maintain constant, gentle contact and periodic light massage. She should learn this technique now in any event, since performing uterine massage periodically will continue to promote uterine contractions. Involving the mother encourages her to participate in managing her own care and be more knowledgeable about her body; it may lessen bleeding, and thus prevent the need for more thorough massage. Finally, if a woman has demonstrated risks for postpartum hemorrhage, oxytocic agents can be continued through this hour.

The mother should also be taught how to gently massage her uterus and check her lochia and encouraged to do so regularly for the first day or so after birth. Breastfeeding mothers can be reminded that nursing will be associated with afterbirth pains for a few days, directly related to the contraction of a uterus stimulated by pitocin release as the baby suckles.

Perineum Ongoing evaluation of edema, bruising, and possible hematoma formation is performed at each check of the lochial flow. This includes observation of the perianal area for hemorrhoids. In addition to application of ice packs, astringents such as witch hazel or Tucks Pads, or anesthetic/analgesic sprays or creams can be used to decrease local discomfort.

Bladder The bladder is assessed again near the end of this time and must be emptied if it is filling and has displaced the uterus. Hypotonicity of the bladder may cause loss of the urge to urinate. Women should always be encouraged to void spontaneously before catheterization is considered, since catheterization, besides being uncomfortable, carries an increased risk of infection. Whenever possible, the woman should be escorted to the bathroom and supported as needed; this is certainly the most comfortable and effective method of promoting urination. Unresolved epidural or spinal anesthesia, the lingering effects of late labor analgesia, or excessive blood loss may prevent this, in which case offering a bedpan is appropriate. Allowing adequate time for the mother to relax and urination to begin is important. Many midwives describe the benefits of using water to promote voiding, for example, by running water in the sink or tub, pouring warm water over the perineal area, or even putting the new mother into a warm shower. Relaxation measures that were helpful in labor may also help the mother at this time.

Initiation of Family Relationships with the Newborn

At the same time that the process of birth is being completed, a new process is beginning, equally as essential to the future of the family. This initial time—in which mother is most open to her infant and the newborn in his or her period of initial reactivity is equally open to new experience—is most valuable for the process of bonding. Klaus and Kennell, among other researchers, have promoted the importance of a sensitive period following birth

[1]. The idea of a sensitive period can be seen at work in the early behaviors of parents who reach out toward their infants, stroke or gently explore the newborn's body, change vocal tone and rhythm to a soothing pattern, position the child *en face*, etc. Cultural and individual variation persists in this as in so many human behaviors. The midwife needs to be aware that women will demonstrate a diversity of behaviors and be open to their range.

Uninterrupted contact between mother and infant during the hour after birth is well demonstrated to promote this attachment process. Righard and Alade studied healthy newborns and observed that, if left undressed on the mother's abdomen at birth, infants would soon begin to creep toward the nipple and latch on [2]. Widström and colleagues, who also studied neonates and their early suckling behaviors, found that mothers whose infants were in skin to skin contact and attempted to nurse in the first hour spent more time with their infants and increased the amount of talking to the infant during breastfeeding [3]. The time from birth to effective suckling is approximately an hour, suggesting that at least an hour of uninterrupted contact is important [2, 4] (see Figure 33-3).

Involving the father or other close family members in this period can promote the family's enjoyment (see Figure 33-4). However, limiting extended visits by well-meaning family and friends during this immediate period can also be a factor in maintaining mother-infant contact. The midwife can be an important part of maintaining the balance between the important work of family bonding and family celebration.

FIGURE 33-3 Initial breastfeeding during the fourth stage.

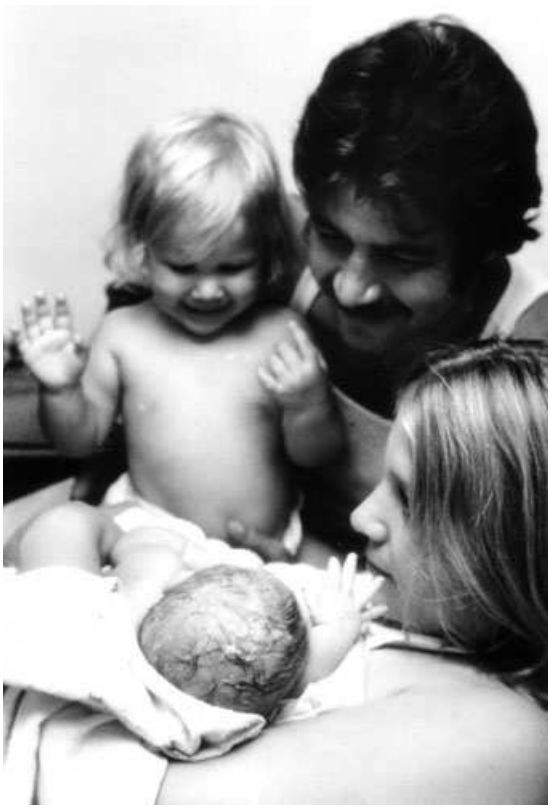

FIGURE 33-4 Family bonding.
Source: Photograph by Artemis/Harriette Hartigan.

For the hospital-based midwife, promotion of this prolonged contact may also involve reeducating hospital staff to provide newborn care at the mother's bedside and delay procedures such as footprinting until after the baby has breastfed. Often, the midwife will need to encourage mothers who are timid about initiating breastfeeding or tired from a long labor to maintain contact. She will also need to attend to her own behavior, working around the baby as she performs her evaluation and completes her tasks from the birth. When medical necessity requires interrupting this period—for example, to resuscitate an infant or deal with postpartum hemorrhage—attention is paid to reuniting the mother-infant couple as soon as possible.

The process of family attachment and relationship formation is an ongoing one. This hour alone is not enough to complete human bonding, nor is its absence fatal to the development of healthy families. It is, however, a particularly beneficial period; thus it is imperative for the midwife to value and promote this process.

CHAPTER

34

Management of Immediate Postpartum Hemorrhage

Postpartum hemorrhage can be categorized as early (from delivery to 24 hours postpartum) or late (24 hours to 6 weeks postpartum). Early postpartum hemorrhage has greater blood loss and morbidity and is more common [1]. This chapter addresses postpartum hemorrhage that occurs immediately after delivery of the placenta.

Hemorrhage, by definition, is an abnormal loss of blood. The average blood loss during an uncomplicated obstetrician-conducted vaginal delivery is slightly more than 500 mL; the average blood loss during a cesarean section is approximately 1000 mL [2]. The average blood loss for a midwife-conducted vaginal delivery is observed to be less but has not been studied and verified. The probable reason for the difference is the fact that midwives do not routinely cut episiotomies and have mastered the art of delivery over an intact perineum. The average blood loss with an uncomplicated obstetrician-conducted vaginal delivery most likely reflects the blood loss from a much higher incidence of episiotomy and laceration.

The long-held and widely accepted definition of postpartum hemorrhage in obstetrics is a loss of 500 milliliters of blood or more. Note that the amount of blood loss specified in this definition of *hemorrhage* is the same as the average blood loss in vaginal delivery by an obstetrician; this is attributable to the fact that the clinical estimation of blood loss is underestimated by 30 to 50 percent [3, 4]. "Thus, the 'classic' definition of postpartum hemorrhage rests on a systematic tendency to underestimate measured blood loss" [5].

One does not, however, wait until there has been a loss of 500 milliliters of blood (actual or estimated) before deciding that the woman may in fact be hemorrhaging and taking appropriate action. Early action in the presence of excessive bleeding may prevent actual hemorrhage and certainly the life-threatening sequelae of hemorrhage that are first manifested by the signs and symptoms of shock.

Causes of Immediate Postpartum Hemorrhage

Immediate postpartum hemorrhage is hemorrhaging that takes place immediately after completion of the delivery of the placenta, which marks the end of the third stage of labor. In 80 to 90 percent of cases of immediate postpartum hemorrhage, the cause is uterine atony resulting from any number of predisposing factors (see below) or from incomplete delivery of the placenta—that is, retained placental fragments or cotyledons. The latter is also a cause of delayed postpartum hemorrhage. The other causes of immediate postpartum hemorrhage that a midwife might encounter include (1) cervical lacerations, (2) extensive lacerations of the vagina and perineum, and, (3) very rarely, laceration of the lower uterine segment or uterine rupture.

There are a number of other situations in which immediate postpartum hemorrhage may be encountered. However, these are, or relate to, abnormal situations in which the woman would already be under the management of a physician (e.g., placenta pre-

via, abruptio placentae, cesarean section, deep and prolonged inhalation anesthesia, operative procedures such as version and extraction, prolonged retention of a dead fetus following intrauterine death).

Predisposing Factors

Uterine atony and the possibility of immediate postpartum hemorrhage in essentially normal women usually can be anticipated prior to delivery. The following conditions should alert the midwife to the potential of immediate postpartum hemorrhage due to uterine atony:

1. Overdistended uterus (multiple gestation, polyhydramnios, a large baby)
2. Oxytocin induction or augmentation
3. Rapid or precipitous labor and delivery
4. Prolonged first and second stage of labor
5. Grand multiparity
6. History of uterine atony/postpartum hemorrhage with previous childbearing
7. Use of uterine-relaxing agents such as magnesium sulfate and terbutaline

Preparatory Measures

Anticipation of immediate postpartum hemorrhage as a result of uterine atony allows the midwife to take preparatory measures to most quickly and effectively prevent or control the amount of blood loss as much as possible. These preparatory measures include the following:

1. Make a deliberate decision regarding the locale of birth. If she has a combination of two or more predisposing factors, the woman should be in the hospital.
2. Alert your consulting physician to the possibility so he or she is prepared for a *STAT* call if needed.
3. Alert the nursing staff to the possibility and request that they draw up and have ready to give your order for oxytocic drugs for use immediately after delivery of the placenta.
4. Make sure that an intravenous infusion is started with a 16-gauge needle and that this venous route is patent at the time of delivery. Use 5% dextrose in lactated Ringer's solution.
5. Draw a type and crossmatch preparatory for obtaining blood if needed.
6. Make sure the woman's bladder is empty at the time of delivery.

Action, Effect, Dosage, and Route of Oxytocic Drugs

Action and Effect

Uterotonins, or oxytocics, cause the uterus to contract. Oxytocin is an endogenous uterotonin from the posterior lobe of the pituitary gland. Exogenous uterotonins include synthetic forms of oxytocin, ergots, and prostaglandins [6].

The synthetic forms of oxytocin (Pitocin, Oxytocin, Syntocinon) stimulate intermittent contractions. They have little to no effect on blood pressure *if* given intramuscularly or added to IV fluids. These are the drugs of choice in most situations. When added to an IV infusion, which will last over time, they supplement oxytocic drugs already being given to effect a sustained contraction; or they may be used by themselves when bleeding is not excessive but the uterus is tending to relax.

The semisynthetic ergot preparation methylergonovine maleate (Methergine) acts directly on the smooth muscle of the uterus and stimulates a sustained, tetanic contraction. Methergine potentiates a hypertensive condition and may cause blood pressure increases in normotensive women because of its peripheral vasoconstrictive effect. Methergine is contraindicated in women with hypertension, preeclampsia, or eclampsia.

The 15-methyl prostaglandin F_2 alpha (15-methyl $PGF_{2\alpha}$) (Hemabate [carboprost tromethamine]; Prostin/15M) stimulates smooth muscle, thus causing myometrial contractions similar to term labor contractions. It also stimulates the smooth muscle of other body systems, causing side effects of diarrhea, nausea, and vomiting; transient temperature elevation; elevated blood pressure; and transient bronchoconstriction. It is contraindicated for women who have acute pelvic inflammatory disease or active cardiac, pulmonary, renal, or hepatic disease. It should not be given to women with asthma. However, it sometimes controls uterine bleeding when other oxytocics have not.

The midwife thus has to decide which uterotonin to use based on the amount of bleeding, the status of the woman's blood pressure, and history of any contraindications. If a woman is having a little heavy bleeding and she is hypertensive, then a synthetic oxytocin most likely will suffice. If a

woman is bleeding excessively as a result of uterine atony (which indicates a need for a drug that will stimulate a sustained contraction) and her blood pressure has been and is normal, then Methergine is the drug of choice. If a woman is bleeding excessively as a result of uterine atony but there is concern for a possible hypertensive effect, Methergine or 15-methyl prostaglandin $F_{2\alpha}$ (Hemabate [carboprost tromethamine]; Prostin/15M) would be the midwife's drug of choice, regardless of the woman's blood pressure, *if* the intermittent contractions produced by synthetic oxytocin are not sufficient for control of the degree of uterine atony and bleeding present.

Dosage and Route

The standard single dose for each of the oxytocic drugs discussed is as follows:

- Pitocin, intramuscular injection, 10 USP units or international units (IU)/mL
- Oxytocin, intramuscular injection, 10 USP units or IU/mL
- Syntocinon, intramuscular injection, 10 USP units or IU/mL
- Methergine, intramuscular injection, 0.2 mg/mL; tablets, 0.2 mg/tablet
- Prostin/15M, intramuscular injection, 0.25 mg/mL
- Hemabate, intramuscular injection, 250 mcg/mL

Pitocin, Oxytocin, and Syntocinon may be given intramuscularly or added to intravenous fluids for a prolonged effect by intravenous infusion. *At no time should these drugs be given IV push.* This practice is fraught with cardiovascular danger [7] and is actually counterproductive to the lifesaving results desired in controlling immediate postpartum hemorrhage, the circumstance for which oxytocin is most often ordered.

The administration of Pitocin, Oxytocin, or Syntocinon 10 IU intramuscularly or 10–40 units diluted in 1000 mL of intravenous fluid has no demonstrable cardiovascular effect. However, intravenous injection (IV push) of even as small an amount as 0.5 unit elicits a pattern of hypotension and tachycardia. The extent of the hypotension and tachycardia and length of time before recovery to preinjection levels are directly proportional to the dosage given. The larger the amount given, the greater the reduction in blood pressure for a longer period of time. There can be nearly a 40 to 50 percent reduction in blood pressure with a dosage of 10 units [7]. This is sufficient to put a woman into shock, if she is not already, or to endanger the life of the mother if she is already in shock. Such an action is counterproductive to the desired results.

Methergine is intended for intramuscular use. Methergine can also be given intravenously, but this practice is *warned against* as it may cause sudden hypertension and a cerebrovascular accident. *At no time should Methergine be given prior to birth of the baby* because a sustained contraction at that time could have the effect of killing the baby (by sustained uteroplacental insufficiency) and rupturing the uterus, thereby endangering the life of the mother. A single 0.2-mg intramuscular dose of Methergine is the effective amount. This may be repeated in 2 to 4 hours if needed. A larger dose does not increase the effectiveness of the drug in the event of hemorrhage but would unnecessarily increase the risk of undesirable side effects. Methergine tablets are used as needed during the postpartum period, as discussed in Chapters 42 and 44.

The idea of giving a combination of Methergine and Pitocin, Oxytocin, or Syntocinon intravenously, on the assumption that their opposite actions will counteract each other, is erroneous. Instead, the woman responds sequentially, first reacting to the synthetic oxytocin by developing hypotension and then reacting to the semisynthetic ergot preparation by developing hypertension.

Prostin 15/M and Hemabate are intended for intramuscular use only. While usually given in the deltoid muscle, prostaglandins may also be given directly into the myometrium through either a transabdominal or a transvaginal route.

The use of uterotonins is invaluable in controlling postpartum uterine bleeding. The desired action can be obtained rapidly by way of the intramuscular route for the semisynthetic ergot preparation or by way of the intramuscular or diluted intravenous infusion routes for the synthetic oxytocin drugs, and without the cardiovascular dangers involved in direct intravenous administration of any of these drugs.

Management Steps

Bleeding should be minimal if the woman's uterus is well contracted after delivery of the placenta. If, instead, there is a steady flow (as opposed to a trickle) or gush of blood from the vagina the midwife should take the following steps to manage this emergency:

1. Check the consistency of the uterus. This step is first, since 80 to 90 percent of immediate postpartum hemorrhage is due to uterine atony.
2. If the uterus is atonic, massage it in order to stimulate contraction so that the bleeding vessels at the placental site will be ligated.
3. If the uterus fails to contract well *immediately* with massage:
   a. Do bimanual compression (see Chapter 78). In addition to stimulating contraction of the uterus, which ligates blood vessels at the placental site, bimanual compression places continuous pressure on the uterine veins and on the lower uterine segment, which may be another site of bleeding.
   b. Simultaneously order the administration of oxytocic drugs (if they have not already been given) or additional oxytocic drugs.
   c. Make sure the IV is patent, or have the nurse start one with a 16-gauge needle and 5% dextrose in lactated Ringer's solution to which is added 10 units of Pitocin per 500 mL of solution. If the woman does have a patent IV, have the nurse add Pitocin to the existing IV solution in the proportion just stated.
4. If the woman's bleeding still is not under control:
   a. Have the nursing staff give your consulting physician a *STAT* call.
   b. Continue bimanual compression.
   c. Have a type and crossmatch drawn, if not already drawn, and sent to the blood bank.
   d. Have the nursing staff monitor the woman's blood pressure and pulse for signs of shock.
5. Examine the placenta, or have it examined, to ascertain if any placental fragments or cotyledons were retained and to determine if a uterine exploration needs to be done.
6. If placental fragments or cotyledons are missing, do a uterine exploration (see Chapter 77). The uterus needs to be completely empty in order to contract effectively.
7. If the uterus is empty and well contracted but bleeding continues, examine the woman for cervical, vaginal, and perineal lacerations since these may be the cause of the hemorrhage (see Chapter 75). Tie off the bleeders that are the source of hemorrhage and repair any lacerations (see Chapter 79).
8. If the woman is developing shock (lowered blood pressure; elevated pulse rate; rapid, shallow respirations; cold, clammy skin), place her in Trendelenburg shock position, cover her with warm blankets, administer oxygen, and order the blood to the floor.
9. In extreme and very rare cases when hemorrhage is rampant, the woman's life is in imminent danger, and the physician has not yet arrived, aortic compression can be carried out in relatively thin women. This involves abdominally compressing the aorta against the spine.

In the vast majority of situations in which a midwife is managing the care of the woman and an immediate postpartum hemorrhage occurs, it is readily controlled with a combination of bimanual compression and oxytocic drugs. Usually management steps are taken so rapidly (because of anticipatory alertness and early detection) that excessive blood loss is avoided. Occasionally the midwife will need to perform an intrauterine exploration (Chapter 77). In an extremely rare situation (never seen by most midwives), the first seven steps listed here will not be sufficient. In such an event the midwife maintains the woman as outlined in the additional last two steps until the physician arrives.

CHAPTER

35

Birth in the Home and in the Birth Center

ALICE J. BAILES, CNM, MSN
MARSHA E. JACKSON, CNM, MSN, FACNM

Introduction

Birth is profoundly affected by the environment in which it takes place. Ideally, every laboring woman and the team that supports and facilitates her efforts to birth work together in an environment that is the most comfortable and safe for the birthing mother. For many women, families, and providers, that safe, comfortable place to birth is in the home or birth center.

The midwife who works in the home or birth center has an opportunity to develop the hands-on, low-tech skills that are a hallmark of midwifery. Expertise in and fascination with normal life processes make midwives keenly aware of how much they depend on the mother's natural abilities to birth. Midwives finely tune perception and interaction skills that amplify the mother's abilities. The women in these birth settings are active in creating a network of support that enables them to optimize their health, and to birth safely, effectively, and with great satisfaction. These women are true partners with their midwives as together they create the process of care. As described by Varney in an earlier edition of this book:

> If one were to place the control and responsibility assumed by the woman on a continuum, the continuum would stretch from the hospital delivery room at one end to home birth at the other. There are two important breaks in this continuum where power is transferred to the woman. The first break is when birth moves out of the hospital. The second break is when it moves from a freestanding out-of-hospital childbirth center to the home. In each instance the woman moves further away from external regulations and policies that are imposed on her childbirth experience. [1]

A wealth of data exists describing safe healthy outcomes in home and birth center births. In the United States and abroad, data have been obtained from small individual practices, larger networks of practices, analysis of birth certificates, and large-scale government sponsored epidemiological studies [2–28]. These studies have shown that planned home and birth center births for healthy women experiencing normal pregnancy are at least as safe as, and in some cases safer than, birth in the hospital. These studies also have documented that rates of obstetrical interventions are lower for women who begin their labors out of the hospital.

Perinatal mortality rates for these study populations range from 1.3 to 4.3/1000. In-labor transfer rates for women planning to birth at home or in a birth center were 2.3 to 23 percent. Cesarean birth rates for women transferred after starting labor at home or in a birth center were between 1.4 to 8.3 percent. For home or birth center born babies, only 0.5 percent of 5-minute Apgar scores were less than 7. Women who gave birth in a freestanding birth center or home had a lower incidence of meconium staining, fetal distress, shoulder dystocia, birth injury, neonatal respiratory distress, and postpartum hemorrhage [22, 29, 30]. In the United States in 1999, 35,977 births (0.9 percent) were

out-of-hospital, with 23,516 (0.6 percent) home births and 9642 (0.2 percent) in freestanding birth centers [31].

Hospitals often advertise their labor and delivery suite as a birth center or an alternative birthing center (ABC). These labels can be very confusing, as they have been used to refer to both in-hospital and out-of-hospital centers. The birth centers under discussion in this chapter are either freestanding or physically separate from the hospital labor and delivery area. In most cases, they are also administratively separate from a hospital. They are autonomous, formulating policies and procedures for operating both the facility and the program for the childbearing families they serve.

There will always be women who prefer to give birth outside of the institutional walls of a hospital—either in the home or the birth center. Many CNMs/CMs and SNMs/SMs do not have opportunities to work in these settings. This chapter describes how the midwife works with the mother who chooses home or birth center as her preferred birth site.

History*

Before 1900, giving birth in a hospital was the rare exception. Fewer than 5 percent of all women gave birth in the hospital and then only because they were desperately sick. Birth happened at home, controlled by women and attended by female midwives.

All this changed in a brief span of time. By 1940 nearly half of all births took place in hospitals and by 1970 the changeover was complete, with over 99 percent of births occurring within hospitals. Birth now happened in the hospital, controlled by men and largely attended by male physicians.

Some of the same factors influencing the status of midwives during the late nineteenth and early twentieth centuries (see Chapter 1) were also responsible for the move of birth from home to hospital. These factors include the evolution of the "male midwife" (physician) in the late eighteenth century; the inclusion of obstetrics in medical practice with the concurrent development of lying-in wards for the urban poor for teaching purposes during the late nineteenth and early twentieth centuries; Semmelweis's conquest of puerperal fever by hand washing, which made hospitals more safe; the concerted effort to abolish midwifery in the early twentieth century; the evolution and refinement of early obstetric technology such as forceps (eighteenth century), anesthesia (ether, 1847; chloroform, 1853; spinal anesthesia, 1885–1946), analgesia (1902), and infant incubators (late nineteenth century).

The physician promise of pain-free birth required that women be in the hospital in order to be near emergency equipment if needed in the event of anesthetic or analgesic complications. Women not only wanted pain-free birth but also demonstrated for it forming such organizations as the National Twilight Sleep Association. But the move into the hospitals brought with it the days of female dependency behaviors during pregnancy, labor, and birth; fear of pain and ignorance; centralized nurseries; and separation of baby from the mother and the mother from the family. The rural and urban poor who could not afford medical insurance or were not able to pay cash were attended by "granny" or immigrant midwives. "Colored" women were refused admission to hospitals. Both groups were denied access to the "comfortable, pain-free" childbirth promoted by the hospitals during this period of transition of birth into the hospital [32].

Another factor influencing the move into hospitals was the development of third party payment for health care. The Emergency Maternity and Infant Care program was instituted in 1943 to pay maternity and infant care costs for the families of servicemen. This specified hospital delivery. A 1948 U.S. Supreme Court decision increased the provision of health insurance by employers in negotiated contracts; by 1950, 50 percent of people in the United States had hospital insurance. This increased to 78 percent by 1970 after the advent of Medicaid and Medicare in 1965 [33].

The early nurse-midwifery services were home birth services (Frontier Nursing Service, founded in 1925; Lobenstine Midwifery Clinic, 1931; Tuskeegee School of Nurse-Midwifery, 1941; Catholic Maternity Institute, 1944). Nurse-midwives did not move into the hospitals until the mid-1950s when they made a deliberate and successful effort to gain access to the public hospitals because these hospitals were where the majority of women they had been caring for were now giving birth [34]. The move into hospitals was also part of moving into educational institutions for the place-

* Authored by Helen Varney Burst, CNM, MSN, DHL (Hon.), FACNM

ment of nurse-midwifery educational programs (Columbia University, 1955; Johns Hopkins University, 1956; Yale University, 1956; the move of the Maternity Center Association School of Nurse-Midwifery into Downstate Medical Center, State University of New York, 1958).

The early expression of consumer desire to reclaim responsibility for birth and promote the normalcy of childbearing, and their dissatisfaction with hospital childbearing practices and routines began in the 1940s. The mid-1940s saw the development of rooming-in in an effort to facilitate early mother-father-infant-family relationships and end the practice of separating mother and baby from each other and from the family. Grantly Dick-Read wrote *Childbirth Without Fear* in 1944 [35]. Herbert Thoms wrote *Understanding Natural Childbirth* in 1950 [36]. Maternity Center Association developed preparation for parenthood and childbirth classes and teaching materials such as *The Birth Atlas* during the 1940s and 1950s. Marjorie Karmel wrote *Thank You, Dr. Lamaze* in 1959 [37], and with her book the use of psychoprophylaxis and a variety of childbirth theories and methods got under way.

The late 1950s and the 1960s and early 1970s also saw consumers and professionals joining together to form national organizations to promote their beliefs in natural, prepared childbirth. Examples include the International Childbirth Education Association (ICEA), the American Society for Psychoprophylaxis in Obstetrics (ASPO), La Leche League International, the National Association of Parents and Professionals for Safe Alternatives in Childbirth (NAPSAC), Childbirth Providers of African Descent, and many smaller organizations. Some organizations were specifically supportive of home birth, such as Home Oriented Maternity Experience (HOME), the Association of Childbirth at Home International (ACHI), and the American College of Home Obstetrics.

The organizational alliances of consumers and professionals began to focus not only on promoting change within hospitals but also on the acceptance of out-of-hospital birth and the services midwives could provide. Consumers recognized that childbirth had not always been in hospitals and wanted a return to the norm of birth as a family event. They perceived this norm as naturally occurring in their homes or in freestanding birth centers with the hospital available in the event of variations of normal or complications requiring the technology and medical care located there.

The first established freestanding out-of-hospital childbirth center was La Casita at Catholic Maternity Institute in Sante Fe, New Mexico. It was started in the mid-1940s by graduates of the Maternity Center Association School of Nurse-Midwifery who were medical mission sisters. It closed in the mid-1960s. During the 1940s and 1950s, maternity shelters or community birthing centers were started in at least two counties in Georgia with nurse-midwives in attendance [33]. There were also a number of so-called maternity hospitals or homes in the 1940s and 1950s that were often associated with residential care for unwed mothers. Most of these closed between the late 1950s and the mid-1960s.

In 1972, Su Clinica Familiar, a migrant health clinic in southern Texas, expanded its services to include births in their clinic setting and became the first out-of-hospital childbirth center in more recent history [38]. The Maternity Center Association in New York City opened its precedent-setting Childbearing Center (CbC) in 1975 [39]. The CbC was designed to be a model that could lend itself to regulation, be financially viable, set standards, and be widely replicated with the intent of changing the maternity care delivery system (see Figure 35-1). Birth centers started to multiply. In 1981, the Cooperative Birth Center Network—a program of the Maternity Center Association of New York, which was funded by the John A. Hartford Foundation—began collecting data on birth centers and establishing a network for the collection and dissemination of information regarding birth centers. Recognizing the need for representation, further development, and help in implementing the birth center concept, and standards in the face of a proliferating number of childbirth centers, the Cooperative Birth Center Network underwent a metamorphosis in 1983 to become a nonprofit membership organization called the National Association of Childbearing Centers (NACC). One early function of this organization was to develop standards and criteria for care and safety in childbirth centers. This led to the formation by NACC of the Commission for the Accreditation of Birth Centers in 1985. Birth centers seeking accreditation undergo a rigorous internal and external review for compliance with established standards for excellence.

The American College of Nurse-Midwives (ACNM) has taken a professional leadership role in promoting the safety of out-of-hospital birth settings. The ACNM first published *Guidelines for Establishing a Home Birth Service* [40] and

FIGURE 35-1 The Childbearing Center of the Maternity Center Association. (top) The family room; (bottom) a multipurpose room used for group discussion and as a playroom for children accompanying their parents.

Guidelines for Establishing an Alternative Birth Center (out-of-hospital) in 1979 [41]. The ACNM based its action on the experience, statistics, and demonstrated safety of nurse-midwives in home birth and birth center settings since 1925. In 1980, revised in 1997 and 1999, the ACNM came out with a position statement on practice settings that states the following:

> Every family has a right to experience a safe and satisfying childbirth, attended by providers who respect cultural variations, human dignity, and the rights of consumers to freedom of choice and self-determination. This includes respect for the client preferences regarding birth site. The education and preparation of CNMs/CMs qualify them to practice in a variety of settings including hospital, home and birth center. [42]

The Office of Migrant Health in the Bureau of Community Health Services of the U.S. Public Health Service contracted with the American College of Nurse-Midwives in 1980 to provide guidelines and consultant help in establishing childbirth centers associated with their clinics.

The National Association of Childbearing Centers conducted a prospective descriptive study between 1985 and 1987 that examined the care provided in birth centers. Known as the National Birth Center Study (NBCS), it examined the experience of 17,856 women who received care in 84 birth centers "to determine if birth centers are safe; and to describe the women who use birth centers, the care provided to those women, and the results of that care" [17, 43, 44]. Safety of care provided in birth centers was affirmed and the descriptive data collected during the study are invaluable.

In 1995, the *Journal of Nurse-Midwifery* published a special issue on home birth [45] and in 1997 the ACNM published *The ACNM Handbook: Home Birth Practice* written by the ACNM Home Birth Committee [46]. Recent studies published in 1995 and 1998 have again confirmed the safety of home birth with CNMs in attendance [4, 15]. This was first documented in 1958 by the Metropolitan Life Insurance Company in their analysis of 10,000 births in the Frontier Nursing Service [47].

There are still women in some segments of society—e.g., migrant workers, rural or urban poor or working poor—who do not receive prenatal care and give birth at home, not by choice but because they do not have access to all the resources and facilities of the health care system. For the vocal individual consumer, consumer groups, and the aforementioned national organizations, however, birth at home or in a birth center is a matter of choice and educated, participatory decision-making. These are knowledgeable consumers who promote a health care system that starts in the home and are disenchanted with what hospitals have to offer in *routine* maternity care and services. Resolving the resulting issues of power, control, responsibility, economics, and safety of both in-hospital and out-of-hospital birth settings have challenged consumers and health care providers alike.

Characteristics of Birth Center and Home Birth

The home and birth center environments have distinctive features that support healthy women experiencing normal birth. According to the World Health Organization:

> A low-risk pregnant woman should give birth in a place where she feels safe . . . that place may be at home, at a small maternity clinic, or birth center in town, or perhaps at the maternity unit of a larger hospital. It must be a place where all the attention and care are focused on her needs and safety, as close to home and her own culture as possible. [48]

The attributes of these settings broaden labor and birth management choices for nonpharmacologic childbirth. The following are characteristics of the home and birth center settings:

1. Centrality of the birthing woman is clearly recognized as essential.
2. Consumers in these settings are healthy women who are
   a. experiencing normal pregnancy
   b. actively working to promote their own health
   c. taking a partnership role in decision-making
3. Environments are optimal for normal birth.
4. Midwife and birthing family have increased authority.
5. Safety is preserved by adherence to essential principles.
6. Complex technologies are deliberately kept at a distance.

7. Practices are often owned by midwives.
8. Independence in midwifery practice is fostered.
9. Bureaucracy is minimized.
10. Preferences for varying levels of family participation are accommodated.

Care Process Characteristics

The centrality of the birthing woman is easy to recognize in the small and intimate environments provided by the home or birth center. Distracting events are minimized, allowing mother and practitioner alike to focus on the mother's all-important task of giving birth. Anticipating birth in a low-tech environment, these women and the midwives who work with them make a commitment to health promotion. They acknowledge that it is the pregnant woman herself who potentiates an excellent outcome, by engaging in the activities that will enhance her health.

A number of factors make these environments optimal for normal birth. First, the mother's natural efforts are respected, and all who work with her are dedicated to the concept that birth is normal. Within these environments, it is expected that the mother has the ability to birth her baby. She can do so with physical, social, and psychological support and without the use of complex technology. She surrounds herself with only the people she chooses, meeting her needs for privacy or companionship. Her team may be as small as four (the woman and her birth partner, the midwife, and the birth assistant) or as large as the home or birth center can accommodate. Able to focus only on the mother, the team offers their skills, presence, and support. They work to enhance the mother's comfort, helping her to use her energy efficiently. They provide an environment of safety and instill confidence, communicating their belief that she is doing fine and has the capacity to get the job done.

The environment itself communicates this expectation of normalcy. It is familiar, without elements foreign to the mother. There is no physical evidence of machinery designed to do the job for her. She is not attached to equipment. She is free to move around and to be in any position she chooses. She can easily alter her environment or make changes within it. She can go outdoors for walks that can invigorate her, occupy her attention, and promote labor progress. She can get in and out of a shower or tub to promote relaxation. Her privacy is protected. She can make sounds without fear of being overheard by strangers close by. She has her own clothes to wear or not wear as she sees fit. Familiar food and drink that she and her family have provided are available to nourish her. At home or in the birth center, women are less likely to encounter pathogenic bacteria and invasive procedures in their birth environment, reducing the risk of exposure. In the home, especially, maternal immunities to familiar bacteria protect the baby via the placenta, lessening the likelihood of infection for the pair [24].

In home and birth center practice, emphasis is placed on labor as a dynamic entity where progress may be rapid sometimes and slow at others. These ebbs and flows are viewed as essentially normal. An important task for the midwife is to attentively observe the mother's available energy and to work with her to maximize its efficient use. Encouraging food and fluid intake to maintain adequate fuel prevents exhaustion. When the woman is tired and contractions are flagging, quieting the environment is a simple task, minimizing interruptions to promote rest. When rest and nourishment have helped the mother to recoup her strength, she can change her activity to increase the effectiveness of the contractions. In the hospital environment, there is pressure from a variety of sources to alter these normal ebbs and flows of progress. These pressures may be physical—for example, the need to make space available to accommodate other laboring women. There may be active management policies and protocols mandating progress. Away from the hospital, attention can be focused on addressing the woman's needs, enabling her to progress or rest, expecting and accommodating plateaus of progress.

All births are owned by the mother and by those she has chosen to share in her maternity experience. At home and in the birth center, this ownership is easier for the woman and her providers to recognize. As a result, the mother feels increased authority to exert control over the birth's environment, management, and outcome. In this personalized milieu, the woman is able to communicate her birth plans directly with the policymakers prior to labor. She feels assured that her preferences will be honored and looks forward to her birth, confident that the providers have a management philosophy congruent with her own. She feels that the only surprises she will encounter are the ones labor brings, and that she has a right not to be distracted from her work while she is in labor.

The midwife practicing in these settings also feels her authority bolstered, as illustrated in the following excerpt:

> I was in a setting where no one could impose external parameters and policies; where I could use my clinical judgment and conclude that all was normal. There was no one around to tell me otherwise, to try to fill me with negativism and doubt, or to tell me I was wrong. [1]

This authority can be liberating and it can be daunting.

Safety Characteristics

In order to preserve safety at home and in the birth center, it is necessary to adhere to the following essential principles [1, 4–8, 11–13, 16, 18–20, 25–28, 49]:

1. *The woman must be committed to actively engage in health promotion*. Without good health, it is unsafe to plan birth at home or in a birth center. A healthy pregnancy is not a gift. Women must work to build excellent health, a strong uterus, an exquisitely functioning placenta, and a vigorous baby.
2. *The place of birth must be planned before the onset of labor*. Adequate planning for the place of birth includes determination that the mother's health and the pregnancy are within normal limits when labor begins and that preparations for appropriate support are in place.
3. *The attendant must be skilled, able to screen appropriately, provide vigilant care, and manage emergency complications should they occur*. In addition to assisting with health promotion antepartally, a skilled home or birth center midwife is vigilant in observation, communication, data collection, and care. This vigilance identifies reassuring signs of normalcy, as well as deviations from the norm that may preclude a home or birth center option. If problems occur or persist at any time in the maternity cycle, the midwife acts to correct the problem or if necessary, works to stabilize the mother's condition and transfer the mother to hospital-based care.
4. *There is a system in place for access to medical consultation, hospitalization, and emergency transport*. Clinical practice guidelines outline indications for consultation and a mechanism for transport. The midwife has established relationships with hospital-based practitioners to ensure a smooth transition into the hospital should a transfer be indicated.

Complex technologies are intentionally kept at a distance at home and birth center births. Minimizing technology may prevent some complications. The cascade of interventions that are often utilized in the hospital setting is well known [50]. Simply putting the mother to bed may have the effect of slowing down labor progress or increasing the possibility of posterior fetal position [51]. Hampering mobility with an intravenous (IV) infusion or discouraging an upright position by attaching a fetal monitor may reduce the mother's comfort and cause her to become anxious. Maternal anxiety increases the level of adrenaline that may interfere with the action of endogenous oxytocin [48]. Adding an oxytocin pump may increase maternal discomfort from augmented or induced contractions, and pharmacologic pain relief may be needed to enable the mother to cope. These more complex technologies are not benign. Some of them cause problems that can be remedied only with still more technologies. A need for complex technologic intervention is an indicator for transfer to the hospital.

Administrative Characteristics

Home and birth center services are owned mostly by the midwives who practice there. The midwives render care within a structure that they create and maintain themselves, fostering independent midwifery practice and leadership skills. These practices tend to be small, minimizing bureaucracy and simplifying communication and policy. Administrative time and paperwork are reduced and the organization is more client-friendly. Care can thus be more responsive to the needs of the mother, her family, and the midwife.

Characteristics Differing in Home and Birth Center Settings

Although both home and birth center practices share philosophical and administrative characteristics utilizing the same equipment and personnel, there are still differences between the two. The primary difference is that a birth center is still the professional's territory to which the woman comes, while a home birth takes place in the woman's territory to which the midwife goes [1]. The balance of power in each setting is different.

A woman who decides to remain in her own home to birth has increased authority. The midwife and the birth assistant are the guests, and the woman is the host. The mother is in her own territory at home where familiarity and privacy are increased, reducing the stresses that may accompany labor and birth. Because the midwife is the one who

travels to the mother, labor, birth, and postpartum are not disturbed by a trip that could slow or stop early labor, cause intense discomfort in active labor, or increase the risk of giving birth en route. When families have their babies at home, there is little interruption in family routines for adults as well as for children, and there is uninterrupted bonding. When the mother and the newborn baby are stable and settled postpartum, the rest period that occurs after the initial period of neonatal alertness is not interrupted by the return trip. Instead, the midwife and the birth assistant tuck the mother and baby into bed and quietly leave the home.

The birth center concept is a replicable model that has become a well-recognized birth option for families. The National Association of Childbearing Centers provides this description of a birth center:

> A homelike facility, existing within a health care system with a program of care designed in the wellness model of pregnancy and birth. Birth centers are guided by principles of prevention, sensitivity, safety, appropriate medical intervention, and cost effectiveness. Birth centers provide family-centered care for healthy women before, during, and after normal pregnancy, labor, and birth. [52]

Because our society has become accustomed to conducting birth in an institution, birth centers provide a compromise for families who wish to avoid the hospital but feel that the home birth choice is "too radical." Some families choose the birth center alternative to gain more privacy than they could achieve in their own busy household. Families who live outside a home birth midwife's geographic service area may choose a birth center birth to get the out-of-hospital birth services they desire. Families choosing birth center births often express concern regarding the "birth mess." The fact that at the birth center the family is relieved of clean up responsibilities may influence the family's decision.

Since birth centers are a birth option more accepted by the general population, families may feel that if an unexpected poor outcome occurred at the birth center, other family members and friends would be somewhat less accusatory than they would be if the birth had occurred at home. Accreditation is another factor that enhances family and practitioner confidence in the birth center choice. The Commission for the Accreditation of Birth Centers (CAB) of the National Association of Childbearing Centers (NACCs) provides a mechanism for external review giving guidance to professionals planning birth centers and practicing in them [53]. There is no comparable agency for home birth.

Birth Center and Home Birth Practice Models

Models of Birth Center Practices

There are two models of freestanding, out-of-hospital childbirth centers: the closed model and the open or community model. The closed model is a birth center that is used by a single practice of midwives and/or physicians. Most often the center is owned by the practice that provides services there. Only women who seek care from that practice may give birth at the center and privileges are not extended to any other providers in the community. Such a birth center is usually a facility not only for maternity services and birth, but also interconceptional care, well-woman gynecological care, and primary care of women [1].

The open model is a community facility owned by a separate corporation. It is available to all women whose health care providers have practice privileges at the birth center. Such a childbirth center may serve as a community resource, providing a media center, childbirth education classes, and other birth-related services. It is primarily a facility for intrapartum and postpartum care (see Figure 35-2). Women receive their prenatal, postpartal, gynecologic, and primary care in the offices of their health care providers and give birth at the birth center. There may or may not be an "in-house" practice that provides prenatal, postpartal, gynecologic, and primary care at the birth center [1].

Models of Home Birth Practices

Home birth practices are usually midwife owned and may be either solo or group practices. Home birth solo practice can be very rewarding but also quite challenging. The relationship between the solo midwife and the mother gives each great satisfaction. However, the intensely personalized relationship makes each reluctant to get assistance, if needed, from another midwife. It is not unusual for families' homes to be far from one another, making it difficult for the midwife to manage more than one labor at a time. The small number of CNMs/CMs in home birth practice makes cross coverage difficult to find. Group home birth practices allow the midwife more collegial support, and help decrease

FIGURE 35-2 Birth room in the Family Childbirth Center, New Haven, Connecticut.

the occurrence of practitioner burnout. When mothers meet more than one midwife from the outset, they are often amenable to having any of the group attend their births. However, relinquishing the unique one-to-one relationship created within the solo practice may decrease satisfaction for both midwife and mother.

For midwives who may not be interested in owning their own practice, a collaborative practice model works well. Usually owned by a physician or corporation, either a solo midwife or a group of midwives is hired to provide home birth services for interested families. This model encourages independent practice for the midwife, while the owner of the practice provides for administration. Financial arrangements may vary. The midwife may have a set salary or there may be other incentives such as profit sharing, bonuses, or payment according to the number of office visits and births attended.

Models of Combination Practices

Many birth center and home birth practices offer a combination of services: home/hospital, home/birth center, birth center/hospital, and home/birth center/hospital. Offering more than one birth option may increase the number of families interested in a midwifery service. This practice model provides the woman continuity of care as she begins her prenatal care with a service that allows her to easily change her planned birth site. In a combination practice, the midwife also has an opportunity to explore birthplace options with women who never would have considered a home or birth center birth. The midwife is not the only source providing information to help women consider all of their choices. For example, other families in the practice's reception area often share their experiences while waiting for their appointments. The mother, armed with information, develops the self-assurance needed to take an active role in selecting her child's birthplace.

Access to Hospital-Based Care

Access to medical consultation is crucial in all midwifery practice models. When women plan to birth at home or in a birth center, not only do they need access to consultation but they also need access to hospitalization should the need arise. Some out-of-hospital CNMs/CMs maintain hospital privileges enabling them to transfer and provide care for the mother who needs interventions that are more safely implemented within the hospital. Other out-of-hospital midwives elect to maintain consultation relationships and transfer care to hospital-based CNMs/CMs, family physicians, or obstetricians.

Plans for consultation and transport may be structured in a variety of ways. The most straightforward way is to have a formal written agreement with hospital-based practitioners or directly with a hospital. The midwife may consult with a solo practitioner, a group practice, several practices, or the house staff employed by the hospital. Each option has benefits and drawbacks.

The main benefit of working with a single solo practitioner is consistency in clinical policy. Management is usually predictable. The main difficulty is that if the consultant is away or unavailable, there may be no other provision for coverage. In addition, the solo consultant may feel overwhelmed if called upon to manage several complicated referrals in quick succession. At the other extreme, having an agreement with a hospital for staff to cover consultation needs provides 24-hour coverage. However, the disadvantage is that the practitioner who receives the mother in an emergency may be completely unfamiliar with home or birth center birth, and have a management philosophy extremely different from the referring midwife's practice. Because this limits the ability to know what to expect, anticipatory guidance in various clinical situations becomes extremely difficult. Having a small number of familiar, reliable consultants who cross-cover for one another works well. Sometimes, several midwifery practices may hire a physician to provide consultation services. The midwives benefit by sharing the cost. However, by covering more than one midwifery service, the physician may become overextended.

While some home and birth center CNMs/CMs maintain hospital privileges, others, for a variety of reasons, elect not to have them or are unable to get them. Out-of-hospital midwives may feel that their first commitment is to serve women who are planning to birth out of the hospital. They feel that if they also tried to serve women planning hospital births, there would not be enough space in their practices to meet the needs of their out-of-hospital census. Others feel that they would not be able to keep up with the bureaucratic and political administrative tasks associated with hospital privileges at the various hospitals that may be close to their clients' homes. In most of the above cases, continuity of care can be accomplished by accompanying the women requiring transfer into the hospital. Making a consultation agreement with hospital-based CNM/CM practices affords a means of access to the hospital, fostering the collegial relationship among midwives. Mothers appreciate this arrangement because even if they transfer to the hospital, they may still have their birth attended by a midwife.

When developing a consultant relationship, the midwife writes the clinical practice guidelines on which the practice is based and identifies those situations for which consultation would be needed. Negotiations for the desired services may then take place. Some consultants may be hesitant to put an agreement in writing due to concerns about professional liability insurance or their position in the community. If it is not possible to make a written agreement, it is reasonable to have an oral agreement. This works only if the midwife has a relationship with the consultant or hospital that is built upon mutual trust, open communication, and respect. This relationship is critical for the midwife and the mother in order to guarantee access to the hospital if more complex technologies are indicated. A difficult and potentially dangerous situation could be encountered if the consultant or hospital denied the midwife access to services for the mother when they were needed [46].

While working with consultants, management dilemmas may occur that have political implications. Once in-hospital CNM/CM or MD consultants become comfortable working with out-of-hospital midwifery management decisions, fewer visits may be required for mothers planning out-of-hospital births. Mothers may still want to meet with the consultant and should be encouraged to do so if they desire. When the mothers' desires conflict with accepted medical community standards, it may be difficult to convince a consultant to implement a plan that may be safe but unpopular in the medical community. The resulting situation can become very uncomfortable. The out-of-hospital midwife now has a dilemma with the medical community on one side and the mother's desires on the other. The out-of-hospital midwife and the consultants are caught in the middle. This has potential to jeopardize the relationship with the consultants and thereby access to the hospital for the entire home or birth center practice. Compromise will be necessary on all sides when working through issues. Because access to the hospital is essential for safety, the consultant arrangement must be nurtured.

Midwife/Client Relationship

In every setting, the relationship between the midwife and the woman is vital. In the home and birth center, it is particularly important to specify the

roles each participant assumes as they share responsibility and work together in a partnership based on mutual trust [54]. Goals and criteria for normal are clearly delineated. Together, along with the mother's support system, all share responsibility for both the process of care and the outcome. Working in this way requires clear and ongoing communication throughout the maternity cycle.

Women who choose to birth in their homes and birth centers are often seeking control over management of their maternity care from preconception through early parenting. They look for a birth attendant who will use a labor management philosophy matching their own. They choose an attendant very intentionally, searching for a good fit and seeking a collaborative nonhierarchic relationship. They want to find a midwife who will share power. Midwives who choose home and birth center practice need a clear sense of their own strengths and limitations. They must be comfortable with sharing power and occupying a role that is not central. This challenges midwives to sharpen communication skills, to be open to discovering how to expand flexibility, and to know how to set and explain evidence-based limits and boundaries. Home and birth center midwives must be able to determine where philosophical gaps lie and strategize to resolve these. They must be comfortable in situations where management does not revolve around the midwife but revolves around the woman.

While home and birth center midwives welcome and expect the woman's active participation in decision-making and management, these midwives must also feel comfortable taking a leadership role in the midwife-client partnership. Using scientific knowledge, clinical skills, past experience, and sensitive communication, the midwife guides the mother through the preparation process that will enable her to reach her goal of birthing in her preferred site. It is critical to convey the importance of the health promotion model, of a commitment to natural birth, and of the necessity to prepare both physically and psychologically. The midwife must also be assertive as she describes the limits of her practice in the home or birth center environments.

Antepartally, the midwife builds the mother's confidence and cultivates her self-reliance. By giving reassurance regarding the normalcy of pregnancy's changes, and communicating faith in the mother's ability to birth, the midwife assists the mother to amplify her strengths and helps her to compensate for any limitations. The midwife gives positive feedback as the mother takes on the necessary preparatory responsibilities of creating her framework of maternity resources, such as a partner for labor support and a social network for her care postpartum. The midwife strengthens the mother's confidence further by ensuring access to the medical system's safety net should it be needed.

During the intrapartum period, the midwife's role is to be the guardian of the birth environment. The mother depends on the midwife to provide a reassuring presence, physical and psychological labor support, and attention to comfort and progress using simple interventions when necessary. She depends on the midwife's ability to assess for continued normalcy. Should any complication occur, the midwife has the skills needed to manage, stabilize, and in many cases resolve the situation, consulting as indicated. If complications cannot be resolved in the home or birth center settings, the midwife effects a transfer to the hospital.

Health status is a dynamic entity throughout life. This is especially true for mother and baby during pregnancy. It is important to assist the mother to recognize and understand the significance of this fluidity. Changes in health may require changes in care. The mother, midwife, and medical system recognize that the mother's changing health status may mandate movement back and forth among providers within the health care system, sometimes requiring a change in the planned site of services. This may be difficult for both midwife and mother. The mother may be very emotionally attached to birthing at home or in the birth center, and grieves leaving her dreams behind. The midwife without hospital privileges may be reluctant to make the referral because in doing so she may lose or limit her opportunity to work with the mother. Neither reason, however, should prevent or delay a necessary transfer from taking place.

The mother plays the central role in her childbearing experience. The midwife is an advocate and a coordinator. The mother knows she can depend on the midwife and vice versa. Together they maintain the safety of the maternity cycle.

Initial Visit

At the initial prenatal visit, the midwife introduces the family to the services and philosophy of the practice. The midwife takes the opportunity to explain that when birth occurs in the home or birth center, both midwife and mother need to have a strong commitment to health promotion, to keeping birth normal, and to nonpharmacologic child-

birth. The midwife, the mother, and her family discuss their needs, and how the mother envisions getting her needs met. The visit also provides an opportunity for both mother and midwife to assess their abilities to work together. It is important that adequate time be allotted to cover these tasks. The components of an initial visit include the following:

1. Selection of birth site and analysis of mother's choice
2. Introduction to an informed consent process
3. Review of midwife responsibilities
4. Review of family responsibilities
5. Outline of safety criteria and outcome statistics
6. Discussion about possibility of transfer of care
7. Complete history and physical exam
8. Calculation of accurate due date

Selection of Birth Site

At the initial visit, the midwife and the mother consider advantages and disadvantages of all available birth options. The midwife and the mother work together to begin consideration of the best birth option for the mother and her family, delineating what can and cannot be done in each setting. When discussing birth site options, both positive and negative aspects of each site should be explored. In our society, the hospital has been assumed to be the safest birthplace. According to research, for healthy women experiencing normal pregnancy, this is not an evidence-based conclusion [2–8, 10–20, 23–27, 30, 32–33, 37, 39, 47, 55–59]. Table 35-1 compares the three birth sites and factors that women may consider when selecting a birth site. Influences on choice of birthplace may include the philosophy

TABLE 35-1 Influences on Birth Site Selection

	Hospital	Birth Center	Home Birth
1. Normalcy of the pregnancy		x	x
2. Prepregnancy medical history	x	x	x
3. Physical and laboratory findings	x	x	x
4. Decreased chance of infection		x	x
5. Extended time for prenatal visits		x	x
6. Education is core component	sometimes	x	x
7. Low-tech, high touch environment	sometimes	x	x
8. Minimal interruption in activities of daily living			x
9. Support for unmedicated birth maximized		x	x

of the mother and the caregivers, preferences regarding technology, mother's health state, feelings about previous birth experiences, societal and family considerations, and financial concerns. Less than 2 percent of women in the United States choose to have their babies at home or in a birth center [31]. Therefore, an understanding of the mother's motivation for her birth choice will enable the midwife and mother to work better together. The attitudes of the mother's support partner should also be included in this discussion.

Some women seek home and birth center services because they lack financial resources. Although the usual profile of the home or birth center mother is an educated middle class person [3, 60, 61], many women who do not fit this picture desire to educate themselves and work to keep themselves and their babies well. The economically disadvantaged mother may benefit from the personalized, nonbureaucratic, respectful, one-on-one care that she may not often encounter elsewhere in the health care system. As long as the mother can accomplish the needed preparation for the birth and the pregnancy remains normal, she is a good candidate for out-of-hospital birth. Although a home or birth center birth may be cheaper if everything is normal, it may be more expensive than a hospital birth if complications occur. To that end, women should be discouraged from seeking services purely for financial reasons.

Informed Consent

The midwife and the mother should review and sign an informed consent document detailing essential considerations regarding home or birth center birth. This document should enumerate the following points [46, 62]:

1. Advantages and disadvantages of the decision to give birth out-of-hospital attended by a midwife
2. Qualifications of the midwife
3. Mother's consent to examination and treatment
4. Responsibilities of mother and midwife
5. Possible complications associated with childbirth
6. Definition of common terms that will be used during the maternity cycle
7. Emergency equipment the midwife brings to the home or has at the birth center
8. Agreement to hospital transfer if indicated according to the midwife's professional judgment

The consent form should not be approached as a substitute for a trusting, nurturing relationship among the midwife, the mother, and her family. In fact:

> The woman's signature means only that she has heard the information, understands it, and agrees to the care offered. Therefore, a good form should prompt good discussion, which is also documented in the record. . . . The challenge is how to inform without creating a climate of doubt about birth, and how to address fear and uncertainty without undermining the birth process. [63]

There should be ongoing communication and exploration of concerns throughout the maternity cycle. In this way, self-care is fostered, good decision-making takes place, and the mother and her family are empowered.

Midwife Responsibilities

A list of the midwife's responsibilities is outlined to clarify the mother's expectations regarding the midwife's role. The midwife explains the concept of working in a midwife/client partnership, each with their own set of responsibilities. Throughout the maternity cycle, the midwife provides education, guidance, and health care, with particular emphasis on signs of normalcy and/or signs of deviation from normal. The role of the primary support partner is discussed, and the midwife makes 24-hour midwifery on-call services available to the mother. Finally, the midwife describes the referral and transport services available and resources to cover remuneration to both midwife and consultant in case of transfer. These are important factors to discuss.

Client Responsibilities

When a woman plans to birth in the home or the birth center, it is easier for her to see the connections between her actions and outcomes. She understands that she has responsibilities and that her actions can make a difference. At the initial visit, enumerating these responsibilities gives the mother an overview of the tasks that she will need to undertake to promote optimal health and to maximize the likelihood of having a normal pregnancy with labor and birth occurring in the birth site that she has chosen.

Basic health promotion includes good nutrition, adequate rest and exercise, stress reduction, keeping scheduled appointments, and avoiding

drugs, alcohol, and cigarettes. Responsibilities also include ensuring the participation of a support partner who will take primary responsibility to be available during pregnancy, labor and birth, and the postpartum period. When small children are to be present at the birth, an adult other than the primary support partner must provide their care.

Other responsibilities introduced during the initial visit will be addressed again later in the pregnancy, including breastfeeding preparation, gathering birth supplies, attending childbirth education classes, touring the hospital, and arranging services of a pediatric health care provider. Mothers may also be required to meet with the consultant service during the pregnancy. Finally, financial arrangements must be clear for both self-pay and insured clients. A written payment plan should be prepared, including insurance information and a schedule for payments. Financial concerns should be discussed openly by all responsible parties.

Safety Criteria and Transfer

The issue of transfer of care should a complication arise needs to be approached at the initial visit. Problems that may occur during the maternity cycle and their frequency of occurrence should be reviewed with women and their families. The importance of self-care and early intervention to promote health should be reemphasized. The midwife reviews the mother's health needs in order to ensure the choice of an appropriate birth site, making the mother aware that some health conditions are best addressed in the hospital (see Table 35-2). It is important to note that problems can occur that can be remedied through self-care, that need the midwife to resolve, or that need a physician to treat. Some problems may require referral or discharge out of the service. The midwife has ultimate responsibility for establishing the link to the hospital system, even though some women arrange or lay the groundwork for consultation/hospital services. Although urgent emergencies are rare in the home or in the birth center [15, 17], mothers need to explore their feelings regarding the worst possible birth outcome for them. This is a very sensitive issue that they may not be ready to discuss at the initial visit, but an introduction needs to be made and follow-up done during subsequent prenatal visits.

TABLE 35-2 Indications for a Change in Birth Site from Home or Birth Center to Hospital

1. Severe chronic hypertension and/or preeclampsia requiring management with medication
2. Current mental illness that the midwife deems would have a harmful effect on the perinatal course
3. Thromboembolic event requiring heparin
4. Current substance abuse including alcohol, cigarettes, and other drugs
5. Insulin-dependent diabetes
6. Clinically significant blood antibodies during current pregnancy
7. Two or more cesarean sections
8. No documented prenatal care
9. Medical indication for induction of labor
10. Placenta previa at term
11. Active preterm labor that cannot be stopped
12. Postdates greater than 42 weeks' gestation
13. Nonreassuring fetal surveillance results
14. Active herpes lesions of cervix, vagina, introitus, labia, or anus during labor
15. Multiple gestation diagnosed before or during labor
16. Persistent noncephalic presentation during labor
17. Febrile condition in labor with or without spontaneous rupture of membranes that does not resolve with hydration
18. Evidence of chorioamnionitis
19. Evidence of fetal intolerance of labor
20. Thick meconium stained amniotic fluid
21. Irresponsible attitude or action of parents
22. Unsafe home or location for birth

Note: The above list is not all-inclusive, and the midwife's clinical judgment may determine that additional conditions indicate a hospital birth. It must also be noted that there are recognized religious communities such as the Amish or Plain people who claim religious exemptions, choosing to give birth in the home or birth center setting even though they have conditions such as breech presentation or multiple gestation. The midwives caring for these women are responsible for acquiring the clinical skills necessary to manage these conditions, for obtaining informed consent from the mother, and for having a consultation agreement in place.

Source: From BirthCare & Women's Health, Ltd., Alexandria, VA, 2001. Reprinted by permission.

Complete History and Physical

During the initial visit, the midwife should be alert to historical and physical predictors of normalcy and predictors of deviation from normal. It is important for the mother and her partner to provide accurate family, medical, menstrual, and conception histories. Records from other health care providers should be requested if needed. With the information obtained through the history and physical, the woman and the midwife can identify factors that have potential to develop into problems. Instituting prevention strategies early increases the likelihood that the mother will birth in her chosen birth site.

Calculation of an Accurate Due Date

Particular attention must be paid to calculation of an accurate due date because there is a five-week window of safety for planned home or birth center birth. A pregnancy is full term from 37 weeks' gestation until 42 weeks' gestation after which it is considered postdates. Births occurring at less than 37 weeks' or more than 42 weeks' gestation, are more safely accomplished in the hospital, but occasionally the window of safety can be expanded a few days with careful fetal surveillance and appropriate consultation. When labor occurs before 37 weeks, lung maturity is a concern [50, 64, 65]. The mother whose preterm labor cannot be stopped is referred to the hospital, where appropriate staff and technology can give long-term support to the baby if needed. Likewise, labors occurring after 42 completed weeks of pregnancy are often transferred. As pregnancy is prolonged, there is an increased incidence of aging placenta, meconium passage, intrauterine fetal demise, and fetal distress during labor, which have been implicated as causes of morbidity and mortality [15].

Return Visits

By spending time with the mother during pregnancy, the midwife has occasion to obtain information that will help or hinder the mother's navigation through the maternity cycle. At every return visit, through an interim history, physical exam, and laboratory and adjunctive studies, mother and midwife identify reassuring signs of normalcy or identify problems that require follow-up. In the role of educator, the home and birth center midwife reminds the mother of symptoms that could indicate deviation from norm. The mother is thus enabled to continue to take a principal role in early identification of problems, allowing for early intervention. Women who plan to birth at home or in the birth center have less leeway to slip into the realm of abnormal. In order to remain out-of-hospital to birth, it is especially vital to intervene early, before problems occur that are not correctable. Women know that if they encounter specific complications (see Table 35-2) they will lose their opportunity to have the birth they had planned. This is a powerful motivator for women to engage in health promotion.

The Family's Preparation for Birth and Postpartum

Planning for birth involves readying the participants and requires considerable time, thought, and energy. More preparation on the part of the family is required when birth occurs out-of-hospital. The list of responsibilities include the following:

1. Continuing commitment to a jointly created plan of care
2. Keeping the midwife informed of any life changes
3. Doing specified reading
4. Attending childbirth education classes
5. Writing a birth plan
6. Confronting and resolving fears
7. Preparing antepartally for breastfeeding
8. Preparing invited participants for their responsibilities
9. Preparing siblings for their participation
10. Paying fees for care and/or conveying insurance information
11. Collecting and organizing specified supplies for home birth
12. Obtaining and packing supplies for transport to the birth center
13. Arranging birth assistant availability
14. Having a clean house
15. Arranging for pet safety and care at the time of labor and birth
16. Obtaining infant car seat and ensuring proper installation
17. Making an accurate, detailed map to the home
18. Visiting obstetric consultant, if needed

19. Making emergency plans and posting them by each telephone and in chart
20. Having a vehicle available with a full tank of gasoline
21. Knowing how to get to the hospital
22. Arranging pediatric care

As the due date nears, childbirth classes help the mother and her primary support partner focus on the upcoming birth. Classes that are most useful emphasize the mother's inner strengths and are presented by an instructor who is knowledgeable about home and/or birth center births, teaching with confidence that unmedicated birth is possible. Women will rely on techniques learned in class to enhance comfort and relaxation, to relieve pain, and to augment labor. Childbirth classes located in hospitals are often an orientation to the hospital system and prepare the mother for labor and birth in that setting.

Writing a birth plan gives women and their partners an opportunity to discuss what is important to them for their birth. These plans detail preferences about the environment, social interaction, and comfort measures, rather than options for medical pain relief and technologic interventions. Women and their partners identify who will be present at the birth, specific duties they may have, planned events with family and friends, the role of siblings, and religious or spiritual observances. Birth plans also describe coping measures learned from previous births, desired positions for labor and birth, and preferences for privacy and company at various points in labor. Plans for music, photography, audio and/or video recording may be outlined. To promote realistic thinking about possible transfers, families should be encouraged to write a hospital birth plan in addition to a home or birth center birth plan. This plan should focus on preferences regarding interventions and contact with the baby. Families must realize that when a transfer to the hospital is indicated, medical interventions are needed and should be expected.

Most home and birth center practices require that women breastfeed unless there are extenuating circumstances. Breastfeeding is an essential safety factor for women giving birth out-of-hospital. When the mother is home without professional assistance, breastfeeding helps to keep the uterus contracted, and, therefore, helps to control bleeding postpartum. La Leche League and other breastfeeding support groups are invaluable to breastfeeding preparation prenatally and support postpartum.

Participants who will be present for the birth require preparation. If children are to be present, they need to be prepared for birth events, including sights and sounds. They also need an adult whose primary responsibility is child care. This adult needs preparation for the labor and birth and for his or her role. Children must be cared for to allow the mother and her partner to focus their complete attention on managing labor. Also, if transport occurs, someone must be available for the children until the mother and/or her partner return from the hospital.

People attending the birth should be selected carefully. Some participants may have fears about out-of-hospital births. Addressing their fears before the birth may change attitudes, and their attendance at the birth can be a transformative experience. It should be made clear that people invited to attend the birth may be asked to leave if the mother seems to be distracted by their presence.

For birth center births, bags should be packed by 36 weeks' gestation and supplies ready for transport to the center. (See Table 35-3 for a list of supplies for birth center births.) Supplies needed for home birth, in addition to an up-to-date copy of the mother's chart, should also be organized by 36 weeks and in or close to the room in which the mother intends to birth. (See Table 35-4 for a list of supplies for home birth.) Siblings can take an active role in preparing supplies. Last minute details to be accomplished when labor starts can be posted on a "to do" list.

A home visit by the midwife or the birth assistant around 36 weeks' gestation confirms that the family is ready for the home or birth center birth. The family prepares a detailed map that can be tested for accuracy when this home visit is made. An emergency plan and important telephone numbers should be posted by each telephone in the home and in the mother's chart. The family should make a "practice run" to the backup hospital to ensure that they know the fastest route, the traffic patterns, where to park, and where to enter the building should a transfer become necessary. A cardinal rule is to be sure that the car that will be used for emergency transportation has adequate fuel to get to the hospital. Having hospital admission forms completed and in the chart before labor begins decreases stress if a transfer to the hospital becomes necessary. For home birth, a relatively clean house and pet control are obvious responsibilities of the family. Most pets can be present at births without causing any difficulties.

TABLE 35-3 Family Supplies for Birth Center Birth

Items Packed for Easy Transport to Birth Center by 36 Weeks

1. Nutritious, easy to prepare meals and snacks for you and your birth team
2. At least 3 quarts of juice, teas, and broths
3. Honey
4. Clothes to wear during labor
5. Extra pillows
6. Music (CDs or cassettes)
7. Bathing suit and towels for partner
8. Entertainment for older kids (books, games, videos, etc.)
9. Nutritious postpartum meal for the new parents
10. Clothes for the mother to wear home
11. Hydrogen peroxide and ammonia for spot removal and laundry
12. For the baby:
    a. Clean thermometer
    b. Six receiving blankets
    c. Vaseline
    d. Five disposable newborn size diapers
    e. Baby clothes suitable for the weather
    f. Car seat in place, adjusted to fit newborn

Source: From BirthCare & Women's Health, Ltd., Alexandria, VA, 2001.

TABLE 35-4 Family Supplies for Home Birth

Items to Be Assembled and Organized by 36 Weeks

Most midwives request that the family provide some supplies. These can be purchased through a company that customizes the birth kit to the specifications of the midwife or the family may obtain the items individually. Items for the family to obtain include the following:

1. Mattress cover (e.g., plastic drop cloth, shower curtain liner)
2. Extra pillows covered with plastic
3. Food and fluids for labor
4. Flexible straws
5. Clean towels
6. Antiseptic solution (e.g., betadine, zephiran)
7. Wash cloths or 4 × 4 gauze pads
8. Flashlight with batteries and extra batteries
9. Mirror
10. Bowl (2 quart size)
11. Bulb syringe
12. Heating pad
13. Baby hats
14. Baby receiving blankets/soft towels
15. Thermometer
16. Measuring tape
17. Peri pads and belt/panties
18. Squeeze bottle
19. Disposable waterproof underpads
20. Baby clothes and diapers
21. Alcohol and cotton balls
22. Large plastic garbage bags
23. Ziploc freezer bags
24. Hydrogen peroxide for removal of blood stains

Source: Adapted from American College of Nurse-Midwives. *ACNM Handbook: Home Birth Practice*. Washington, DC: ACNM, 2001 and from Varney, H. *Varney's Midwifery*, 3rd ed. Sudbury, MA: Jones and Bartlett, 1997.

The Experience of Birth at Home or in the Birth Center

When labor begins, the family contacts the midwife, the birth assistant, and the other people who are invited to attend the birth. Preparations by both family and midwife should be complete by 36 weeks' gestation so that all supplies and arrangements are in place when the midwife is notified that the mother may be in labor. During the initial labor call, the midwife gathers data about how the mother is experiencing her labor, her needs, and her support systems. Taking into account the mother's perceptions and prenatal history, the midwife, the mother, and her support network review choices and make appropriate management plans. Plans may include further telephone contact or a decision for the midwife to meet the mother for additional assessment.

If the mother is comfortable at home, has the support she needs, and there are no concerns that require immediate follow-up, continued telephone contact with her midwife may be all that is necessary. The mother may want to continue her activities of daily living while emphasizing hydration, nutrition, and increased rest. There should be a variety of food choices for the laboring mother and food should be available for the entire birth team. Friends and family may come to help with final preparation and management of other household activities, freeing the mother and her primary support partner to focus on the labor.

A woman planning a home birth may "double make" her bed to protect the mattress. The bed can be made with a full set of linen and then completely covered with plastic such as a plastic mattress cover, a drop cloth, or a shower curtain. A clean old sheet is placed on top of the plastic so that the bed may be used as desired for labor or birth. When the birth is completed, it is a simple matter to remove the top sheet and the plastic. Clean linen is then readily available for the mother's comfort postpartum.

The midwife may do the first physical assessment of labor in the mother's home, the birth center, or the midwife's office regardless of where the birth is planned. The midwife may also choose to delegate this assessment to birth center nursing staff or to home birth assistants. The initial assessment should include a review of the prenatal record, a physical to assess presentation, vital signs of the mother and baby, uterine contractions, and maternal response to labor. A pelvic exam may be part of the initial physical assessment to confirm labor progress, verify the presenting part, or provide information that the mother requests. This exam may be delayed until labor becomes more active.

As labor intensifies and the woman is working harder, the midwife augments the birth partner's support measures, gives reassurance, guides the mother to conserve her energy, and assesses maternal and fetal well-being as per clinical practice guidelines. The mother is free to move around and be in any position she chooses. The midwife may suggest positions that promote comfort, encourage progress, and maintain fetal well-being. In the birth center or home, mothers very frequently birth out of bed.

During the second stage, it is not unusual for the mother to continue to change positions moving from the bed to other locations within the home or birth center. The midwife must be alert, flexible, and able to anticipate the mother's movements. Sterile instruments should be placed on a portable sterile surface allowing the midwife to move, following the mother's lead. Good communication among the midwife, the mother, and her birth team helps everyone work together effectively. When the mother describes where and how she feels the baby's descent, the midwife can give feedback confirming or correcting her perceptions. If the mother is reluctant to change position, the midwife may need to use persuasive communication to suggest positions that will help effect the birth.

As the baby emerges, the mother and/or her partner often reach down to bring the baby out of the birth canal onto the mother's abdomen or chest. The baby remains skin to skin with the mother, the midwife observes the baby for signs of successful transition from intrauterine to extrauterine life, and breastfeeding is encouraged immediately. The focus of the family is directed toward welcoming the new baby (Figure 35-3). Siblings are often present at the birth or they can be invited in when the mother wishes.

The midwife is attentive to the progress of the third stage. Birth of the placenta is usually unhurried. If the mother needs or chooses to, she may squat or sit on the toilet to facilitate the completion of third stage. The family has the option of keeping their placenta to bury under a plant or tree or the midwife may dispose of it through a medical waste management company.

Source: Photo credit, Kari Horton.

Birth is simple. In the home and birth center settings, where interruptions are limited to those necessary to ensure safety, birth can more easily unfold. Welcoming the new baby can take place as the family has planned. An out-of-hospital birth can have long-lasting, positive effects on parental and sibling bonding and attachment, confidence for parenting, and memories of the birth as a peak emotional experience for the family.

The Early Postpartum Period and Follow-up

The postpartum period is a special time for the mother, her family, and friends to welcome and bond with the new baby. The midwife in the home and birth center setting is a participant in this time of welcome. The tasks that the midwife must accomplish are both similar to and different from tasks in the hospital environment. During this postpartum period, it is not unusual for the midwife to spend at least two to four hours actively working at jobs typically accomplished in the hospital by nursing, secretarial, housekeeping, and dietary staff [66].

The mother and her baby are more likely to remain stable after breastfeeding is established. Once vital signs are stable and within normal limits, the midwife can leave the family in private, facilitating a period of family bonding. During this time, the midwife can accomplish the usual postpartum responsibility of documenting the birth. The midwife, along with the birth assistant, also ensures nourishment of the mother, helps with breastfeeding, assists the mother to shower and void, washes the instruments, and puts the birth site in order. Quite often, family and friends who have attended the birth as guests become helpers during this postpartum family time.

The midwife does a complete newborn physical examination, often using a heating pad for a warm surface. The exam provides an opportunity for teaching, usually taking place on the mother's bed in the presence of excited children greeting the new sibling (Figure 35-4). Family members often participate in weighing, measuring, and dressing the new baby in the midst of friends taking photographs and a great deal of socializing and celebration [66].

The very positive side of this time is the intimacy, emotion, and social closeness involved in spending this time with a family. For many midwives, the tenderness, bonding, and beauty of these postpartum hours fuel their love for midwifery and out-of-hospital birth on a fundamental level [66].

After the midwife departs the home or the family leaves the birth center, it is recommended that the baby stay close to the mother and not receive a bath for the first 24 to 48 hours to aid the baby's ability to stabilize temperature. The mother and baby are assessed in the first 24 to 48 hours (see Chapter 42) at either a home or office visit. A phone assessment may also be made. The developing family relationships, adequacy of help in the home, infant caretaking abilities, and follow-up appointments with the baby's health care provider are also assessed at this visit [1]. The family may be seen in the midwife's office at 2 weeks and 6 weeks postpartum to evaluate postpartum recovery (see Chapter 42). Follow-up thereafter is in accord with the woman's needs for gynecologic and primary health care.

FIGURE 35-4 Cutting the umbilical cord: sibling participation.

Maintaining Safety

Maintaining safety is the primary priority in all settings where midwifery is practiced. Mechanisms for handling problems must be clearly outlined by providers and institutions wherever birth takes place. In the home and birth center environments, careful planning for these requirements is also essential.

Prevention is the first line of defense for safety maintenance. Safety is most effectively maintained when you work to enhance health and strategize to reduce risk. Most women who choose home and birth center birth understand that in order to achieve their goal of birthing in their preferred site, they have to work to build an optimum maternity experience by bolstering excellent health and promoting a pregnancy free from complications. Appropriate birth site planning also reduces the incidence of problems during labor and birth (see Table 35-2). However, birth is not 100 percent predictable. Even when you and the mother have worked together to select the birth site to match her needs, challenges and problems may occur during labor and birth [2, 4, 15, 19, 21, 25, 43].

The second line of defense is early recognition of problems and appropriate early interventions to resolve them. Research demonstrates that the screening process will yield a limited and predictable pool of potential complications that can be anticipated [3, 10, 11, 19, 25, 67, 68]. Early problem recognition makes it possible to effectively intervene utilizing the small number of provider personnel and the simple technologies typically present at a home or birth center birth. When the midwife determines that more personnel and complex technologies are needed, previously arranged plans are implemented for transport.

Equipment, Personnel, and Clinical Judgment

The equipment that you need intrapartally to assist with normal birth as well as to intervene for problems or complications is remarkably simple. You may want to make changes in the suggested list of equipment and its organization as you actually use it for births (see Table 35-5).

Most home and birth center practices utilize two intrapartum providers: the primary midwife and a birth assistant [46]. This ensures that adequate staff is available to meet the laboring family's needs for support and safety maintenance without compromising privacy. The physical needs of the woman require physical strength to meet them. Labor is often long, and in order to meet the woman's needs, the midwife may need rest to keep her mind fresh, her attention focused, and her body strong. Providing both a midwife and a birth assistant reduces distracting staff changes while providing adequate help.

A birth assistant is a person with supportive and technical labor, birth, and postpartum skills. These skills include evaluation of the mother's physical and emotional needs and status during labor, and the ability to monitor maternal, fetal, and newborn vital signs. The birth assistant should also be able to provide assistance with breastfeeding and postpartum care. A positive attitude toward out-of-hospital birth is essential. Some birth assistants are registered nurses or emergency medical technicians, but it is not necessary for the birth assistant to be a medical professional. Childbirth educators, La Leche League leaders, and doulas have many of the above skills and make good birth assistants. The additional technical skills can be readily obtained.

Each time the midwife and the birth assistant set up for a birth, they organize and check the equipment. A review of the mother's chart and her birth plan will focus attention on her individual needs. The midwife and birth assistant may desire to ready equipment and review the skills needed to address potential problems. Drills may be scheduled to ensure that the midwife and assistant will be able to work together smoothly.

For complications such as shoulder dystocia, postpartum hemorrhage, and neonatal resuscitation, there is value in having help. The birth assistant should also be able to perform emergency measures as needed, including suprapubic pressure, fundal massage, and assistance with the administration of medication. CPR certification and familiarity with neonatal advanced life support are essential.

Problems may develop that are a challenge to manage with the limited equipment and personnel available in the home or birth center setting. In a hospital practice, the infrastructure of the hospital's technology and personnel provides layers of additional support. Away from the hospital, clinical judgment takes into account the known delay between some decisions and the implementation of necessary interventions. Management of problems depends on written clinical practice guidelines, characteristics of the mother and her support system, the network of medical support, and the midwife's ability to perform clinically [46]. Other factors that influence decision-making may include the following:

1. Level of experience of CNM/CM
2. Distance from the hospital
3. Quality of the consultant relationship
4. Road conditions
5. Mother's previous birth experiences and commitment to out-of-hospital birth
6. Quality of communication between the CNM/CM and the parents

TABLE 35-5 Midwife Equipment for Birth at Home or in the Birth Center

Essentials

1. Up-to-date copy of chart available
2. Forms for intrapartum, postpartum, and newborn charting
3. Birth certificate forms
4. Blood pressure cuff, stethoscope
5. Fetoscope/Doppler
6. Gloves (sterile; nonsterile)
7. Lubricant (sterile; nonsterile)
8. Sterile instruments
   a. scissors (2 pairs)
   b. large clamps (Kelly or Rochester-Ochsner)
   c. needle holder
   d. ring forceps
   e. amnihook
   f. cord clamp or cord tape
9. Sterile 4 × 4 gauze pads
10. Baby blankets
11. Heating pad for baby blankets
12. Bulb syringe
13. Baby scale
14. Measuring tape
15. Vitamin K
16. Erythromycin ophthalmic ointment
17. Sharps box and mechanism for hazardous waste disposal
18. Light source (e.g., flashlight, gooseneck lamp)
19. DeLee suction trap or suction machine
20. Baby ambu-bag
21. Laryngoscope with infant blade
22. Endotracheal tubes, size 3.5 mm and 4 mm
23. Oral airways (infant, adult)
24. Small oxygen tank, oxygen tubing, mask (neonatal and adult)
25. Injectable oxytocin (Pitocin) and methylergonovine maleate (Methergine)
26. Oral methergine
27. Urinary catheters
28. Suture with needles
29. Local anesthetic, syringes, and needles
30. Urine dipsticks
31. Nitrazine paper
32. Intravenous fluids: lactated Ringer's/5% dextrose in Ringer's lactate/5% dextrose in water/normal saline
33. Angiocaths, long intravenous tubing, tape, antiseptic ointment, gauze pads
34. Blood-collecting equipment: tourniquet, tubes, vacutainer, and needles
35. Newborn screening collection forms and lancets

Extras to Consider

1. Otoscope/ophthalmoscope
2. Hot water bottle or heating pad
3. Flexible straws
4. Electrolyte replacement drink (e.g., Pedialyte, Gatorade)
5. Massage roller
6. Instruments
   a. tissue forceps
   b. Allis clamps
   c. hemostats
7. Combs for acupressure points
8. Antibiotics for intravenous use
9. Crock-pot for hot perineal compresses
10. Adult ambu-bag
11. Cotton baby hats
12. Culturettes
13. Camera
14. Apron or gown and protective eyewear
15. Change of clothes
16. Toilet articles
17. Mirror
18. Speculum
19. Dextrostix

Source: Adapted from American College of Nurse-Midwives. *ACNM Handbook: Home Birth Practice*. Washington, DC: ACNM, 2001 and from Varney, H. *Varney's Midwifery*, 3rd ed. Sudbury, MA: Jones and Bartlett, 1997.

It is important to remember that for home and birth center births, it is rare for transfers to the hospital to be of an urgent or emergency nature. Research shows that 97.5 to 99 percent of women in labor planning a home or birth center birth actually give birth in their chosen setting or are transferred in a nonemergency fashion [3, 4, 17]. Appropriate birth site selection, familiarity with the research, and sound clinical knowledge enable the midwife to plan appropriately for prevention, correction, or stabilization of problems and, if necessary, for transport of the mother and/or the baby to the hospital.

Home and birth center midwives need to remember that in an urgent emergency, the midwife has ultimate responsibility for decision-making. If time permits, the birthing woman and her family may provide input. Consultation with a colleague or a physician may be possible only by telephone, but time constraints and birth setting may mandate decision-making and clinical action by the midwife alone, usually with the help of a birth assistant.

Many times the midwife will be tempted to be led by the heart instead of the head. The midwife may also be pressured by families who wish that their midwife would attend them in labor in spite of

complications. Wish management does not work. Learning to say "no" is not only important, it is crucial. Midwives must be brutally honest with themselves in describing their own skills, their own comfort level, and their own experience.

Some clinical situations have become a focus of attention and curiosity causing concern or controversy among researchers, maternity care providers, and consumers alike regarding appropriate management of home or birth center birth. The following sections include a discussion of selected clinical situations along with some management strategies that are utilized when planning a home or birth center birth. Management of these situations may be divided into three categories for home and birth center management: (1) preventive, (2) nonurgent, and (3) emergency.

Preventive Management

Antepartal prevention is the key for dealing with iron deficiency anemia, gestational diabetes, and pregnancy-induced hypertension. These conditions, if not properly managed, can preclude a birth center or home birth. If a tendency toward low hematocrit, increased glucose levels, or pregnancy-induced hypertension is identified during pregnancy, greater attention to self-care, including diet, exercise, rest, and stress reduction can help prevent the problem or restore normalcy. Mothers who are motivated and successful in keeping their lab values and other signs and symptoms within normal limits, may continue their out-of-hospital birth plans if no underlying disease is present. To ensure good communication and to cultivate the mother's readiness to transfer, a consultation visit may be indicated. If lab work, vital signs, or symptoms cannot be maintained within the range of normal, antepartal referral to a physician should be arranged. If health status remains outside the range of normal, the technologies and staff for monitoring the needs of mother and baby are too complex for intrapartal management in the home or birth center.

Management of Nonurgent Clinical Situations

Multiple studies have identified prolonged labor in nulliparas as the most common reason for transfer into the hospital [2–4, 10, 14, 19, 25, 67–69]. Patience and attention to supporting the mother's efficient use of energy during labor are the most important interventions that the midwife can effect. Adequate hydration and nutritional sources of energy are essential. The environmental variety found within the birth center and home can help the mother pass the time and maintain progress. When slow progress is a concern, it must be clearly understood that oxytocin cannot be administered to augment or induce labor in home or birth center. Exogenous oxytocin may cause hyperstimulation of the uterus that significantly reduces the placental blood flow, causing hypoxia in the baby who then needs increased technology to be rescued from the labor. If labor stimulation cannot be accomplished by more natural means such as walking, nutritional support, castor oil, making love, or nipple stimulation, then a hospital transfer is indicated.

Sometimes when labor has been long, the mother may lose her ability to cope with labor pain and may find that strategies for nonpharmacologic pain relief are no longer effective. At home or in the birth center, medication for pain is avoided or minimized because of the medicine's potential for reducing effectiveness of contractions and potential depression of the baby's respiratory centers. In cases when narcotic analgesics such as nalbuphine (Nubain) are used, naloxone hydrochloride (Narcan) for the baby must be available. If the mother's need for pain relief cannot be met by nonpharmacologic means or with limited amounts of mild analgesia, a transfer is indicated. A nonurgent transfer may take place in the family car as long as vital signs are observed indicating good health in both mother and baby. Mothers transferred for prolonged labor with their first baby can usually complete subsequent births out-of-hospital.

In cases of prolonged rupture of the membranes at home or in the birth center, concern about infection is much reduced, but not eliminated. Pathogenic bacteria are not in abundance, and the intravaginal instrumentation that often occurs in the hospital setting is not done. Nevertheless, limiting pelvic exams and monitoring for signs of infection remain of critical importance. A time limit before transfer to the hospital, if necessary, will depend on the midwife's preferences, the mother's preferences, and negotiations with the medical system, including obstetric, pediatric, and neonatal protocols.

Clients with positive Group B Streptococcus (+GBS) status may birth safely at home or the birth center. When intravenous antibiotic prophylaxis is indicated, it may be administered in the home or birth center. Positive GBS mothers and their partners should discuss neonatal follow-up plans with the baby's pediatric care provider during the prena-

tal period. Families may be taught to monitor and record the baby's vital signs on a newborn monitoring form such as the one shown in Figure 35-5. This will enable them to convey information about the baby's health to their pediatric care provider within 12 to 48 hours after birth.

Because vaginal birth after cesarean (VBAC) labors tend to be long, the home or birth center may be the ideal birthplace for the VBAC mother, especially if she feels that the initial cesarean was unnecessary. The VBAC mother needs support to empower herself to labor and to protect herself from disappointment again. It may be liberating for her not to go back to the hospital [70]. Feelings of profound hurt may not be totally resolved until after the current pregnancy is completed and the mother births her baby vaginally or via repeat cesarean. Documentation of a low transverse uterine incision

Newborn Monitoring Form

Baby's name _____ **Date and time of birth** _____
Birth weight _____
Notable factors _____

Use this form to record your baby's vital signs and appearance every 3 to 4 hours. Temperature may be taken under the baby's arm. Count heart rate (HR) and respiratory rate (RR) for a full minute. Note the baby's activity, feeding, and excretory patterns—e.g., sleeping, alertness, crying, diaper changes, and any other observations—in the comments column.

Time	Temperature	Heart Rate (HR)	Respiratory Rate (RR)	Color	Comments

Note: Normal range for heart rate is 120 to 160 beats per minute. It may be lower when baby is sleeping. A heart rate over 160 when baby is at rest is not normal. The respiratory rate should be within 30 to 60 breaths per minute. A rate over 60 when baby is at rest is also not normal. The baby's axillary temperature should be between 97.7 and 98.6°F. Notify your midwife or baby's health care provider if your baby's heart rate, respiratory rate, or temperature are not normal or if you notice irritability, inactivity, poor feeding, vomiting and abdominal distention, jaundice, episodes of blue or gray color, or increasing respiratory effort.

FIGURE 35-5 Newborn monitoring form.

Source: From BirthCare & Women's Health, Ltd., Alexandria, VA, 2001. Reprinted by permission.

must be obtained. The mother should have a history of only one previous cesarean, as there is a slightly higher incidence of uterine rupture with two or more previous incisions. If the mother has had a previous vaginal birth, her chances of having a successful VBAC are greatly increased [71–75]. Informed consent specific to VBAC should be obtained from the outset with careful review of the practice's successful VBAC rate, repeat cesarean rate, possible complications, arrangement for transport to the hospital, and discussion of realistic expectations. Obtain a clear jointly agreed upon management plan with the obstetrical consultant.

If meconium appears at any time after rupture of the membranes, consistency of the meconium should be evaluated. Notification of the consultant depends on the consultation agreement and the type of meconium present. Meconium stained amniotic fluid combined with a fetal assessment that evidences fetal well-being does not always indicate need to transfer the mother to the hospital. However, a discussion with the mother and her support partner regarding your assessment, possible consequences of meconium aspiration, and treatment options both in and out of the hospital should always be initiated and documented. The decision to transport or not should occur with the midwife's guidance and with consideration of the family's preferences. If the decision is made to remain out-of-hospital for the birth, a DeLee suction trap and other resuscitation equipment should be readied. Amniotic fluid with thick meconium indicates that the mother should be transferred to the hospital before the birth, if there is adequate time.

Management of Emergency Clinical Situations

Some variations and abnormalities in fetal heart rates and patterns may require emergency transport to the hospital. If at any point during the labor the midwife feels a need to monitor the baby more closely than intermittent use of the fetoscope or Doppler allows, then the mother should be moved to the hospital rather than a fetal monitor moved to the mother. Abnormal fetal heart rate patterns that do not resolve with increased hydration, a change in maternal position, and a brief period of oxygen by mask indicate that the baby is at increased risk. A transfer to the hospital is indicated to allow access to the needed personnel and technology to manage the problem.

Women with breech presentation diagnosed antepartally should have an informed consent discussion about getting the baby to turn and/or planned hospitalization for vaginal breech birth, or cesarean for breech. If by the onset of labor the breech presentation persists, the plan for hospitalization should continue. Rarely, a client in labor at home or in the birth center may present with a previously undetected breech. If this occurs, it is important for the home and birth center midwife to implement care for breech birth, and if time allows to call 911 for extra personnel and equipment, to call the consultant, and to transport to the hospital if possible.

Home birth is for normal birth. Part of planning for safe home birth is considering the "what ifs": what if a birth is complicated and the mother needs to go to the hospital? Safe home birth depends on skilled assistance and technology being available 24 hours a day for complications and emergencies.

The question of most concern that the general population asks regarding home and birth center birth is "What if the baby doesn't breathe?" The reality is that in the healthy population experiencing normal pregnancy, unmedicated labor, and uncomplicated birth at home and in the birth center, birth requiring resuscitation is very rare [29, 30]. However, dealing with such fears is essential. Neonatal Advanced Life Support (NALS) certification or an equivalent is a critical skill for both midwife and birth assistant who attend home and birth center births. Having two trained people present for all births is advisable. When a need for resuscitation occurs in these settings, help is remote and you are truly on your own. The resuscitation equipment and skills provided by home and birth center midwives are usually successful in stimulating the baby's respiratory effort, and the baby is likely to recover immediately. If this does not occur, your goal is to stabilize the baby, oxygenating adequately until transport to a neonatal intensive care unit is completed.

Another common concern regarding home or birth center birth is "What if the mother bleeds too much?" The reality is that postpartum hemorrhage requiring transport is *extremely* rare. The incidence reported is 0.2 to 1 percent [4, 15, 17]. In research that examines out-of-hospital birth with a comparison low-risk group birthing in the hospital, there is a greater incidence of postpartum hemorrhage in the hospital group [30]. In out-of-hospital settings, intravenous volume expanders with added oxytocin (Pitocin) can be started, or methylergonovine maleate (Methergine) can be administered intramuscularly or orally. Oxytocin administration in the home or birth center is limited to placental manage-

ment and postpartum hemorrhage. Management of postpartum hemorrhage as outlined in Chapter 34 can take place safely and successfully in the home or birth center, with the exception of the administration of blood or blood products that are not available in these settings. However, a hematocrit of less than 30 percent or a hemoglobin of less than 10 g/dL may predispose a woman to anemia symptomatology, and antepartal transfer to hospital-based care may be considered. If an immediate or delayed postpartum blood loss causes symptoms of hypovolemia making ambulation difficult, reducing self-care abilities, delaying the onset of milk production, or reducing the mother's ability to compensate, she may need professional assistance beyond the capabilities of family and friends and may require hospitalization for evaluation and treatment if indicated. It is important to remember that mothers birthing at home or in a birth center will not have continuous professional postpartum support beyond 3 to 12 hours postpartum.

Coping with Unexpected Outcomes

If transfer to the hospital due to complications becomes necessary, women who had planned a home or birth center birth must cope with two concerns: worrying about their health and/or their baby's health, and experiencing the feelings of the loss of their planned home or birth center birth. Anticipatory guidance prenatally can reduce the family's distress if transport becomes a reality. Reminding families late in pregnancy of the possibility that transfer could be necessary, reviewing practice statistics, and describing actual transport experiences may be helpful. Discussion may include a review of the decision-making process, consultation, the trip to the hospital, and admission. Women need help to understand that if they are going to the hospital, they are going to obtain the technical interventions they had hoped to avoid but now need.

During the process of informed consent at the first visit, and again around 36 weeks, women should be made aware of the possibility that their baby could be injured or die during the birth process regardless of their chosen birth setting [46, 63]. Although most people hesitate to focus on this frightening issue, women need to ask themselves what they would do and how they would cope. They also need to explore how they would respond to family or friends who may not have been supportive of their decision to give birth outside the hospital. The excerpt in Figure 35-6 offers a moving perspective that can help with preparation of the family.

Final Thoughts

Part of birth is death. Conception is the beginning of life and every life must end sometime. It may be at the time of implantation of the egg in the uterine nest, or it may be a true knot in the cord that tightens in pregnancy, or it may be a car accident that takes this new life. Part of pregnancy is the excitement of new life and the fear of its loss. This is normal human reality and is in part why pregnancy deepens and matures a woman and a man spiritually and emotionally.

The last "what if" to consider is what if your baby is injured or dies as a result of an accident of nature? How would you feel? How would your family treat you? You will need to live with your decision and face family and the public in a culture where the norm is to go to the hospital for childbirth. Please explore these questions in your self and discuss them with your partner and your midwives.

The safety of home birth is well documented (see Marjory Tew's *A Safer Childbirth*), but childbirth by its nature is a threshold passage for the baby. Some babies are born with defects and injuries despite all the technology, tests, and skills of the attendants. Despite the fact that hospitalization of birth has failed to eliminate fetal or neonatal death, there is a cultural expectation that doctors and hospitals can guarantee a "perfect baby" every time.

We believe that by being prepared for all scenarios you will have a deeper more empowering birth experience and will feel that you made the best choices possible given the best information available at the time. The facts are not all in yet. We as a culture are still all learning about the wonders of pregnancy and birth.

FIGURE 35-6 Final thoughts.

How to Accomplish an Effective Hospital Transfer

When problems occur intrapartally and a transfer to medical management is necessary, it is often a time of stress for providers and families alike. Credibility will be increased on arrival at the hospital if a professional image is maintained. Sometimes this is hard to preserve when working quickly with little time to chart. In times such as these, it is worthwhile to have a previous arrangement already in place with a referral system, and a transfer form to quickly summarize the clinical picture.

Ideally, the problem necessitating transfer is identified as it is emerging. Decision-making, clinical skills, and good communication among midwife, woman, family, and consulting practice take the midwife's full concentration and attention. Unfortunately, transfers often occur when labor has been long, and mother and midwife are tired. The mother and her family may be disappointed, and sometimes may blame the midwife for letting them down. Under such circumstances, it may be difficult to find the time and mental ability to document completely and accurately, but it is even more critical in these circumstances to do so.

The transfer summary (Figure 35-7) is a straightforward, simple form that elicits pertinent data and relieves much of the worry that some important documentation is being omitted. It can be easily utilized by the midwife or the birth assistant. Communication by phone with the clinicians who will receive the mother is also important. It is good to have no-carbon-required (NCR) forms or to make a copy of the chart before you get to the hospital. The midwife transferring the mother to the hospital must retain the original copy of all the records.

When consultation, collaboration, or referral including transfer is needed, a concise, complete, and easy-to-read chart is an ambassador for the mother and the referring midwifery service. This is

TRANSFER SUMMARY

Date	Time	Event
		Reason for transfer
		Review with client and family YES/NO
		Name of consultant
		Consultation and plan
		Transport called (if applicable) YES/NO
		Mode of Transport
		Arrival of transport vehicle (if applicable)
		Mom: T _____ P _____ R _____ BP _____
		Baby: FHT _____ T _____ P _____ R _____
		Departure from home/birth center
		Arrival at hospital
		Signature of receiving provider
		Type of intervention
		Initiation of treatment
		Birth info: Vag C/S Apgars ____ / ____
		Outcome summary
		Release for hospital records sent
		Hospital records received

FIGURE 35-7 Transfer summary.

especially important in home and birth center practice, since the hospital staff who receives the woman may not be familiar with home or birth center birth. They may not be aware of the statistics that have shown just how safe this birth option really is and may believe that the woman's original plans were unwise. The chart can sway the attitudes of the clinicians who render care and may determine what care the woman receives. In addition, hospital providers actually see only the mothers for whom transfers are needed. Their experience has not been shaped by the reassurance and satisfaction of seeing the other 85 to 90 percent of labors and births that proceed safely and superbly at home or in the birth center [4, 30].

Business Issues

Although most birth centers and home birth services are small, regulatory and business issues still must be addressed when opening a practice. The same legal and professional documents that are necessary when starting a hospital practice are also necessary for a home or birth center practice. A reliable financial management system must also be in place. Combining the on-call lifestyle with practice management may cause the midwife to overlook either clinical or administrative issues. These are not easy tasks to accomplish, particularly when a night of sleep is missed. A midwife needs administrative help to run a service.

A self-employed independent midwife has more control over decision-making and administration. There is less vulnerability to losing the practice due to a change in priority on the part of a physician, an HMO, or a hospital administration. Knowing the cost of every item used, the midwife is able to determine the economic advantages and disadvantages of business strategies. By the same token, there is much more responsibility and financial risk. The midwife understands when to go "that extra mile" to keep the practice alive.

Financial management can make or break a practice, and administrative structure may need to be adjusted often. There may not be much of a budget to work with in the beginning, so it is important to make realistic predictions. If the overhead of the practice can be kept low, salaries may be adjusted higher. Even in established practices, it is not uncommon for home birth or birth center midwives to have lower salaries than their hospital-based colleagues.

Salaries for clinical staff should amount to approximately 50 percent of the income generated. However, when the practice first opens, overhead may use up all of the income from services, leaving little for the owner(s). In most practices, the person in charge of billing and collections is key to financial survival. Interpersonal skills and a commitment to the practice help keep the service afloat financially.

The major changes that have occurred in the health insurance industry in recent years affect all providers. Many home birth and birth center midwives are providers on managed care panels, and they are reimbursed by Medicaid and indemnity plans. Some insurance companies require accreditation through the Commission for Accreditation of Birth Centers in order for birth center based midwives to become participating providers. Negotiations with insurance companies require patience, persistence, and expertise. ACNM has developed materials to help midwives become skillful negotiators, thereby keeping services viable and available to women [46, 76–79]. Unfortunately, insurance may limit provider choice for women unless they have the resources to pay out of pocket. This can be especially sad for returning clients whose insurance has changed, precluding birth with their previous midwifery service.

Financial arrangements with consulting practices should be clear. The consultant may elect not to charge a consultation fee to the midwife for providing services but will charge the woman for services actually rendered. This works out well financially for the midwife, as long as the families pay the consultant. If women have past due balances with the consulting practice, it is wise for the midwife to pay the consultant adding the woman's unpaid balance to her bill from the referring midwife's office. By ensuring prompt payment of fees, the midwife fosters the relationship with the consultant.

A mechanism for statistical collection should be in place before a practice opens. Accurate statistics facilitate evaluation, quality management, validation of effective practice, peer review, and research. These practice statistics should be collected regularly and analyzed at least annually. Computer programs are available to assist in data collection and analysis. When arrayed clearly, statistics also serve as a public relations tool conveying important information to families about outcomes and transfers.

Although the home and birth center environments are less bureaucratic, they are not less political. Emotions run high about out-of-hospital-birth.

People in the medical community are often unfamiliar with and hesitant to show support for birth center and home birth, harboring misconceptions that are not based on fact. Their attitudes can be a significant barrier to practice. Sometimes when physicians serve as consultants for home and birth center practices, they may benefit from referrals not only from the midwife practice but also from client networks and sympathetic childbirth educators. However, this can have its costs in the medical community. As the consultant's practice grows, competition among physicians may also grow. Some physician colleagues may refuse to cross-cover for a midwife's consultant physician.

Midwives practicing in the home and birth center settings need to be astutely aware of who wields power, both in their local medical community and in their legislative and regulatory arenas. ACNM has legislative liaisons and lobbyists both nationally and at the chapter level to keep members aware of political and practice issues. In order to break down barriers, safeguard the profession, and protect the health care rights of women and their families, midwives have to be alert and proactive.

Special Home and Birth Center Resources

Working in the home and birth center environments, midwives have increased access to the important resources of time, place, and social interaction. In the hospital, the staff may become inured to and unconscious of interruptions:

> Studies found that a woman with a low risk delivery giving birth to her first child in a teaching hospital could be attended by as many as 16 people during 6 hours of labor and still be left alone for most of the time. Routine, though unfamiliar, procedures, the presence of strangers and being left alone during labor and/or delivery caused stress, and stress can interfere with the course of birth by prolonging it. . . . [48]

In birth centers and homes, midwives are able to provide more time and privacy to the birthing woman and her support partner. Observing unobtrusively and vigilantly for continued normalcy and for early signs and symptoms of problems, midwives' lifeguarding skills, in the vast majority of cases, remain only in their minds, tucked away in their bags, and behind the closed doors of cabinets. As long as birth remains normal, midwives limit their role to helping the woman be as comfortable as possible, validating the efforts the mother makes to bring forth her baby. In the out-of-hospital environment, midwives maximize opportunities to practice "the art of doing nothing well" [80].

All laboring women seek ways in which they can be most comfortable and most productive. In the home and birth center, women and their partners feel that they have more permission to be creative in finding ways to help themselves birth their babies. The primary support partner knows better than anyone what is needed to help the mother be herself and do her best.

The birthing family's job is to invent and claim their coping strategies [81]. The midwife's job is knowing when and how to augment the partner's supportive efforts and when to assist in their inventions. The home and birth center environment fosters continuity of care that takes on a new meaning within this paradigm. The midwife is more free to offer a continuous presence during labor, benefiting those mothers who desire increased support. This continuity enables the midwife to watch the way the mother and her partner work with labor and how labor energy is being used. Because home and birth center birth is dependent on the mother's natural abilities, continuity provides the midwife an opportunity to watch the dynamic process of labor as it ebbs and flows. This enables her to know when it is beneficial to wait and when to push labor along before the mother's energy cannot be replenished.

In the home and birth center, the midwife can make physical changes in the birth environment to promote the mother's coping ability. Energy to promote labor is affected by the connotative values and physical attributes of spaces. The control over and accessibility of the environment will have an effect on how labor energy is used. Home and birth center environments open up opportunities not often available in the hospital.

The woman conserves labor energy simply by knowing where things are and not having to ask for permission to enter a space or touch things inside the space. Helping a woman move to another room can alter labor, enabling the mother to leave behind nonproductive reactions and coping mechanisms. In the home and birth center, the character of each room gives variation to the quality of the energy. The bedroom has a restful feel to it, the living room or lounge is more social, and the kitchen is a place where people are busy and move around. As the social dynamic changes, activities that are acceptable also change. In a bedroom, the mother feels she has

permission to be naked, to cuddle with her partner in privacy, or even to have sex, which can increase effectiveness of contractions. In the lounge or living room, dancing to music at whatever volume she chooses seems natural. In going from room to room the lighting and temperatures change, and change more still when going outdoors. If the children are present, a variety of familiar spaces are available in which the children can keep busy while waiting. When children are content, their mother is better able to concentrate [82].

In the mother's own home, the environment is more complex. Her home is richly textured with reminders of life's experiences. She is usually less inhibited in her own home and is free to unself-consciously express and engage in religious or social activities [82]. Conversely, some women find these familiar reminders too distracting and need to leave them behind in order to labor. The birth center can be a haven providing a private, quiet out-of-hospital alternative to a busy household.

A complex familiar environment can both energize and relax the laboring woman. In early labor, familiar objects, scents, and activities of daily living keep the laboring woman's mind engaged and help to pass time. As labor proceeds and she needs to be more focused, it is easy for her to ignore these familiar stimuli. When unfamiliar stimuli are present, they are a distraction, taking up energy that she could better use for labor and birth. The midwife carefully selects interventions and utilizes them only when the mother needs them and without interrupting the flow of labor. Being aware of and encouraging changes in place, time, and social interaction are special tasks of the midwife in the home and birth center settings.

CHAPTER

36

Physiological Transition to Extrauterine Life

MARY KATHLEEN MCHUGH, CNM, MSN

The first few moments and hours of extrauterine life are among the most dynamic of the entire life cycle. At birth, the newborn moves from complete dependence to physiological independence. This complex process of change is known as the transitional period—a period that starts when the infant emerges from the mother and continues over a matter of weeks for certain organ systems. Some organs, such as the lungs, make rapid changes that are fully accomplished within days of birth. Other organ systems, like the hepatic system, take longer to convert to extrauterine functioning. Overall, the transition to extrauterine life should be viewed as an ongoing process that occurs during the entire first month of life. It is the midwife's responsibility to understand and facilitate this extrauterine adaptation. At times the midwife will need to provide extraordinary support to the newborn in order for the transition to extrauterine life to occur successfully.

The transition to extrauterine life is part of a continuum that started with conception and extended through the prenatal life of the fetus. The extrauterine transition can be profoundly influenced by prenatal factors as well as intrapartum events. At each birth, the midwife should be thinking about which antepartal or intrapartal factors could cause compromise in the first extrauterine hours. Events during conception and prenatal life that might cause compromise include congenital malformations, genetic disorders, the residual effect of environmental or workplace teratogens, substance use by the mother, prenatal infections (especially viral), chronic poor nutrition, prematurity or postmaturity, maternal chronic disease (cardiac, renal, hepatic, diabetes), and any condition causing blood loss. Labor and birth events that might influence extrauterine transition include prolonged labor, maternal starvation during labor, hypoxic uterine conditions, birth trauma, infection, passage of meconium, fetal blood loss, use of medications during labor, and conditions causing fetal dehydration such as prolonged rupture of membranes.

The midwife must make every effort to predict the potential for a difficult extrauterine transition. Accurate prediction of risk is essential if the midwife is to select the proper site for birth and alert proper personnel.

Immediate Extrauterine Transition

The newborn's most dramatic, quick extrauterine transitions occur in four areas: in the respiratory system, in the circulatory system, in the ability to thermoregulate, and in the ability to procure a source of glucose. Each area of change will be reviewed separately.

Respiratory Changes

The respiratory system is the system most challenged in the change from an intrauterine to an extrauterine environment—the newborn must begin respiration immediately on arrival in the atmosphere. The organ responsible for fetal oxygenation

prior to birth is the placenta. During gestation, there are numerous developments that provide the infrastructure for the onset of respiration. The fetus develops the musculature needed to breath and shows breathing movements throughout the second and third trimesters. The alveoli develop throughout gestation, as does the fetus's ability to produce surfactant, the phospholipid that reduces surface tension at the alveolar-air interface. The interstitial space between the alveoli markedly thins and allows maximum contact between capillaries and the alveoli for air exchange.

The term fetus experiences a decrease in lung fluid in the days before labor, and during labor. This is in response to an increase in stress hormones and to an increase in circulating plasma proteins causing oncotic pressure to increase with a flow of lung water into the pulmonary interstitial space for absorption into the lymphatic circulation. At birth, up to 35 percent of the fetal lung fluid is gone [1]. The term fetus is prepared on many levels to initiate successful respiration.

The phenomena that stimulate the neonate to take the first breath are only partially understood (see Figure 36-1). There are biochemical events such as the relative hypoxia of the end of labor and physical stimuli to which the neonate is subjected, such as cold, gravity, pain, light, and noise, which cause excitation of the respiratory center. The work of taking the first breath may be slightly assisted by the squeezing of the thorax that occurs in the last minutes of fetal life. The high pressure on the thorax as the fetus passes through the vagina is suddenly eliminated with birth. Fluid filling the mouth and trachea is partially released and air begins to fill the tracheal column. Neonates born by cesarean section, especially in the absence of labor, do not get the benefit of the diminution of lung water and the thoracic squeeze and therefore have more persistent wet lungs. This situation can lead to transient tachypnea of the newborn (TTN).

The newborn cannot sustain respiration unless both the brain's respiratory center and the respiratory muscles act to regulate respiration. The response of the newborn lungs to chemoreceptors (located in the aortic and carotid bodies) and mechanoreceptors of the lung becomes a driving force in the regulation of further breaths. The strength of respiratory muscles and the ability of the diaphragm to move directly affect the adequacy of each inspiration and expiration. The healthy newborn autoregulates many aspects of its respiratory efforts, achieving the proper balance of oxygen, carbon dioxide, and functional residual capacity.

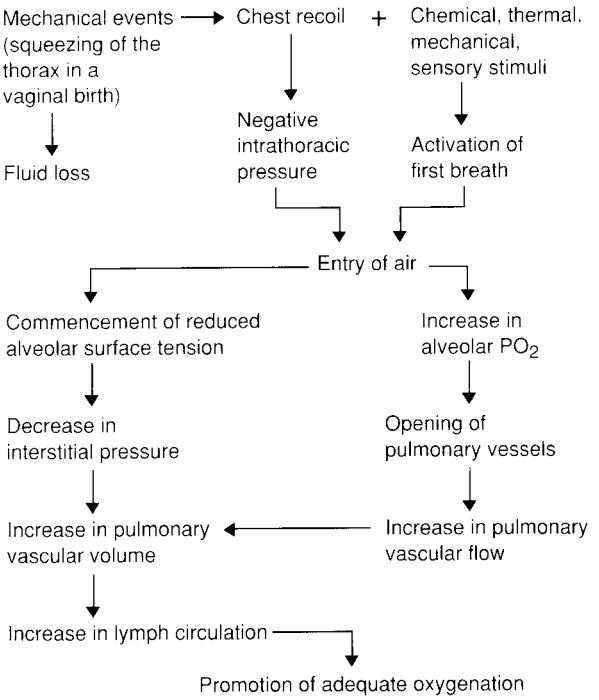

FIGURE 36-1 Initiation of respiration.

Source: Maternal-Newborn & Child Nursing: Family Centered Care by London/Ladewing/Ball/Bindler, © Reprinted by permission of Pearson Education, Inc. Upper Saddle River, NJ, 2002.

The first active breaths set in motion a seamless chain of events that (1) assists with the conversion from fetal to adult circulation, (2) empties the lungs of liquid, (3) establishes neonatal lung volume and the characteristics of pulmonary function in the newly born infant, and (4) decreases pulmonary artery pressure.

When the head is born, mucus drains from the nares and mouth. Many newborns gasp and even cry at this time. Therefore, suctioning the mouth and nares with a bulb syringe may not be necessary. Use of a suctioning device such as a bulb syringe or wall suction should be limited to situations in which the newborn's respiratory efforts are diminished or when meconium needs to be cleared from the airway. The first few breaths require a large amount of pressure because the air is flowing into a fluid-filled space. Newborns who are exhausted and compromised by the birth process will need the midwife's assistance in clearing the fluid and mucus from the upper airway.

Tactile stimulation such as gently rubbing the neonate's back, drying the wet infant, or flicking

the sole of the foot is sufficient to stimulate respiration in most newborns. Stimulation that is too vigorous, such as slapping or exposure to extreme cold, is no better than mild stimulation and merely delays the initiation of appropriate resuscitation.

With the first few breaths, room air starts to fill the large airways of the neonate's trachea and bronchi. Fluid within the lung is pushed to the lung periphery, where it is absorbed. All the alveoli expand with air over time. Maximum function of the alveoli occurs in the presence of adequate surfactant and adequate blood flow through the pulmonary microcirculation. The surfactant helps to stabilize the walls of the alveoli so that they do not collapse onto themselves at the end of a breath. This reduces the pressure needed for respiration, thereby decreasing the workload of breathing. Adequate oxygenation is a critical factor in maintenance of adequate air exchange. In the presence of hypoxia, the pulmonary vasculature vasoconstricts. Therefore, air that is in the alveoli cannot be transported into blood vessels for oxygenation of other areas of the body.

The respiratory pattern varies with onset of respiration. Respirations fluctuate and are not stable for a period of time. Breathing in a newborn may sound noisy and wet during this period of transition. There are, however, certain normal and abnormal responses to look for in the newborn. A respiratory rate consistently greater than 60 breaths per minute, with or without flaring, grunting, or retractions, is clearly abnormal at 2 hours of life. Other normal and abnormal responses are summarized in Table 36-1.

Circulatory Changes

The blood flow from the placenta stops with the clamping of the umbilical cord. This eliminates the placental supply of oxygen and causes a subsequent series of reactions. These reactions are complemented by the reactions occurring in the lungs in response to the first breath.

Fetal circulation is characterized as a low-pressure system. Because the lungs are a closed, fluid-filled organ, they need minimal blood flow. Most oxygenated fetal blood bypasses the lungs and instead flows through the opening between the right and left atria called the foramen ovale. This oxygenated blood then preferentially flows to the brain through the ductus arteriosus.

Clamping the umbilical cord shuts down the low-pressure system that was the fetal-placental unit (see Figure 36-2). The newborn circulatory system is now a freestanding, closed, high-pressure system. The immediate effect of the cord clamping is a rise in the systemic vascular resistance (SVR). Most importantly, this rise occurs at the same time as the newborn's first breaths. The oxygen from those breaths causes the pulmonary vasculature to relax and open. The lungs now become a low-pressure system.

The combination of pressure that is increasing in the systemic circulation but decreasing in the pulmonary circulation causes changes in the pressure of blood flow in the heart. The pressure from increased blood flow in the left side of the heart causes the foramen ovale to shut. The ductus arteriosus, which shunted oxygenated placental blood to the brain in fetal life, is now unnecessary. In 48 hours it constricts and functionally closes secondary to the falling levels of prostaglandin E2, previously provided by the placenta. The oxygenated blood now routinely passing by the ductus arteriosus also causes it to constrict. The results of the change in systemic and pulmonary resistance, and the closure of the shunts of the ductus arteriosus and the foramen ovale complete the radical changes in the anatomy and physiology of the heart. Deoxygenated blood enters the neonatal heart, becomes fully oxygenated in the lungs, and is pumped to all other body tissues.

Within a few moments, tremendous pressure changes have occurred in the newborn heart and circulation. Although these changes are not anatomically complete for weeks, the functional closure of the foramen ovale and the ductus arteriosus occurs soon after birth. It is of the utmost importance for the midwife to understand that the changes from fetal to newborn circulation are totally interrelated with adequate respiratory function and oxygenation.

TABLE 36-1 Normal and Abnormal Respiratory Responses

Normal	Abnormal
Average rate: 40 bpm	—
Range: 30–60 bpm	—
Diaphragmatic and abdominal breathing	Intercostal retractions, retractions of the xyphoid
Obligate nose breather	Flared nostrils
—	Grunting on expiration

Thermoregulation

The newborn has the tendency to become rapidly stressed by changes in environmental temperature. Because the intrauterine temperature fluctuates little, the fetus has no need to regulate temperature. The fetal temperature is typically 0.6°C higher than the maternal temperature. At birth, factors that contribute to heat loss in the newborn include the large surface area of a newborn, varying levels of subcutaneous fat insulation, and degree of muscle flexion. Term babies of high birth weight with good muscle flexion have the best natural protection against heat loss. Yet even the healthy term newborn does not stabilize in its ability to control temperature adequately until after 2 days of life. The midwife has an obligation to organize the birth environment so that heat loss by the wet newborn is minimized.

Newborns can lose heat through four mechanisms: (1) convection, (2) conduction, (3) radiation, and (4) evaporation [2]. The birth site should be adequately prepared to minimize heat loss by the neonate. The following methods of heat conservation are commonly used:

Pre-warm any blankets, hats, or clothing prior to the birth.

Dry newborn immediately.

Replace wet blankets after drying newborn.

Pre-warm the newborn resuscitation area.

Set birth room temperature at 75°F.

Do not suction newborn on wet birthing bed sheets.

Postpone newborn bath until newborn temperature has been stable for 2 hours.

Place newborn care areas away from windows, outside walls, or doorways.

Keep newborn head covered and body well wrapped for 48 hours.

The neonate can create heat in three ways: shivering, voluntary muscle activity, and nonshivering thermogenesis. Shivering is inefficient and, in neonates, is seen only in the most severe cold stress. Muscular activity can generate heat but is of limited benefit, even in term infants with sufficient muscle strength to cry and remain in a flexed position.

Nonshivering thermogenesis refers to one of two pathways: an increased metabolic rate or the utilization of brown fat for heat production. Neonates can generate an impressive amount of heat through increasing their metabolic rate. In this reaction, norepinephrine triggers the splitting of fatty acids, which

are oxidized and released into the circulation. This causes a marked increase in oxygen utilization and can exhaust even a healthy, term neonate.

In the second pathway brown fat is mobilized to create heat. Brown fat deposits are located in and around the upper spine, the clavicles and the sternum, and the kidneys and major blood vessels. The amount of brown fat depends on gestational age and is decreased in growth-retarded newborns. Brown fat is a nonrenewable resource of the newborn. Creation of heat through utilization of brown fat stores starts at birth with a surge of catecholamines and withdrawal of the placental suppressors prostaglandin and adenosine [3]. The cold stimulus of leaving the mother's warm body triggers activity in the hypothalamus. Chemical messages are sent to the brown fat cells. Through the mediation of glucose and glycogen, the cells produce energy that converts multiple small intracellular fat vacuoles into heat energy. In a newborn experiencing hypoglycemia or thyroid dysfunction, the use of brown fat stores does not proceed efficiently.

The sequelae of heat loss in the neonate can cascade quickly into effects that include hypoglycemia, hypoxia, and acidosis (see Figure 36-3). These effects are consequences of the increased metabolic demands that result from the newborn's attempts to create a neutral thermal zone.

Clinical symptoms of hypothermia may be subtle and include tachypnea and an increased heart rate. Any newborn who has been stressed by hypothermia should be evaluated for hypoglycemia and hypoxia and closely observed. The re-warming process will take a number of hours. Attempts to rapidly re-warm a newborn may lead to apnea. If an infant has become hypothermic, head coverings should be removed during the re-warming process if the hypothermia occurs in an incubator or radiant warmer. Because the head is a large surface area, temporarily uncovering it during the re-warming maximizes heat gain from the warming source.

The newborn's temperature can be assessed at various sites with different types of thermometers. It is recommended that rectal and axillary temperatures remain in the range of 36.5–37.5°C (97.7–99.5°F) and abdominal skin temperature in the range of 36–36.5°C (96.8–97.7°F). Infrared tympanic thermometers (2 seconds in the ear) can be used to measure temperature but are probably the least reliable in infants [4]. Core (rectal) temperatures are usually slightly higher (0.4°C) than axillary temperatures [5] and can be up to 2° higher.

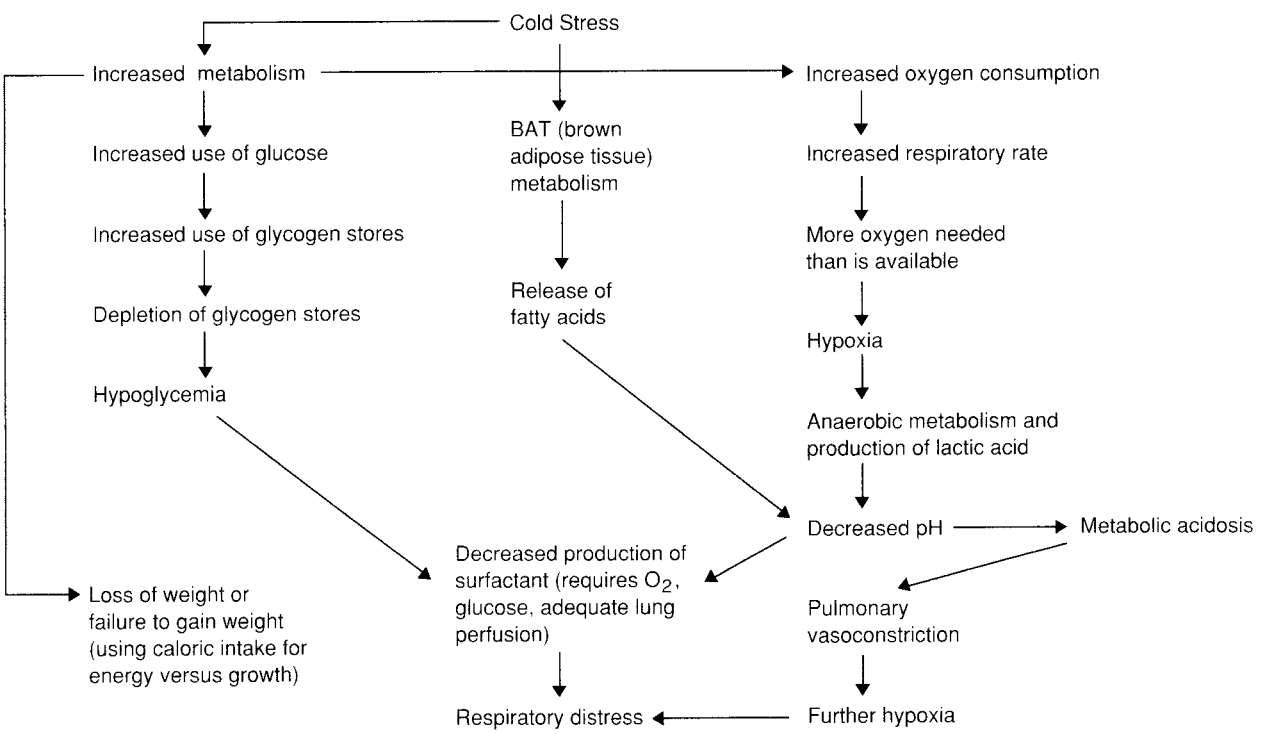

FIGURE 36-3 Sequelae of newborn heat loss.

Source: From Blackburn, S. *Maternal, Fetal, and Neonatal Physiology: A Clinical Perspective*. Philadelphia, PA: Saunders, 2003, p. 725. Reproduced by permission.

Axillary temperatures may be falsely elevated in a cold-stressed infant secondary to metabolism of brown fat. Noncontinuous temperature assessment is accurate only if the thermometer is in place for an adequate time (2 minutes for rectal, 3 minutes for axillary). If temperature is assessed with an abdominal skin sensor, the sensor must be in good contact with the skin and covered with a reflective shield. Skin temperatures should be slightly lower than core temperatures.

Glucose Regulation

Prior to birth the fetus is exposed to nearly constant blood glucose levels that are approximately 60 to 70 percent of maternal levels. In preparation for extrauterine life the healthy fetus stores glucose as glycogen, especially in the liver. Most glycogen storage occurs in the third trimester. Although any infant may develop symptomatic or nonsymptomatic hypoglycemia, newborns with intrauterine growth retardation, postterm infants, preterm infants, and infants experiencing fetal distress are at particular risk. In all of these infants there has been an alteration in the amount of glycogen stored.

The moment the cord is clamped, the newborn must find a way to maintain the balance of glucose that is essential for neonatal brain function. In every newborn, blood glucose falls for a short period of time (1 to 2 hours after birth). Studies of healthy term newborns discovered that the physiologic low occurred at 1 to 1.5 hours after birth and that levels stabilized at 3 to 4 hours. There is no strict definition of the cutoff number upon which intervention is necessary. If a neonate is symptomatic, general recommendations are to intervene with a plasma glucose level of 45 mg/dL and to intervene at 35 mg/dL for the asymptomatic infant [6, 7]. On average mean glucose levels from 4 to 72 hours are 60–70 mg/dL [8].

The healthy newborn's system learns to self-correct the physiologic fall in glucose. The correction of falling blood glucose can occur in three ways: (1) through utilization of breast milk/formula; (2) through utilization of the glycogen stores; or (3) through creation of glucose from other sources, especially lipids. These last two activities are called glycogenolysis and gluconeogenesis. The healthy newborn generates glucose in the amount of 4–8 mg/kg/min in response to a need. The need to self-correct blood glucose is a permanent part of extrauterine existence.

The healthy newborn should be encouraged to feed as soon as possible after birth. Many newborns are active feeders during the first period of reactivity. This is an ideal time to imprint the infant with a breastfeeding experience. Newborns who are exhausted and stressed from long labor may show minimal interest in feeding. Even if an infant feeds successfully, the amount of calories taken in will be minimal and may not be adequate for the glucose needs of a stressed newborn.

Newborns who cannot ingest adequate food will create glucose from glycogen. However, glycogenolysis can only occur if the baby has adequate stores of glycogen. An infant stressed through chronic intrauterine deprivation may have nearly depleted glycogen stores at birth. An infant exposed to major stress at birth through hypothermia, with resulting hypoxia, may use much of its glycogen stores within the first hour of birth. Although it is possible for the newborn to create glucose from fats or proteins, the process of gluconeogenesis is inefficient and can create many metabolic by-products. The midwife must make an accurate assessment of the neonate's at-risk status for hypoglycemia and institute proper surveillance.

The midwife can facilitate the adjustment of glucose level by an emphasis on early feeding of healthy newborns. At the same time, the midwife must evaluate each newborn realistically for the possibility of hypoglycemia. Symptoms of hypoglycemia can be vague and nonspecific and can include jitteriness, cyanosis, apnea, weak cry, lethargy, limpness, and refusal to feed. The midwife must keep in mind that hypoglycemia may be asymptomatic at first. A long-term sequela of uncorrected hypoglycemia can be widespread damage to brain cells sometimes evidenced by seizures.

Evaluation of hypoglycemia is done with a blood sample. Blood taken from the newborn heel contains capillary blood and blood glucose levels in such a sample can be falsely low if there has been venous stasis in the foot. The heel should be warmed prior to sampling to increase blood flow. Care should be taken to avoid puncturing the sensitive structures on the back of the heel (see Figure 36-4). There is some evidence that use of an automated blood collection device may cause less trauma and lead to more successful sample collection results than use of manual lancets [9]. Blood taken from a heel sample is frequently evaluated using a test strip that can be read at the bedside with or without a reflectance colorimeter; use of the colorimeter may increase accuracy. However, the test strip methods have many limitations that relate to operator technique and neonatal hematocrit.

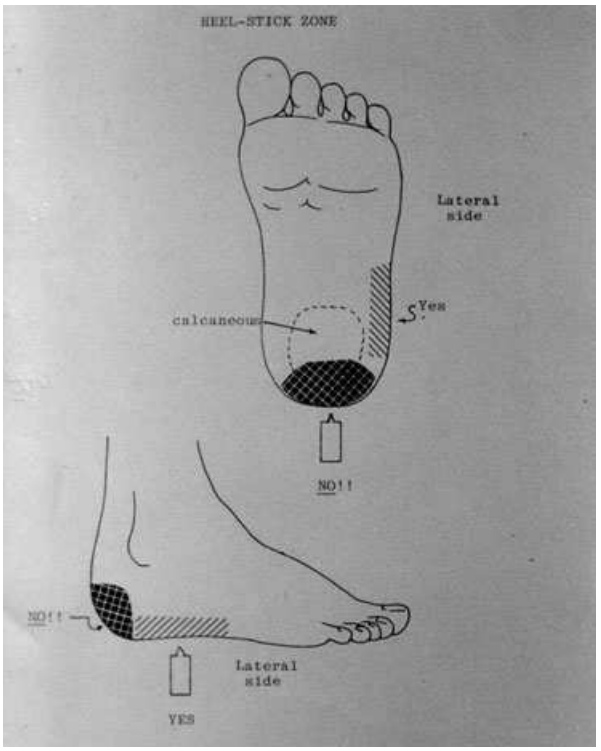

FIGURE 36-4 Anatomic landmarks for heel sticks.

Test strips that have been open for more than 1 month may also produce inaccurate results. Any borderline glucose level (40–45 mg/dL) requires that the midwife intervene and attempt to get the newborn to feed. A repeat test is performed in 30 minutes and if the borderline level continues a venous sample must be checked. Values lower than 45 mg/dL should be evaluated immediately with a venous sample drawn from scalp vein or the antecubital fossa. If the low value is confirmed, treatment is indicated.

Venous samples can be analyzed using the whole blood or the plasma (serum). Samples should be chilled during transport to the lab. Most labs report the plasma result, which will be close to 15 percent higher than a sample run on whole blood. The midwife should understand the testing method used by a particular lab.

Ongoing Extrauterine Transition

Changes in the Blood

The newborn's blood values vary in many ways from those of an adult or older child. The midwife must be aware of the range for normal and the implications of any unusual values for the care of the newborn (see Table 36-2).

TABLE 36-2 Cord Blood Values of a Full-Term Newborn

Component	Optimal Range
Hemoglobin concentration	14.0–20.0 g/dL
Red blood cell (RBC) count	4,200,000–5,800,000/mm^3
Hematocrit	43–63%
Mean cell diameter	8.0–8.3 μm
Mean corpuscular volume (MCV)	100–120 μm^3
Mean corpuscular hemoglobin (MCH)	32–40 pg
Mean corpuscular hemoglobin concentration (MCHC)	30–34%
Reticulocyte count	3–7%
Nucleated red blood cell count	200–600/mm^3
White blood cell count	10,000–30,000/mm^3
Granulocytes	40–80%
Lymphocytes	20–40%
Monocytes	3–10%
Platelet count	150,000–350,000/mm^3
Serum iron concentration	125–225 μg/dL
Total iron-binding capacity	150–350 μg/dL

Source: From Fanaroff, A., and Martin, R., *Neonatal and Perinatal Medicine: Diseases of the Fetus and Infant*, 7th ed. St. Louis, MO: Mosby, 2002, p. 1661. Reprinted by permission.

Newborns are born with a high hemoglobin/hematocrit value. Normal hemoglobin concentrations can range from 13.7 to 20.0 g/dL. If the hematocrit is obtained using a heel stick, it may be higher than normal because of venous stasis in the foot. Values higher than 65 percent need to be confirmed by a venous sample.

The hemoglobin that predominates in the fetal period, hemoglobin F, is gradually eliminated over the first month of life. Fetal hemoglobin has a high affinity for oxygen, a beneficial effect for the fetus. During the first few days of life, the hemoglobin value shifts slightly upward, as plasma volume decreases. As a result of these shifts in plasma volume, the hematocrit—normally in the range of 51 to 56 percent at birth—shifts upward from 3 to 6 percent. The hemoglobin then decreases slowly but steadily over the first 7 to 9 weeks after birth. The average hemoglobin value of a 2-month-old child will be 12.0 g/dL.

The initial hemoglobin values in a newborn are markedly influenced by the timing of clamping of

the cord and the newborn's position immediately after birth. This is an area of controversy in both the obstetric and pediatric communities. Delay in clamping the umbilical cord can increase the neonate's blood volume between 25 to 40 percent [10]. The custom of immediate cord clamping is related to modern obstetrical practices and is not practiced in many areas of the world. Proponents of early clamping have concerns about the potential of side effects from placental transfusion including respiratory distress, polycythemia, hyperviscosity syndrome, and hyperbilirubinemia. The midwife who lowers the neonate markedly below the introitus and actively strips the cord toward the newborn can cause an excessively large transfusion.

Proponents of delayed clamping believe that the increased blood volume is beneficial and supports the natural physiological course of transition to extrauterine life. Some of the benefits of a delay in clamping include the following:

1. A continuing bolus of oxygenated blood during the first tumultuous breaths
2. Volume expansion that promotes pulmonary capillary perfusion
3. A more rapid achievement of adequate oxygenation leading to closure of fetal structures like the ductus arteriosus [11]

If a midwife wants to support the physiologic transfusion that occurs over the first 1 to 3 minutes of life, the newborn is placed on the mother's abdomen with the cord intact. This position promotes modest amounts of blood flow to the newborn without the potential danger of a forced and large bolus of blood. By 3 minutes, most of the blood flow from the cord to the neonate is accomplished.

Although it is possible for blood flow to reverse from infant to placenta, this situation is unusual because the umbilical arteries (carrying blood from the fetus back to the placenta) spasm quickly in the ambient temperature of the birthing room. If reverse flow occurs, the newborn could become profoundly hypovolemic. Therefore, the midwife should make every effort to minimize extremes of position of the infant in relation to the vaginal introitus.

The newborn's red blood cells have a short life span of 80 days on average (in contrast to an adult RBC lifespan of 120 days). This rapid cell turnover creates more by-products of cell breakdown, including bilirubin, which must be metabolized. This excess bilirubin load contributes to the physiological jaundice seen in newborns. There is a correspondingly high reticulocyte count in newborns, reflecting the high formation of new red blood cells.

The average white blood cell levels in a newborn range from 10,000 to 30,000/mm^3. There can be a further elevation in a normal newborn during the first 24 hours of life. Prolonged periods of crying can also cause a shift upward. The white blood cell differential contains a preponderance of granulocytes.

Platelet counts in newborns are within the same range as adult values. However, platelet aggregation can vary in term newborns. There is an overall deficiency of many of the clotting factors that are dependent on vitamin K. Prothrombin time, thrombin time, and partial thromboplastin time are slightly prolonged. Because of this general deficiency in certain clotting factors, it is customary to give newborns supplementary vitamin K after birth (see Chapter 37, page 978).

Whenever a blood sample is being obtained from a newborn, the midwife should be aware that capillary samples from heel sticks might give erroneous results because of venous stasis in the extremities. Venous stasis will be exacerbated in any infant who is cold or who has experienced recent hypoxia. Before sampling, the midwife should try to maximize blood flow by warming the heel. Any suspicious values need to be confirmed with a venous sampling.

Changes in the Gastrointestinal System

The gastrointestinal system in a term newborn is relatively mature. Prior to birth, the term fetus practices sucking and swallowing. Mature gag and cough reflexes are intact at birth. Meconium, although sterile, contains debris from the amniotic fluid, which confirms that the fetus ingests amniotic fluid and that the fluid passes through the gastrointestinal passage.

The ability of the term newborn to ingest and digest exogenous food sources is limited in some ways. Much of the limitation has to do with the varying amount of digestive enzymes and hormones present in all portions of the gastrointestinal tract, from the mouth to the intestines. Newborns are less able to digest proteins and fats than adults. Carbohydrate absorption is relatively efficient but still less than adult abilities. The newborn is particularly efficient at the absorption of monosaccharides such as glucose, as long as the amount of glucose is not too large.

The cardiac sphincter—the juncture of the lower esophagus and the stomach—is incomplete,

which contributes to the widespread regurgitation of stomach contents in newborns and young infants. The capacity of the stomach itself is quite limited, less than 30 cc for a term newborn.

The newborn's intestines are relatively immature. The underlying musculature is thinner and less efficient than in the adult, leading to unpredictable peristaltic waves. The folds and villi of the intestinal wall are not fully developed. The epithelial cells lining the newborn's small intestine do not have the rapid cell turnover that promotes most effective absorption. The beginning of oral feedings stimulates the intestinal lining to mature by promotion of rapid cell turnover and production of microvillous enzymes such as amylase, trypsin, and pancreatic lipase [12]. The midwife's support for early newborn feeding will aid in this maturation of intestinal capabilities.

The immaturity of the intestinal epithelium affects the ability of the gut to protect itself from harmful substances. In humans, the entire gastrointestinal tract serves as part of the natural immune system, a system of defense for the host. Among the defenses present in the GI tract are the chemical barriers of increased acidity, the digestive enzymes that break down large molecules, and the secretory IgA that lines the small intestine.

During early infancy, the newborn faces the substantial task of "gut closure," the process by which the epithelial surfaces of the intestine become impermeable to antigens [13]. Prior to gut closure, the infant is vulnerable to bacterial/viral infection and also to allergenic stimulation through intestinal absorption of large molecules. All enteral feedings, even in very small amounts, lead to helpful surges in gastrointestinal trophic factors—mainly hormones that lead to a full maturation in functioning [14]. Breastfeeding in particular promotes gut closure because it provides a large amount of secretory IgA and stimulates intestinal enzyme proliferation. The midwife should strongly promote early and frequent feedings of the infant, whether by breast or bottle.

The colon in the newborn conserves water less efficiently than in the adult, therefore predisposing the newborn to water loss complications. This makes diarrheal illness potentially serious in a young infant.

Changes in the Immune System

The neonatal immune system is immature on a number of significant levels. This functional immaturity makes the neonate vulnerable to many infections and allergic responses. The mature immune system offers both natural and acquired immunity. Table 36-3 reviews some of the differences in newborn immune response.

TABLE 36-3 Alterations in Immune Response Mechanisms in the Neonate

Alteration	Result	Implication
Innate Immunity		
Structural alterations of polymorphonuclear neutrophils (PMNs) (e.g., more rigid, less deformable, poorer response to chemotactic stimulation)	Altered movement kinetics and orientation of PMNs	Delayed initial response to invasion by pathogenic organisms
Altered PMN chemotaxis and adherence	Slower movement to site of antigenic invasion	Less able to localize infection
	Poorer PMN aggregation	Increased risk of generalized sepsis
Reduced bactericidal activity in stressed neonates	Delayed initial response to infection	Increased risk of severe infection
Decreased fibronectin	Delayed initial response to infection	Less able to localize infection
		Increased risk of generalized sepsis
Decreased natural killer cell activity	Delayed initial response to infection	Less able to localize infection
		Increased risk of generalized sepsis
Poor hypothalamic response to pyrogens	Fever is not a reliable sign of sepsis	Signs of sepsis often subtle and nonspecific

TABLE 36-3 Alterations in Immune Response Mechanisms in the Neonate (*continued*)

Alteration	Result	Implication
Antibody-Mediated Immunity		
Decreased immunoglobulin G (IgG) in preterm infant	Due to lack of transfer from mother	Reduced defense against many bacteria Increased risk of bacterial sepsis, especially from gram-positive cocci
Decreased IgA and absent sigA; defective switch from IgM to other immunoglobulins	Reduced defense against gastrointestinal (GI) and respiratory infections; increased defense in breastfed infants	Increased risk of respiratory and GI infections
Decreased IgM with less specificity	Reduced defense against viral and gram-negative organisms	Increased risk of *Esherichia coli* sepsis and rubella, syphilis, toxoplasmosis, cytomegalovirus (CMV), and other viral infections
Altered of B-cell function due to reduced T-cell activity and cytokine production	Slower switch from IgM to IgA and IgG production	Increased risk of severe infection and generalized septicemia
Lack of previous exposure of B cells to many organisms, with lack of development of memory cells	Delayed specific responses to pathogenic organisms	Increased risk of severe or overwhelming infection
Cell-Mediated Immunity		
Decreased T-cell function (reduced cytokine production, cytotoxic activity)	Reduced defenses against viral and fungal infections	Increased risk and severity of infection from herpes, CMV, and other TORCH organisms
T-suppressor activity commences	Alteration in B-lymphocyte function	Increased risk and severity of bacterial infection
Reduced levels of IL-2, IL-5, IL-8, and IFN-γ	Altered cell-mediated responses, immunoglobulin production, and innate response	Less able to localize infection Increased risk of generalized sepsis
"Naïve" T cells	Delayed responses to specific pathogenic organisms	Increased risk of viral and fungal infections
Complement		
Decreased complement proteins C1, C3, C4, C7, and C9	Decreased opsonization	Decreased ability to localize infection
Deficient activity of alternative pathway	Decreased chemotaxis Decreased cell lysis	Decreased ability to opsonize and eliminate organisms with capsular polysaccharide such as Group B Streptococci (GBS) Increased risk and severity of bacterial sepsis

Source: From Blackburn, S. *Maternal, Fetal and Neonatal Physiology: A Clinical Perspective*. Philadelphia, PA: Saunders, 2003, p. 498. Reprinted by permission.

Natural Immunity Natural immunity consists of bodily structures that prevent or minimize infection. Some examples of natural immunity include (1) the barrier protection offered by the skin and mucous membranes; (2) the sievelike action of the respiratory passages; (3) the colonization of skin and gut by protective microbes; and (4) the chemical protection offered by the acidic environment of the stomach. The gut closure that leads to the mature intestinal lining, discussed above, also provides natural immunity.

Natural immunity is also provided at the cellular level by blood cells that are available at birth to help the newborn kill foreign microorganisms. Three cell types effect their action by the phagocytosis (engulfing and killing) of invaders: (1) polymorphonuclear neutrophils (PMN), (2) monocytes, and (3) macrophages. The process of phagocytosis is enhanced if the foreign cells are prepared by substances called complement components. Other cells called natural killer (NK) cells are part of the natural immunity system but kill without phagocytosis.

The polymorphonuclear neutrophil (PMN) will eventually become the primary phagocyte in the defense of the host. However, in the neonate, the PMN is compromised both in its ability to mobilize and move in the right direction and in its ability to adhere to inflammatory sites. These deficiencies do not reflect inadequate numbers of the PMN cells but rather inadequate chemotaxis and opsonization. Chemotaxis refers to the organized movement of a phagocytic cell—its actual travel around the body. Opsonization is the alteration, or "marking," of the cell surface of a foreign microbe or antigen. This marking promotes the destruction of foreign cells. This immaturity of chemotaxis and opsonization decreases the effectiveness of the phagocytic response and leads to one of the main weaknesses of the neonatal immune system: its inability to localize infection. This tendency to have systemic rather than local infection drives the midwife in vigilant assessment of any neonate where infection is likely or suspected.

Acquired Immunity The neonate is born with passive immunity to viruses and bacteria that the mother has encountered. The fetus acquires this immunity via the transplacental travel of immunoglobulins of the IgG variety. Other immunoglobulins, such as IgM and IgA, cannot cross the placenta. Finding them in cord blood is an indication that the fetus has actively responded to an infection while in utero. The neonate will not have a passive immunity to diseases or microbes unless the mother has responded to those infections during her life.

Gradually, the young infant will begin to produce adequate circulating antibodies of the IgG class. This takes time, and the full antibody response to a foreign antigen is not possible until well into early childhood. This accounts for the numbers of illnesses experienced by small children. The full antibody response corresponds with the diminution of the IgG acquired prenatally from the mother. One of the primary biological tasks during infancy and early childhood is the building of immunity.

Because of these deficiencies in both natural and acquired immunities, the neonate is very vulnerable to infection. Neonatal response to infection is sluggish and inadequate, leading to a predisposition to systemic rather than localized infections. The midwife caring for a mother during pregnancy, birth, and the postpartum course must be vigilant in identifying the risk for infection, minimizing exposure to microbes, and recognizing symptoms of infection in the neonate.

Changes in the Renal System

The term newborn has some structural and functional deficits in the renal system. Many of these deficits correct themselves over the first month of life and are only a problem for sick or stressed newborns. The limitations of the renal system become of particular consequence if the newborn needs intravenous fluids or medications, which increase the possibility of iatrogenic fluid overload.

The newborn kidney shows decreased renal blood flow and a decreased glomerular filtration rate. These can lead easily to fluid retention and water intoxication. Tubular function is immature, which can lead to large sodium losses and other electrolyte imbalances [15]. The newborn is unable to concentrate urine very well, which is reflected in a low specific gravity (as low as 1.004) and urine osmolality. All of these renal limitations are worse in the preterm infant.

The newborn excretes a small quantity of urine in the first 48 hours of life, often as little as 30 to 60 mL. There should not be protein or blood in newborn urine. Large amounts of cellular debris may indicate injury or irritation within the renal system. The midwife should remember that abdominal masses found on physical exam frequently are renal and may reflect tumors, enlargement, or deviations within the kidneys.

CHAPTER

37

Immediate Care and Assessment of the Healthy Newborn

MARY KATHLEEN MCHUGH, CNM, MSN

Assessment Prior to Birth

Today, the assessment of the newborn starts long before birth. The midwife's knowledge and careful review of all available data on the prenatal period creates a database for assessment of the child about to be born. The labor and birth history contributes more information to the midwife's assessment of the child. Of particular importance are the characteristics of the fetal heart rate during labor. Information pertinent to the newborn that the midwife should know prior to birth is listed in Table 37-1.

Assessment at the Moment of Birth

Newborn assessment begins when the fetal head is crowning. The midwife can observe the color of the scalp and check the capillary refill by gently depressing scalp tissue. Good color and a quick refill after blanching are two reassuring signs that the infant is well-perfused.

At the moment of birth the midwife's hands and eyes assess the neonate's tone and skin color. The midwife scans the baby's body for signs of any obvious physical deformities. Touching the umbilical cord close to the insertion point in the abdomen

TABLE 37-1 Historical Factors Pertinent to Newborn Care

Genetic Factors	Maternal Factors	Prenatal Factors	Perinatal Factors
Family history of structural or metabolic defects	Cardiac disease	No prenatal care	Preterm/postterm labor
History of genetic syndromes	Diabetes	Bleeding during pregnancy	Prolonged labor
	Kidney disease	Size-dates discrepancy	Drug use in labor
	Liver disease	Pregnancy-induced hypertension	Fetal distress
	Hypertension	Gestational diabetes	Maternal fever
	Sexually transmitted diseases	Polyhydramnios/oligohydramnios	Abnormal presentation or position of fetus
	Substance abuse	Infection	Meconium-stained fluid
	Rh or other isoimmunization		Prolonged rupture of membranes
	History of prior pregnancy losses		Excess bleeding in labor
			Prolapsed cord
			Maternal hypotension
			Fetal acidosis
			Type of delivery

lets the midwife assess the newborn's heart rate. All of these assessments can occur in the few seconds it takes to assist the birth of the infant's body.

With the birth of the neonate, the midwife must vigilantly observe for signs that the child is able to clear mucus and take the first breaths. The neonate is assisted onto the mother's abdomen and is immediately covered with a pre-warmed blanket. If the midwife is distracted at this point by maternal bleeding or placental delivery, it is important that a nurse or trained assistant continue to observe the newborn closely. On occasion, a newborn will make an initial deep breath or cry and then proceed to become apneic or unable to breathe because of mucus or an underlying disorder.

Successful transition to extrauterine life is evaluated with the Apgar score. Developed during the 1950s by Dr. Virginia Apgar [1] to predict survival of the neonate, this score helps the midwife to evaluate transition and the need for resuscitation. A recent retrospective analysis of a large cohort of infants reaffirmed the predictive value of the 5-minute Apgar score. It found that a score of less than 3 predicted the highest incidence of death during the neonatal period (the first 28 days of life), regardless of gestational age [2]. This relationship was even stronger when associated with an umbilical artery blood pH of less than 7.0 at birth.

There have been many attempts to use Apgar scores as predictors of permanent neurological damage. A low 1-minute or 5-minute Apgar score is not predictive of future neurological damage and a high Apgar score, while reassuring, cannot always predict health. If a low Apgar score persists until 10 or 20 minutes after birth, there is a very strong association with the development of cerebral palsy [3].

At this time, the sole use for an Apgar score is to evaluate the newborn in a standardized way to assess the need for resuscitation (see Table 37-2). The Apgar score evaluates neonatal heart rate, respiratory effort, color, overall tone, and reflex irritability. The first Apgar score is assigned at 1 minute of age. Few newborns score a perfect 10 at this point. At 1 minute most newborns are not fully pink. However, the midwife must never withhold resuscitation waiting for the newborn to attain a 1-minute score.

The midwife, a nurse, or a trained assistant may assign the Apgar score. Some settings utilize an Apgar timer that rings at 1 minute and 5 minutes after birth. Only the person making the Apgar assessment should record it in the newborn record.

The healthy term newborn should have an Apgar score of 7 to 10 at both 1 minute and 5 minutes of age. These infants need minimal supportive care from the midwife. They need to be kept warm, have a clear airway, and be evaluated for readiness to feed. Newborns showing signs of a compromised transition to extrauterine life need intervention, as discussed in Chapter 38.

Care During the First Hours After Birth

The Transitional Period

A characteristic set of behaviors is apparent during the transition hours immediately after birth. The midwife who understands these behaviors will attribute the proper meaning to the variations that occur during those hours. The transitional period is the time when the infant stabilizes and adjusts to extrauterine independence. This transitional period was first described by Desmond et al. [4]. The activities of this transitional period reflect a combination of sympathetic responses to the stress of birth (tachypnea, tachycardia) and parasympathetic responses (as evidenced by the presence of mucus, vomiting, and peristalsis), as illustrated in Figure 37-1. The presence of the stress hormones helps to

TABLE 37-2 The Apgar Scoring System

	Score		
Sign	**0**	**1**	**2**
Heart rate	Absent	Slow—below 100	Above 100
Respiratory effort	Absent	Slow—irregular	Good crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	None	Grimace	Vigorous cry
Color	Pale blue	Body pink, extremities blue	Completely pink

fully activate many of the activities of extrauterine life. The behaviors of the newborn during the transitional period may be altered if the infant was significantly distressed or heavily affected by use of medications in labor.

The period of transition is divided into three stages. The first stage is a reactive period that begins immediately after birth and lasts approximately 30 minutes; the second stage is the interval lasting from 30 minutes until about 2 hours after birth, during which the newborn sleeps; and the third stage is another reactive period that continues from 2 hours after birth until the baby is around 6 hours old. During the entire transition period, the midwife assesses heart rate, respiratory rate, temperature, mucus, neurological function (which includes activity, reactivity, tone, and posture), and bowel function (which includes peristalsis and passage of meconium). These assessments and normal findings are summarized in Table 37-3.

The infant is stressed during the process of birth and should be allowed to stabilize prior to being examined or handled by several people. It is possible to observe and perform unobtrusive yet thorough assessments that cause minimal disruption to mother and baby.

The healthy term newborn has an innate pattern of behavior that will lead it to seek the maternal breast and suckle within the first hour after birth. This behavior, seen in multiple species,

TABLE 37-3 Signs of Normal Transition

Assessment	Normal Value
Tone	Predominantly flexed
Sucking reflex	Intact
Behavior	Alertness alternating with sleep
Bowel sounds	Present after 30 minutes
Pulse	120 to 160 bpm; may vary with sleep or crying from 100 to 180 bpm
Respirations	30 to 60 rpm; diaphragmatic with abdominal wall movement
Temperature	Axillary: 36.5°–37° C (97.7°–98.6°F) Skin: 36°–36.5° C (96.8°–97.7°F)
Dextrostix	Greater than 45 mg %
Hematocrit	Less than 65 to 70 %

should be supported whenever possible [5]. The newborn is left naked on the mother's unclothed abdomen for the first hour after birth, covered with pre-warmed blankets and with a cotton cap on the head. If the birth room is cool, a radiant heat panel can be placed over mother and neonate. The neonate will use odor to locate the female breast and move upward to root and eventually suckle. During this time period of skin-to-skin contact characteristic infant hand massage of the breast occurs, which, along with suckling, promotes the release of oxytocin [6, 7].

The midwife must never fail to remember that both mother and baby continue to need her attention during the time immediately after birth. Procedures that can be deferred include bathing, circumcision, or a fatiguing complete physical and neurological examination.

The First Period of Reactivity

The first period of reactivity begins at birth and lasts 30 minutes. During this time the newborn's heart rate is rapid and cord pulsation is evident. The newborn's color shows transient cyanosis or acrocyanosis. Respirations are rapid at the upper end of the range of normal, and rales and rhonchi are present. The rales should disappear within 20 minutes. The baby may exhibit flaring of the alae nasi with grunting respirations and retractions. The presence of mucus usually is a consequence of the expulsion of retained lung fluid. This mucus is thin, clear, and may have small bubbles.

During the first period of reactivity following birth, the newborn's eyes are open and the baby manifests alert behavior. The baby may cry, startle, or root. During this alert period, every effort should be made to facilitate contact between mother and newborn. Even if breastfeeding is not planned, allowing the mother to hold the infant at this time aids in the acquaintance process. The infant focuses visually on the mother or father when they are in the appropriate field of vision (Figure 37-2). The baby shows increased muscle tone with the upper extremities flexed and the lower extremities extended; this position allows the infant to mold itself into the mother's body while being held.

Many infants will breastfeed during this first period of reactivity. Breastfeeding should be encouraged while the newborn is in this highly alert stage as a protection against the physiological hypoglycemia that occurs after birth (see Chapter 36). The midwife should make every effort to minimize any uncomfortable maternal procedures during this time period, even delaying perineal repair for a short time if the mother so desires.

FIGURE 37-2 Getting acquainted.
Source: Photo used by permission of Tracy Mitchell.

The infant frequently has a stool immediately after birth and bowel sounds are usually present by 30 minutes of age. Bowel sounds indicate the digestive system is capable of functioning. The presence of stool alone, however, does not indicate that peristalsis is present. It only indicates that the anus is patent.

Period of Unresponsive Sleep

The second stage of transition lasts from approximately 30 minutes to 2 hours of age. The newborn's cardiac rate decreases during this period to less than 140 beats per minute. A murmur can be heard; this is merely an indication that the ductus arteriosus has not fully closed and is not considered an abnormal finding. The infant's respiratory rate becomes more slow and even. The infant is in a deep sleep. Bowel sounds are present but diminished. If possible the newborn should not be disturbed for major

examinations or bathing during this period. The first deep sleep allows the newborn to recover from the demands of birth and the immediate transition to extrauterine life.

The Second Period of Reactivity

During the second period of reactivity (third stage of transition), from approximately 2 to 6 hours of age, the baby's heart rate is labile and there are swift changes in color, which are related to environmental stimuli. The respiratory rate is variable and related to activity. The respiratory rate should remain under 60 bpm and there should no longer be rales or rhonchi. Newborns may be interested in feeding and should be encouraged to breastfeed.

Early feeding is critical in the prevention of hypoglycemia and, by stimulation of stool passage, the prevention of jaundice. Early feeding also provides the bacterial colonization of the intestines that leads to the development of vitamin K by the intestinal tract. The newborn may react to the first feeds by spitting milk mixed with mucus. The midwife should assist breastfeeding mothers during the first feeds (see Chapter 43). Infants who are bottle-fed will usually take no more than an ounce per feeding during the first day of life. New mothers should be shown techniques for burping the newborn (see Chapter 40, page 1023).

Any mucus that is present during early feeding may interfere with adequate feeding, particularly if the mucus is excessive. The presence of large amounts of mucus may be an indication of a problem such as esophageal atresia. Bile-stained mucus is always a sign of illness in the newborn infant and feeding should be delayed until the cause has been investigated thoroughly.

Plan of Care for the First Few Days of Life

The period of transition to extrauterine life ends with the second period of reactivity. This occurs approximately 2 to 6 hours after birth. At this point the midwife should make a plan of care for the newborn for the first few days of life. This plan should take into consideration the parents' desires.

In a hospital setting, the newborn's care may be taken over by a pediatric provider. In a birth center or home birth setting the midwife may continue to be responsible for the care of the newborn. The midwife must have an adequate arrangement with a pediatric provider for consultation and referral of newborns. The midwifery practice must also employ adequate nursing help to provide proper care to both mother and newborn.

At some point after the initial transition to extrauterine life, the newborn should be given a complete physical examination and gestational age assessment (see Chapter 39). The gestational age assessment is important because, when plotted on a chart with birth weight and length, it indicates whether the infant is average for gestational age (AGA), small for gestational age (SGA), or large for gestational age (LGA). The complete plan of care will be influenced by these findings.

The skin and gastrointestinal tract of the newborn child have not yet been colonized by many types of bacteria. The newborn therefore is not protected from benign bacteria. All caregivers should scrub their hands and forearms for 3 minutes with an antibacterial soap prior to touching a newborn. Caregivers should rewash their hands briefly between contacts with other babies or the mother. This activity is the single most powerful protection against infection that the newborn has.

Newborn vital signs (temperature, heart rate, and respirations) should be assessed and recorded every 4 hours after the first 2 hours of close assessment. Color, tone, and cry should be noted.

The plan of care for the newborn includes ongoing observation, plans for physical care, feeding, assessment of elimination, blood work, screening tests, and medications. The midwife should observe for signs that the mother and other family members are ready to assume responsibility for care of the newborn.

The midwife should record the time and characteristics of the first urination and passage of stool. The initial newborn stool is a sticky, black substance called meconium. Over the first 3 to 4 days of life the stool will change from black to greenish brown. Passage of meconium and the presence of bowel sounds are reassuring evidence of the integrity of the GI tract. The urinary stream of a male newborn should be strong and forceful. A newborn who has not voided by 24 hours of age should be referred to a pediatric provider.

Current thinking discourages full baths and the use of antibacterial soap in the first days of life. Initial skin care can be "dry care," whereby the infant is dried and the skin folds are wiped clean with soft gauze. Later on day 1, the newborn skin folds and scalp can be washed clean of blood and meconium with warm water and a pH neutral soap,

without dyes or perfumes [8]. An infant who is experiencing temperature lability should not be bathed. There is no routine need to use skin care products, and in fact these can be associated with rashes and inhalation pneumonia. However, the occasional use of a skin emollient may help to hydrate the skin if excess dry skin is a problem. The prevention of skin fissures and cracking can be an important defense against infection.

For many years caregivers used a variety of means to clean and disinfect the umbilical cord, including isopropyl alcohol, triple dye, and antibiotic ointment. Studies have compared alcohol with natural drying and found no increased incidence of infection and a quicker detachment of the cord with air-drying alone [9]. Cord infections are infrequent and the midwife should advise the family to keep the cord dry, clean with water only, and report any odor, pus, or redness that extends onto the abdomen.

Newborns should receive eye prophylaxis against infections caused by gonorrhea or chlamydia. Most states require this and families who defer eye prophylaxis may need to sign a waiver. The best eye protection against gonorrhea and chlamydia is 0.5% erythromycin ointment, which is spread from the inner to the outer canthus of each eye. Irrigation of the eye afterward is not necessary. Eye care should be deferred until after the first period of reactivity, when the alert newborn is searching for the faces of the parents.

Vitamin K is routinely administered to the newborn to prevent hemorrhagic disease. The neonatal gut synthesizes vitamin K, which is used to activate precursor proteins that make blood-clotting proteins. This gut synthesis cannot occur until the gut has been colonized by bacteria. This process takes a few days and can be hampered by a delay in newborn feeding. The clinical manifestations of hemorrhagic disease include bleeding from the intestinal tract, the skin, and the circumcision area. Lab tests reveal markedly long PT and PTT. As a preventive measure, vitamin K is given intramuscularly 1 mg in the lateral thigh for newborns weighing greater than 2.5 kg. It rapidly works to activate the blood clotting precursors. Use of oral vitamin K is not recommended at this time because of questions about its effectiveness [10].

Most practices save cord blood at the time of birth. This can then be sent for newborn blood typing and a direct Coombs test. The practice of "banking" cord blood for a possible future use if the newborn develops certain genetic, hematological, and oncologic disorders is controversial. The chances of the newborn developing one of these conditions are not great. Because there is only a 25 percent match between siblings, use of cord blood for other family members is rarely possible. Current policy of the American Academy of Pediatrics discourages this type of private cord banking unless there is a family member with a known condition that might benefit from cord blood transplantation [11].

A heel stick for a hematocrit and glucose test strip may be part of routine care in the first 2 hours after birth. The midwife should avoid sticks directly on the back of the heel and instead make a puncture on the lateral side of the foot (see Figure 36-4). There are many variations that can occur in glucose testing as a result of testing a capillary sample from a heel stick. The following must be considered possible limitations of this screening procedure [12]:

1. Glucose oxidase reagent strips are affected by venous stasis in an unwarmed foot, leading to false high test results.
2. The strips measure whole blood glucose, which is 10 to 15 percent lower than plasma glucose concentrations.
3. Heel sticks sample venous blood, which has a lower glucose concentration than arterial blood. If a capillary sample from the foot is low (less than 45 mg/dL), or, if it is normal but the newborn is symptomatic, then a plasma glucose sample must be obtained by venipuncture.

The procedure for glucose testing by heel stick is as follows:

1. Gather equipment, including alcohol swabs, cotton ball, sterile gauze square, lancet, glucose strips and bottle, gloves, bandage.
2. Pre-warm foot with warm wet wrap for 30 seconds to decrease stasis.
3. Wash your hands, put on gloves.
4. Grasp foot firmly with hand, using some pressure to briefly occlude blood flow.
5. Prep skin with alcohol and blot dry with sterile gauze.
6. Select an area on the lateral aspect of the foot—not on the heel where a lancet stick can cause permanent damage.
7. Pierce the foot with the lancet. Consider use of a microlancet designed for neonates [13].
8. Following instructions on the glucose test strip bottle, place the correct number of drops of blood on the reagent strip.
9. Time test accurately. Compare color on test strip with chart on bottle.

10. Wipe heel with cotton and place bandage on puncture.

All states require some newborn screening tests for metabolic and genetic conditions. Midwives need to be aware of requirements in the state where they practice. The screening for phenylketonuria and hypothyroidism is required in all 50 states. Neither condition is clinically evident immediately after birth. Left undiagnosed, both cause physical abnormalities and mental retardation. In order to successfully test for phenylketonuria, the newborn needs to have established feeding. A blood sample is taken at 48 hours of age or older. Screening for hypothyroidism (a T4 and TSH) can be done at any time, but it is customarily performed on a blood sample obtained at the same heel stick as the PKU test. If a newborn has an early discharge, the midwife must make sure that a viable plan is in place for obtaining the blood sample.

The Centers for Disease Control recommends that all newborns begin their immunization series for hepatitis B shortly after birth. In part, this provides protection to newborns whose mothers had undiagnosed hepatitis B surface antigen at delivery, with subsequent exposure of the newborn. The vaccine alone is effective at preventing perinatal transmission in many newborns [14]. The midwife should order the first dose of the vaccine, which is administered within 12 hours of birth. Subsequent doses will be given at 1 month and 6 months of age. Some parents are concerned about vaccination because of a mercury-containing additive called thimerosal previously found in hepatitis vaccine. The vaccine is now available without this additive.

If the midwife is not providing direct care of the newborn, she or he should provide written orders for the nurse or birth assistant. Birth centers frequently have standing protocols of care for the newborn until discharge. The following might be included in such a protocol or written orders.

1. Admit to well-baby nursery (in-hospital).
2. Check temperature, pulse, and respirations every 30 minute × 4, then every hour until stable.
3. Record urination and bowel movements.
4. Weigh infant.
5. Administer 1 mg vitamin K intramuscularly into right anterolateral thigh.
6. Administer eye prophylaxis: erythromycin ointment 0.5% in each eye.
7. Use soap and water to care for umbilical cord. Dry and expose to air when possible.
8. Administer sponge bath to infant after temperature has been stable 1 hour.
9. May place infant in bassinet with cotton cap (in-hospital).
10. Offer breast prn or at least every 2 hours or offer bottle (name formula type) every 3 hours.
11. Administer 0.5 ml (10 mcg) hepatitis B vaccine into left anterolateral thigh.
12. Screen for PKU and hypothyroid (others as required by law) as per protocol at 48 hours of age.

Planning Discharge

The new mother and baby should not be unattended for at least 24 hours. If the mother is planning to leave the hospital or birth center shortly after birth, the midwife must explore what assistance the mother will have at home.

Standard practice for postpartum care of women and newborns has evolved to include a very brief stay in most hospitals. Increasingly, insurance companies expect healthy term newborns to be discharged from the hospital after 24 hours. Birth center stays are usually less than 24 hours, sometimes as short as 6 hours. The midwife must continually assess whether mother and baby are healthy enough for discharge.

Ideally, the midwife has spent time during the prenatal period discussing how to prepare the home environment to give the proper support to the new mother and baby. The father, grandmother, or significant other should be involved in some of the prenatal discussion. They must clearly understand that the mother and baby should not be alone during the first few days at home. Typically, in the United States, the mother is showered with baby clothing and equipment but has few support persons during the first week at home. The midwife needs to help the expectant mother be realistic about how tired and overwhelmed she may feel after she comes home.

During the late 1990s, there was scrutiny of the increasing practice of early discharge of mother and baby after birth. Legislation passed at the federal level in 1996 guaranteed the right of the mother and newborn to stay in the hospital for 48 hours after birth if so desired.

Pediatric providers are particularly concerned about feeding problems, weight loss, infection, and hyperbilirubinemia after early discharge. A

Cochrane Review noted that varying methodology in studies made conclusions about the safety of early discharge difficult [15]. A study of a large series of infants in Texas found that 8 percent of term low-risk newborns developed problems requiring special attention and 31 percent of these problems developed after 24 hours of age [16]. The most frequent problems encountered at any age were tachypnea, temperature instability, and cyanotic episodes. Some states now mandate home visits to a mother and newborn after early discharge.

The midwife supervising the discharge of a newborn from a birth center or hospital should evaluate the infant using the criteria established by the American Academy of Pediatrics (Table 37-4) [17]. Assessment of the postpartum mother prior to discharge or prior to the midwife's departure from a home birth is discussed in previous chapters. A midwife who does not believe that the criteria have been met satisfactorily should evaluate whether discharge is safe at this time and be an advocate for the newborn.

If early discharge is indicated, the family should be given written information that is culturally appropriate and written at an appropriate literacy level. It should reiterate any instructions the midwife has already given and describe home assessment of the newborn (see Figure 37-3). The excited and tired family has probably retained only a fraction of the information that has been offered.

TABLE 37-4 Criteria for Short Hospital Stay (<48 Hours) of Term Newborns

The antepartum, intrapartum, and postpartum courses for both mother and baby are uncomplicated.

Delivery is vaginal.

The baby is a single birth at 38 to 42 weeks' gestation and the birth weight is appropriate for gestational age according to appropriate intrauterine growth curves.

The baby's vital signs are documented as being normal and stable for the 12 hours preceding discharge, including a respiratory rate below 60/min, a heart rate of 100 to 160 beats per minute, and an axillary temperature of 36.1°C to 37°C in an open crib with appropriate clothing.

The baby has urinated and passed at least one stool.

The baby has completed at least two successful feedings, with documentation that the baby is able to coordinate sucking, swallowing, and breathing while feeding.

Physical examination reveals no abnormalities that require continued hospitalization.

There is no evidence of excessive bleeding at the circumcision site for at least 2 hours.

There is no evidence of significant jaundice in the first 24 hours of life.

The mother's knowledge, ability, and confidence to provide adequate care for her baby are documented by the fact that they have received training sessions regarding:

1. Breastfeeding or bottle-feeding. The breastfeeding mother–infant dyad should be assessed by trained staff regarding nursing position, latch-on, adequacy of swallowing, and mother's knowledge of urine and stool frequency.
2. Cord, skin, and infant genital care.
3. Ability to recognize signs of illness and common infant problems, particularly jaundice.
4. Proper infant safety (e.g., proper use of a car seat and positioning for sleeping).

Family members or other support person(s), including health care providers, such as the family pediatrician or his/her designees, familiar with newborn care and knowledgeable about lactation and the recognition of jaundice and dehydration are available to the mother and the baby for the first few days after discharge.

Laboratory data are available and reviewed, including: Maternal syphilis and hepatitis B surface antigen status. Cord or infant blood type and direct Coombs' test result as clinically indicated.

Screening tests are performed in accordance with state regulations. If the test is performed before 24 hours of milk feeding, a system for repeating the test must be assured during the follow-up visit.

Initial hepatitis B vaccine is administered or a scheduled appointment for its administration has been made within the first week of life.

A physician-directed source of continuing medical care for both the mother and the baby is identified. For newborns discharged in less than 48 hours after delivery, a definitive appointment has been made for the baby to be examined within 48 hours of discharge.

Your New Baby—the First Few Days

Eating
Your baby will probably be hungry every 2 to 4 hours around the clock. To help your baby adjust to a schedule like yours, wake him or her to feed every 3 to 4 hours when you are awake. Babies need only breast milk or formula for the first six months. Feeding your baby anything else will not help him or her to sleep better and may cause an allergic reaction. Remember to help the baby burp up swallowed air after each feeding (whether formula or breast milk).

Sleeping
Babies need a lot of sleep. To help your baby sleep when you want to sleep, provide a restful atmosphere and minimize interruptions or stimulation. Place your baby on his or her back to sleep.

Bowel Movements
Babies have greenish-black sticky stool for the first two days or so. This is called meconium. Breastfed babies' stool will then become golden-green, soft, and seedy-looking. Bottlefed babies have dark brown, pasty, or formed stools. Your baby may have one to four stools a day. If your baby goes without a bowel movement for more than 2 days, contact your pediatrician or nurse-practitioner.

Voiding
Your baby should wet at least 4 to 5 diapers per day. This may be hard to tell if you are using paper diapers. If you have questions, use cloth.

Skin Care
Wash your baby with mild soap such as Ivory or Dove. Do not immerse the baby completely until the cord stump has fallen off and dried. This will happen in 1 to 2 weeks. Before then, wipe around the base of the cord with a damp cloth. Fold the front of the baby's diaper down so that the cord is not irritated by it. When changing diapers, wash the baby's bottom with soap and water. Avoid using powder and perfumed creams to help prevent diaper rash.

Safety
It is Pennsylvania and New Jersey State law that babies ride in car seats. Keep your baby as safe as he or she has been for the first nine months! Newborns can roll, so they must never be left unattended on changing tables, dressers, tables, or beds. Do not keep pillows, stuffed animals, quilts, and extra blankets in the baby's crib, because they can prevent the baby from getting enough air to breathe.

Danger Signs
Contact your prediatrician or nurse-practitioner immediately if:

- The baby becomes listless, will not eat, or behaves in an unusual way.
- The baby does not urinate within the first 24 hours.
- The baby has no bowel movement for 48 hours.
- The cord starts to smell bad or has pus oozing from it.
- The baby's temperature is below 97 degrees or above 99 degrees when taken under the baby's arm.
- The whites of the baby's eyes become yellow and the skin color looks yellow, tan, or peach.

Newborn Home Assessment

As your baby adjusts to life outside of your uterus, he or she will undergo many changes. To ensure that the changes your baby is experiencing are normal, it is helpful to check each of the following twice a day. Report any variations from normal to your midwife or physician.

	Day 1		Day 2		Day 3	
	9 AM	5 PM	9 AM	5 PM	9 AM	5 PM
Temperature Take under the baby's arm for 3–5 minutes. The temperature should be between 97° and 99°						
Skin Check for jaundice or yellowing in the skin and whites of the eyes. Look at the baby in daylight near a window. Press on the baby's nose or breatbone; note the skin color when you release the pressure.						
Urination Note each time the baby has a wet diaper. There should be 5 or more a day.						
Bowel Movement Note color and number of bowel movements.						
Feeding The baby should be nursing or feeding every 2 to 3 hours for 15 to 20 minutes (2 to 4 ounces).						
Cord should become black and hard. Any pus or blood oozing from the stump is abnormal.

CHAPTER

38

Resuscitation at Birth

MARY KATHLEEN MCHUGH, CNM, MSN

Infrastructure for Safe Resuscitation of the Newborn

Any midwife attending births has a moral and ethical obligation to provide a birth environment in which resuscitation of the newborn can be effectively accomplished. To achieve that goal, the midwife needs (1) training in resuscitation techniques; (2) available and functional resuscitation equipment; (3) adequate support personnel; and (4) a clear-cut system for neonatal transport and/or referral to pediatric providers.

The content in this chapter reflects the latest guidelines for neonatal resuscitation established by the International Cardiopulmonary Resuscitation and Emergency Cardiac Care conference, last held in the year 2000. The conference meets every five years and its recommendations are adopted by the American Academy of Pediatrics (AAP) and the American Heart Association (AHA). Midwives should regularly check the AAP Web site (www.aap.org/nrp) for new developments and online review materials.

Every midwife and birth assistant attending births should be certified in neonatal advanced life support. The training course, the Neonatal Resuscitation Program (NRP), was jointly developed by the American Heart Association and the American Academy of Pediatrics and is available nationally. Midwives interested in taking the course can find a local course at the AAP Web site. After initial certification, annual skill refreshers are essential.

In a hospital setting, the midwife should be familiar with the neonatal personnel who will attend the birth of a compromised infant. This information should be part of the orientation of any new midwife. The midwife can then request appropriate help and explain the neonatal support team to worried parents.

In a free-standing birth center or home birth practice the midwife has an obligation to establish a clear-cut mechanism for transport and/or referral of compromised newborns. There must be access to both pediatric providers and a hospital nursery capable of providing acute care for a compromised newborn. Occasionally, a consultation can take place on site at a birth center. More typically, a transport team from the receiving hospital, or a local ambulance team, will pick up the compromised newborn. The responsibility for initiating the consultation and transport rests with the midwife attending the birth. During the interval before the transport team arrives, the midwife must continue to care for the newborn. The National Association of Childbearing Centers (NACC) has national standards related to the organization of a birth center's newborn care contingencies [1].

Equipment for Resuscitation

The basic equipment necessary for resuscitation of the newborn should be available in all sites (see Table 38-1). Certain medications, electrocardiograms, and an umbilical artery catheterization tray may only be available in a hospital site where trained neonatal providers will make use of them. In a hospital setting, nursing staffs are usually responsible for checking and maintaining equipment and supplies. In a birth center or home birth practice this responsibility may remain with the midwife or a nurse. Equipment should be checked at frequent intervals and a signature log should be kept.

TABLE 38-1 Neonatal Resuscitation Supplies and Equipment

Suction Equipment	Bag-and-Mask Equipment	Intubation Equipment	Medications	Miscellaneous
Bulb syringe Mechanical suction and tubing Suction catheters, 5F or 6F, 8F, 10F or 12F 8F feeding tube and 20-mL syringe Meconium aspirator	Neonatal resuscitation bag with pressure-release valve or pressure manometer; the bag must be capable of delivering 90 to 100% oxygen Face masks, newborn and premature sizes (cushioned rim masks preferred) Oxygen with flowmeter (flow rate up to 10 L/min) and tubing	Laryngoscope with straight blades, no. 0 (preterm) and no. 1 (term) Extra bulbs and batteries for laryngoscope Endotracheal tubes, 2.5, 3.0, 3.5, 4.0 mm internal diameter (ID) Stylet (optional) Scissors Tape or securing device for endotracheal tube Alcohol sponges CO_2 detector (optional) Laryngeal mask airway (optional)	Epinephrine 1:10,000 (0.1 mg/ml) in 3-mL or 10-mL ampules Isotonic crystalloid (normal saline, or Ringer's lactate) for volume expansion—100 or 250 ml. Sodium bicarbonate 4.2% (5 mEq/10mL) in 10-mL ampules Naloxone hydrochloride 0.4 mg/mL in 1-mL ampules or 1.0 mg/mL in 2-mL ampules Dextrose 10%, 250 mL Normal saline for flushes Feeding tube, 5F (optional) Umbilical vessel catheterization supplies: Sterile gloves Scalpel or scissors Povidone-iodine solution Umbilical tape Umbilical catheters, 3.5F, 5F Three-way stopcock Syringes, 1, 3, 5, 10, 20, 50 ml Needles, 25, 21, 18 gauge, or puncture device for needleless system	Gloves and appropriate personal protection Radiant warmer (see text) Firm, padded resuscitation surface Clock (timer optional) Warmed linens Stethoscope (neonatal head preferred) Tape, 1/2 or 3/4 inch Cardiac monitor and electrodes or pulse oximeter and probe (optional for delivery room) Oropharyngeal airways (0, 00, 000 sizes or 30-, 40-, 50-mm lengths)

Pathophysiology of Asphyxia

The underlying pathophysiological events in asphyxia include lack of oxygenation of cells, excess carbon dioxide retention, and metabolic acidosis. These three events combine to cause cell damage and a biochemical environment that is incompatible with life. The goal of resuscitation is timely intervention that reverses the biochemical effects of asphyxia, thus preventing irreversible brain and organ damage that may have sequelae throughout life.

The onset of hypoxia causes a series of reactions outlined in Figures 38-1 and 38-2. The heart rate and blood pressure initially rise and the infant will make gasping attempts. The infant will then enter a period of primary apnea. Infants receiving adequate stimulation during primary apnea will begin respiratory effort again. Stimulation can con-

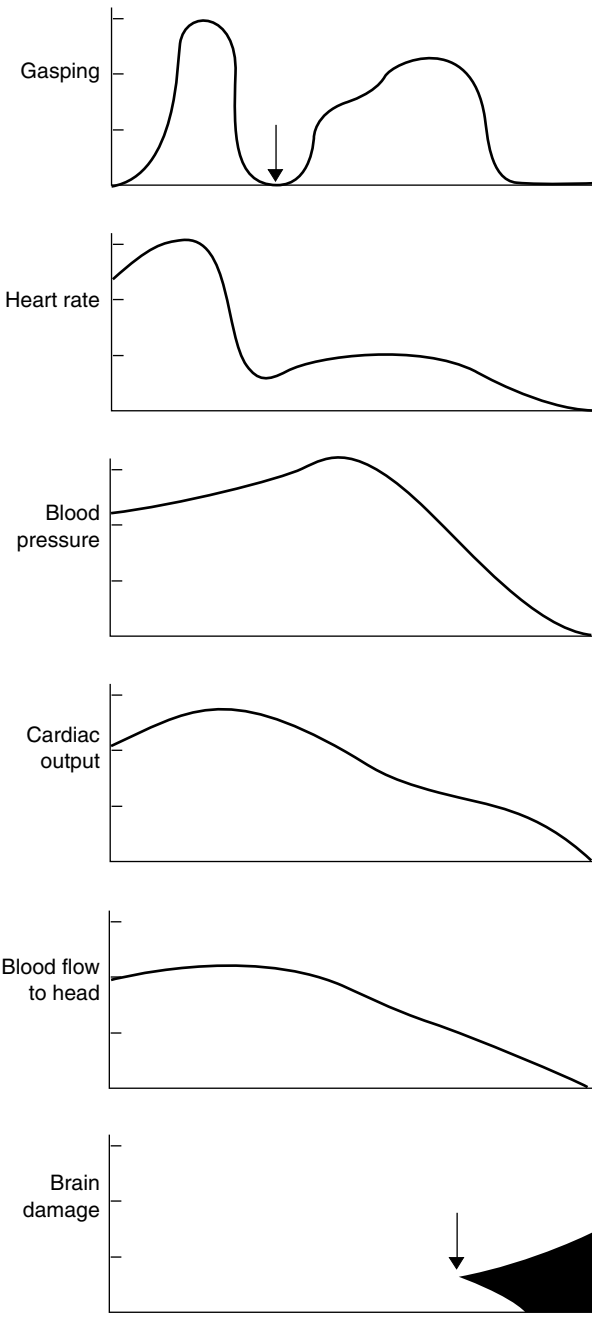

FIGURE 38-1 Physiological effects of asphyxia. Arrow in the topmost graph indicates the point of primary apnea; arrow in the lowest graph indicates the point at which brain damage begins.

sist of tactile stimulation (drying the infant) and thermal stimulation (provided by the cooler temperature of the birth room).

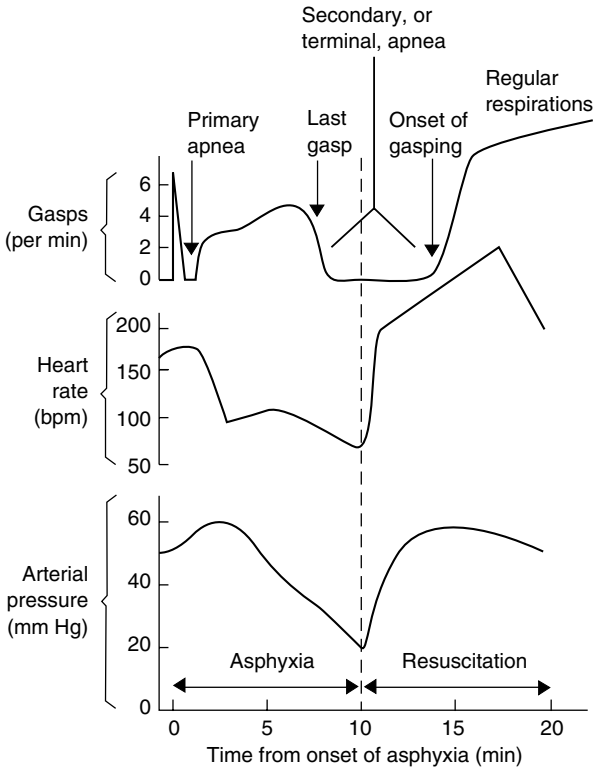

FIGURE 38-2 Response of Rhesus monkeys to asphyxia and resuscitation.

Infants further along in the asphyxial process are in a stage of secondary apnea. Secondary apnea will quickly lead to death if the infant is not fully supported with artificial respiration and, as needed, cardiac compression. During secondary apnea, the heart rate and blood pressure plummet. Color changes from blue to white as the newborn shuts down peripheral circulation in an attempt to maximize blood flow to organs such as the heart, the kidneys, and the adrenals.

The midwife assisting at the birth of an apneic newborn can only know retrospectively whether the newborn was in primary or secondary apnea. The fetus may have started the asphyxial gasping prior to birth and may be born dying. Recovery from secondary apnea is prolonged and is directly related to the length of asphyxia.

During apnea, the decreased available oxygen causes constriction of the blood vessels in the lungs. This vasoconstriction causes the lungs to be resistant to expansion, thus compounding the work of resuscitation. One of the effects of hypoxia on the

circulation in the heart is persistent fetal circulation. The foramen ovale continues to shunt blood from the right to the left atrium and the ductus arteriosus continues to shunt blood to the aorta, past the constricted lungs. The newborn in a state of asphyxia retains many of the features of fetal circulation.

During hypoxia, serious biochemical changes cause a buildup of the by-products of anaerobic metabolism. Because of the lack of adequate ventilation, the newborn quickly builds up carbon dioxide. This hypercarbia leads to a respiratory acidosis that will further depress respiratory efforts.

Within a short period of time, the lack of oxygen causes the newborn to switch to an anaerobic pathway for metabolism, especially of the glucose needed for emergency fuel. This leads to an accumulation of lactate and metabolic acidosis. Metabolic acidosis will only clear over a significant period of time and is a residual problem even after adequate respirations and heart rates are established.

The effect of hypoxia on the brain is especially pronounced. With initial hypoxia, the blood flow to the brain increases, as part of a compensatory mechanism. This can only provide a partial adjustment and, in the face of continuing hypoxia, is quickly overwhelmed. Among the many effects of hypoxia on the brain cells, some of the most severe come from the lack of energy-providing substances such as ATP; a cessation of the transcellular pumping of ions; an accumulation of water, sodium, and calcium; and damage from oxygen free radicals. As the flow of oxygenated blood decreases, amino acids that promote swelling of brain tissues are released. This process can lead to gross or subtle neurological damage. Seizures may start during the first 24 hours after birth. The onset of seizures during this period is an ominous sign and signals the increased probability that there has been permanent brain damage [2].

Care of the Newborn Following Resuscitation

The seriousness of the newborn's distress at birth can be estimated after the resuscitation is completed. As noted above, quick recovery of respiratory abilities after tactile stimulation or very brief artificial ventilation is consistent with primary apnea. Secondary apnea requires a longer recovery period that starts with a few gasps followed many minutes later by regular respirations. The Apgar score can be used to evaluate the successful recovery from asphyxia. However the Apgar score, which is not assigned until minutes 1 and 5, is not used to lead decisions regarding resuscitation. The midwife will be making resuscitation decisions from the moment the neonate's color can be first evaluated.

Deviations in blood gases will also reflect the seriousness of the asphyxia at birth (see Table 38-2). The midwife can estimate the acidosis present at delivery by sending cord blood to the lab to evaluate acid-base balance. The midwife should attempt to draw blood from the umbilical artery, which contains blood exiting from the fetus. If that is not possible, a sample can be obtained from the umbilical vein. In studies of thousands of neonates, umbilical artery mean pH levels were 7.28 and umbilical vein means were between 7.32 and 7.35. Values below a pH of 7.0 from the umbilical artery are considered significantly acidotic [3]. (See Chapter 27, page 813 for more information about cord blood pH.)

During and after resuscitation, blood gas measurements will reflect the success of the interventions offered to the newborn. Many facilities have equipment to indirectly measure oxygenation. One technique uses pulse oximetry and measures oxygen saturation. This noninvasive procedure involves attachment of a sensor to one of the infant's extremities. From the underlying arterial pulsations in the extremity, the sensor computes the arterial oxygen saturation. A second type of testing involves the placement of a heated electrode on the abdomen and transcutaneously measures the partial pressure of oxygen—the $tcPO_2$. In this measurement the caregiver needs to be concerned with long-term skin care issues, especially in a premature infant. The midwife may initiate use of a pulse oximeter or a transcutaneous electrode on the neonate while awaiting a transport team or neonatal backup.

After a successful resuscitation, the asphyxiated infant must be observed carefully for residual effects of ischemia and metabolic acidosis and for temperature stability, adequate blood pressure, blood glucose and serum electrolytes, and adequate urine output. Glucose should be given prophylactically, with the route of administration dependent on the severity of the asphyxia. Metabolic acidosis may need to be treated with medications like sodium bicarbonate. Ultrasounds, EEGs, or CT scans of the resuscitated infant's brain will be used for follow-up of the severely asphyxiated newborn.

TABLE 38-2 Normal Blood Gases After Birth

	Immediately After Birth					
	Value	*Standard Deviation*	*Range*	*5 min*	*10 min*	*1 hr*
pH

The Process of Resuscitation

Neonatal resuscitation is not an isolated procedure. It is instead a complex web of decisions about care. If resuscitation is done correctly, the newborn is exposed to the proper level of support and intervention needed for a successful transition to extrauterine life. The midwife making resuscitation decisions will be following the same critical thinking process used in every area of midwifery care: data collection, problem identification, formulation of a plan, action, and evaluation. Failure to follow the critical thinking process can lead to resuscitation that is needlessly vigorous—or worse, woefully inadequate.

Decision-Making in Newborn Resuscitation

One of the most serious errors a midwife can make is to be unprepared for newborn resuscitation. There are many factors that predispose a newborn to need resuscitation. It is estimated that approximately 6 percent of newborns will need some type of resuscitation [4]. Some of the most common reasons for resuscitation are summarized in the "TAMMSS" acronym devised by McCollum [5]:

T = Trauma
A = Fetal asphyxia
M = Maternal medication
M = Malformations
S = Sepsis
S = Shock

Based on the presence or likelihood of these factors, the midwife should decide, prior to the birth, the safest site and personnel for the birth. In labor at home or in a birth center, there may be such a high likelihood of the need for resuscitation that the midwife will choose a hospital transfer during

labor. In a hospital birth, the midwife may choose to call in the neonatal team for the birth.

The amount of obstetrical trauma and maternal medication that affect a newborn are closely related to the quality of the midwifery care given during labor. Of the four common reasons for resuscitation, asphyxia is the most common. Whether asphyxia can be predicted is questionable [6]. Events from the antepartal, intrapartal, and immediate neonatal periods can overlap to increase the deleterious effects of any hypoxia. At present, our ability to foretell fetal asphyxia and subsequent neonatal outcomes is limited. The duration of the hypoxia is currently the most reliable indicator of subsequent neonatal sequelae [7]. Table 38-3 summarizes situations that cause asphyxia in utero.

The infant who needs resuscitation secondary to maternal medication or malformations may be pink, take a few breaths, and then decompensate. As emphasized in Chapter 37, the need for vigilant observation of the newborn continues throughout the first hour of life. Newborns who are well-wrapped and nestled on their mother's abdomen must be frequently checked for ongoing healthy transition to extrauterine life.

If, at birth or later, the midwife has any concerns about the newborn's respiratory effort, color, heartbeat, or muscle tone, the newborn should be placed in the resuscitation area for a full assessment under good lights and an adequate heat source.

Some general principles underlie any resuscitation decisions.

1. Resuscitation equipment should always be available and functioning and the midwife should know how to use it.
2. Thermal stress should be avoided.
3. A blocked newborn airway cannot be easily ventilated.
4. Adequate ventilation is the most important part of neonatal resuscitation.
5. Adequate circulatory support prevents long-term metabolic sequelae.
6. Personnel attending the infant should follow universal precautions.

With these premises in mind, the midwife attending a birth should move ahead assertively with the following activities:

1. Dry and cover the newborn.
2. Observe the newborn for signs of a vigorous first breath and subsequent regular breaths.
3. Assess the heartbeat and tone of the infant.
4. Watch for a change of color from dusky to pink.

If the midwife is not satisfied with the assessment of the newborn, she or he should recall the classic "ABC" priorities of resuscitation: airway, breathing, and circulation. The midwife then begins those activities that will support newborn oxygenation and circulation at a level appropriate for the situation. In the hospital, the neonatal team may take over at this point. However, until a team of experienced neonatal caregivers arrives, it is the midwife's duty to direct and/or perform resuscitation.

Because midwives specialize in the care of low-risk women, a midwife's experience with neonatal resuscitation may be limited. Aside from participating in yearly NRP recertification, every midwife should mentally review on the way to every birth the steps of decision-making and assessment that are part of a smooth resuscitation. In particular, the midwife should review the points at which resuscitation efforts should be started, stopped temporarily for an assessment, or stopped permanently because of success. The midwife should reflect on those situations in which the typical steps of resuscitation do not yield a positive result and be prepared for unusual problems like diaphragmatic hernia and upper airway obstruction that require the use of alternative methods of resuscitation.

TABLE 38-3 Conditions Under Which Fetal Asphyxia Is Likely

Problem	Pathophysiology	Type
Cord prolapse (overt/occult)	Decreased blood flow to fetus	Acute
Placenta previa	Disruption of placental flow	Acute
Abruptio placentae	Disruption of placental flow	Acute
Cord compression	Intermittent umbilical vein flow	Acute/chronic
Fetal isoimmunization	Destruction of red blood cells	Chronic
Placental insufficiency	Inadequate placental function	Chronic
Maternal vascular disease	Poor oxygenation of mother/fetus	Chronic
Maternal hypotension	Inadequate placental blood flow	Acute
Uterine overstimulation	Inadequate placental oxygenation	Acute

The following cardinal principles, part of the resuscitation overview of the NRP [8], should contribute to decision-making regarding neonatal resuscitation (see Figure 38-3):

1. Clear the airway.
2. If heart rate is less than 100 bpm, begin resuscitation with positive pressure ventilation (PPV).

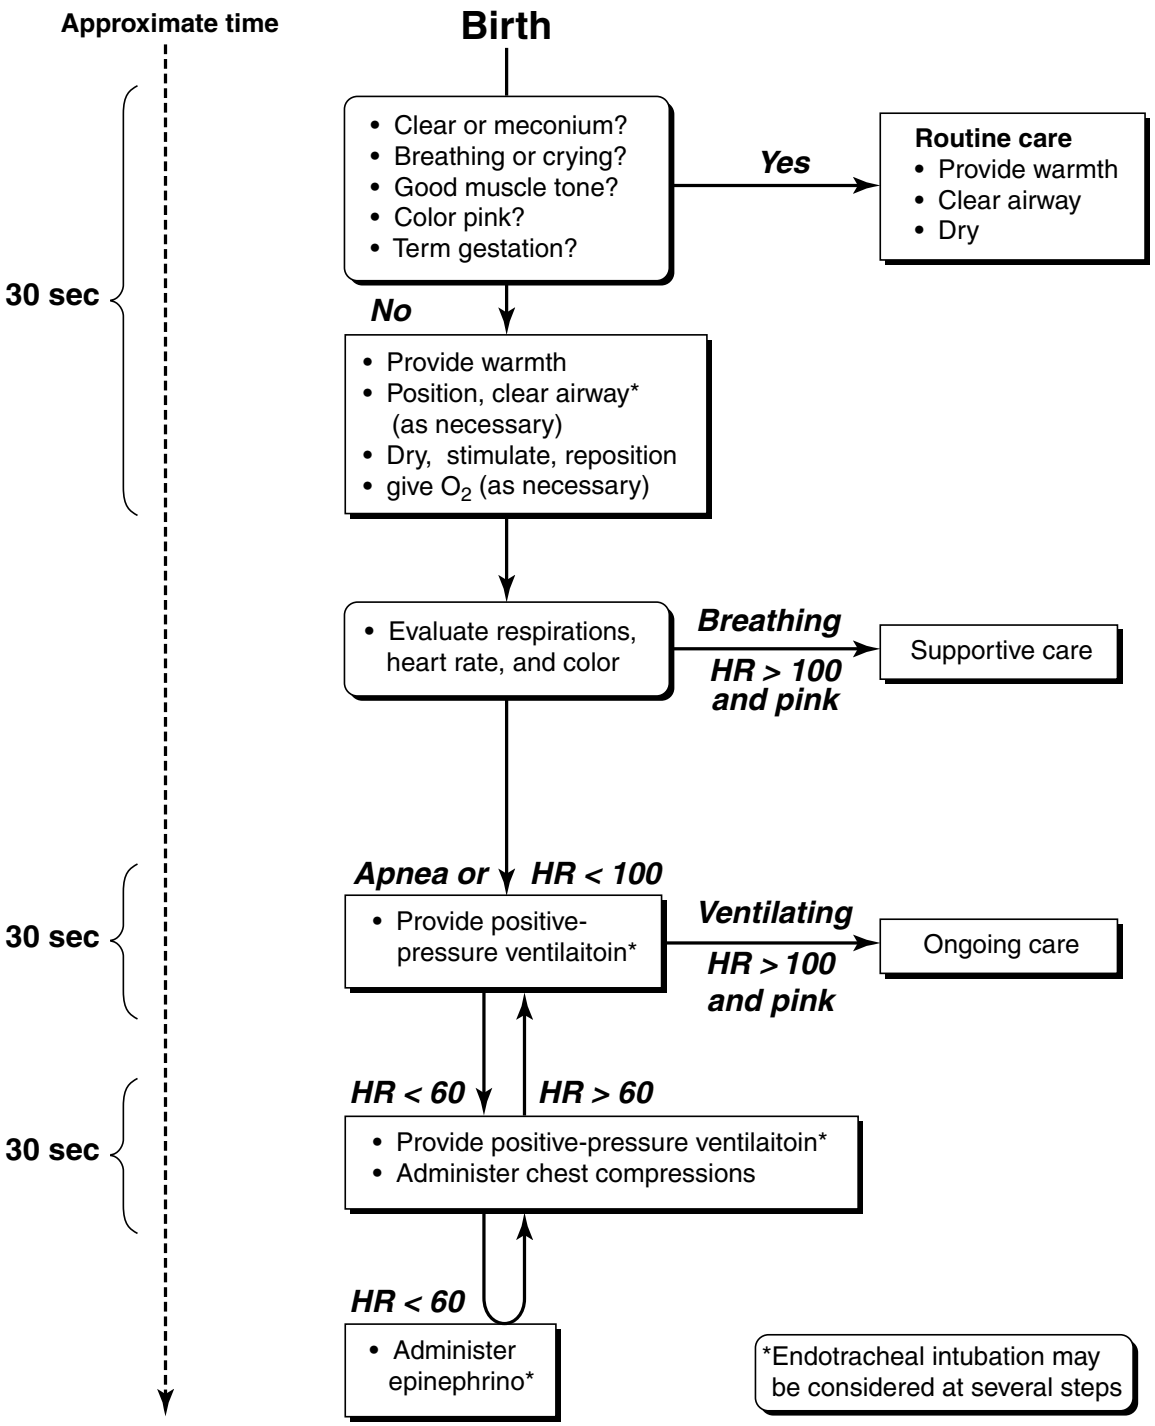

FIGURE 38-3 Algorithm for resuscitation of the newly born infant.

Source: Niermeyer, S., Kattwinkel, J., Van Reempts, P., et al. International guidelines for neonatal resuscitation: an excerpt from the guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care. International consensus on science, contributors and reviewers for the neonatal resuscitation guidelines. *Pediatrics* 106(3):E29, September 2000. Used by permission.

3. After 30 seconds, evaluate heart rate while continuing PPV.
4. If heart rate is less than 60 bpm, start chest compressions with PPV. Evaluate at 30 seconds. Continue PPV. If heart rate is above 60, stop chest compressions and continue PPV.
5. Perform endotracheal intubation if PPV seems ineffective (inadequate chest expansion, signs of diaphragmatic hernia).
6. Consider use of Naloxone or epinephrine if there is no increase in heart rate.
7. Stop PPV if there are spontaneous respirations. Continue free-flow oxygen.

Techniques for Effective Newborn Resuscitation

Techniques to Establish Adequate Respiration Basic support of the newborn needing resuscitation starts with the establishment of an adequate airway. Newborns who do not make immediate efforts to breathe and clear their own mucus should be suctioned: first the mouth, then the nose. The greatest amount of fluid is in the oropharynx. Bulb suction or wall suction (less than 100 mg Hg) can be used. The use of DeLee suction catheters is in decline because of the small chance of operator exposure to the newborn's bodily secretions. Occasionally, an oral airway may need to be inserted in an infant with a congenital defect of the mouth, nose, tongue, or palate to encourage adequate respiration in a mouth-breather. Infants showing respiratory compromise should be positioned on their backs with a very slight extension of the neck. This helps to minimize tracheal narrowing and maximizes air flow. If an infant has a very swollen occiput, it may be necessary to put a half-inch roll of cloth under the shoulders in order to keep the airway slightly hyperextended.

Breathing efforts should be evaluated next. Tactile stimulation should be enough to stimulate most infants to breathe. Apneic infants who respond to tactile stimulation were in a period of primary apnea.

If there are spontaneous regular respirations but the infant's color is dusky, the infant can be given 100 percent free-flow oxygen. To deliver this free-flow oxygen, the midwife should use either oxygen tubing with a face mask or an anesthesia bag with mask placed near the newborn's face. Self-inflating resuscitation bags will not deliver any oxygen in a free-flow manner and should not be used to administer free-flow oxygen. An increasingly pink color will be a sign of success from this intervention. As color improves the oxygen can be gradually withdrawn.

If there are not spontaneous, regular respirations or if the newborn color remains dusky, the midwife should start positive pressure ventilation using a resuscitation bag and mask (see Table 38-4 and Figure 38-4). The oxygen source should be set at a liter flow of 5–10 L/min. There are two types of bags—flow-inflating and self-inflating—and the midwife needs to become familiar with the type of bag used at each facility. Flow-inflating bags need

TABLE 38-4 Procedure for Positive Pressure Ventilation

Equipment	Method	Precautions
1. Anesthesia bag with pressure gauge (manometer) or self-inflating bag with oxygen reservoir attachment 2. Infant- and premature-size face masks 3. Stethoscope 4. Feeding tube 5. Source of humidified oxygen with flowmeter	1. Suction nares and oropharynx to clear secretions. 2. Place infant's head in a neutral position (when hyperextended, air enters esophagus). 3. Place mask over nose and mouth, making sure seal is tight. 4. Pressure for first breath should be 40–50 cm H_20. 5. Subsequent breaths need about 25 cm H_20 or the lowest pressure that will allow you to see the chest wall expanding. 6. Ventilate 40–50 times per minute for 23 minutes. 7. Have assistant auscultate anterior upper lobes of the lungs for aeration. 8. Continue to provide free-flow 0_2 by face mask after infant has established respirations.	1. Inadequate ventilation may be caused by poor seal around mask, flexed or hyperextended neck, or inadequate pressure of ventilation. 2. Face mask pressure near the infant's eyes can cause tissue damage. 3. Positive pressure ventilation will cause air retention in the stomach. After bagging for a brief period of time, vent the stomach by passing a feeding tube. Any gastric contents should also be emptied. If bagging is going to continue over time (e.g., while awaiting a transport team), stop momentarily to slip a tube into the stomach to vent the stomach and prevent or reduce distention. Secure tube in place while continuing to ventilate.

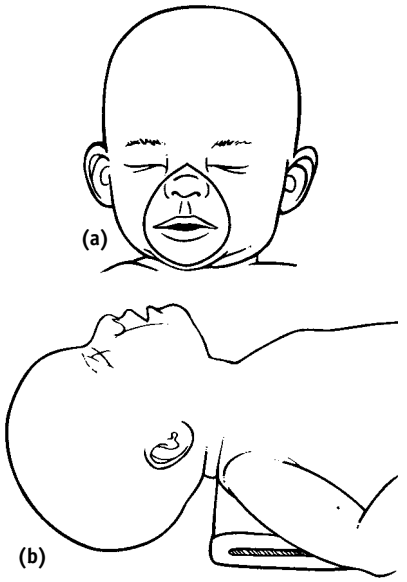

FIGURE 38-4 (a) Correct-sized mask covers mouth, nose, and tip of chin, but not the eyes. (b) Correct position for assisted ventilation.

Source: From Kattwinkel, J. *Textbook of Neonatal Resuscitation*, 4th ed. Elk Grove Village, IL: American Heart Association and Academy of Pediatrics, 2000, p. 3-22. Used with permission of the American Academy of Pediatrics.

compressed oxygen to inflate and can be used to deliver different pressures and concentrations of oxygen. If not used properly, they can inflict damage from pressure on the newborn lungs. A flow-inflating bag should be adjusted to have a resting pressure of 5 cm H_2O and a peak pressure of 30–40 cm H_2O.

Self-inflating bags are easier to manage if a midwife performs resuscitation only occasionally. They deliver a peak pressure of 30–40 cm H_2O, after which they "pop-off" extra pressure. However, self-inflating bags will not deliver high concentrations of oxygen (90–100 percent) unless they have a closed-ended reservoir attached to them. It is recommended that a self-inflating bag be used to deliver room air to a neonate if there is no functional source of compressed oxygen [9].

Problems connected with positive pressure ventilation include a poor seal between mask and face, inadequate oxygen delivery, blockage of the airway by the tongue, and a poor technique that delivers too few or too many breaths to the newborn.

The midwife should be assisted in the resuscitation. During positive pressure ventilation, the bag should be positioned so that it does not obstruct the ability of the assistant to evaluate chest expansion and heart rate. Between 40 and 60 breaths per minute should be delivered via PPV. The rhythm that can be developed is illustrated in Figure 38-5. The PPV should be stopped for a moment every 30 seconds to see if there are spontaneous respirations.

If the PPV continues for more than a brief period, the newborn stomach will have to be vented of air by passage of an orogastric (feeding) tube. The PPV should be stopped for the 10 seconds it will take to pass the feeding tube through the mouth. Failure to do this will lead to an accumulation of air that may compromise lung expansion. The midwife should be comforted to know that if adequate respirations are delivered, most newborns will show prompt signs of recovery.

Technique of Cardiac Compression The new AAP/AHA guidelines recommend initiating cardiac compressions if the heart rate is less than 60 bpm [9]. The goal of cardiac compression is to provide the proper frequency of compression accompanied by a pressure that is effective yet avoids damage to internal organs. It will be nearly impossible for the midwife to continue resuscitation successfully if there is not assistance from a second trained person. During cardiac compressions, ventilatory support must continue.

The caregiver's fingers should give pressure downward, without splaying pressure out in a lateral direction. The fingers or thumbs can be posi-

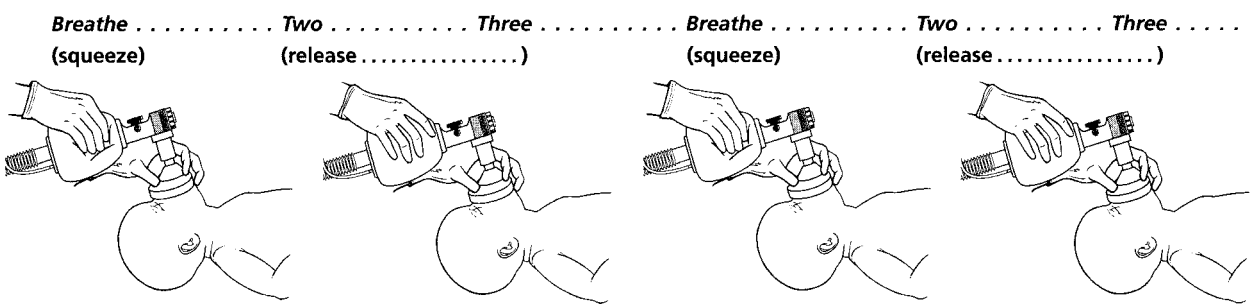

FIGURE 38-5 Rhythm for effective positive pressure ventilation. Count out loud to maintain a rate of 40 to 60 breaths per minute.

tioned side-by-side in either the thumb technique or the two-finger technique (see Figure 38-6). The fingers should be applied to the lower third of the sternum, the area that would be directly below a line drawn between the nipples. The sternum should be compressed to a depth of one-third of the anterior-posterior diameter of the chest. Between compressions, it is important that the caregiver not remove his or her fingers from the newborn. Repositioning of fingers wastes time and increases the chances that compressions will occur lateral to the sternum.

Cardiac compressions should be delivered at the rate of 90 compressions per minute. The compressions must be interspersed with adequate ventilations in a ratio of 3:1, or three cardiac compressions to one ventilation every 2 seconds. After 30 seconds, the caregiver should pause and evaluate the heart rate for 6 seconds. If the heart rate is above 60 bpm, cardiac compressions can be discontinued. However, PPV must continue until there are spontaneous respirations. If the heart rate is less than 60 bpm, cardiac compressions must continue. At this point, the newborn may be in need of medications that will strengthen and increase the heart rate so that cardiac output will be adequate. If the heart rate is over 100 bpm, the cardiac compressions can be stopped and PPV gradually decreased.

Techniques of Endotracheal Intubation The midwife may choose to perform endotracheal intubation on a newborn in certain situations, including (1) when diaphragmatic hernia is suspected; (2) when the newborn needs prolonged ventilation (i.e., during a transport to another facility); (3) if the newborn must be on a ventilator; (4) when adequate oxygenation cannot be achieved with bag and mask; or (5) when the midwife must suction meconium in a nonvigorous newborn. The procedure is outlined in Table 38-5.

Skillfulness at endotracheal intubation arises in part from detailed knowledge of the anatomy of the pharynx, trachea, and bronchi. The midwife should frequently review the anatomic landmarks in this area. The endotracheal tube is passed between the vocal cords within the glottis (see Figure 38-7). The opening to the glottis can be seen only if the epiglottis (the covering of the glottis) is lifted out of the way. This is accomplished by positioning the tip of the laryngoscope blade so that pressure in the space between the tongue and the epiglottis (the vallecula) causes the epiglottis to be open (see Figure 38-8). It is important to note that the blade of the laryngoscope is not creating the space for the tube—the blade is merely causing the epiglottis to be open so that the tube can be passed down further. If the blade is not inserted far enough, you will see only the tongue; if the blade is inserted too far, you will see the esophagus.

For a term infant, the usual endotracheal tube (ET) diameter is 3.5 to 4.0 millimeters. Tubes should be precut to be approximately 13 centimeters long and should have an adaptor on top that will fit onto the resuscitation bag. Tubes should be prepared and the laryngoscope light bulb should be checked prior to the birth of the infant. Adhesive tape should also be cut and ready.

TABLE 38-5 Endotracheal Intubation

Equipment	Method	Precautions
1. DeLee suction catheters **2.** Endotracheal tubes, various sizes with adapters **3.** Laryngoscope with blades **4.** Positive pressure bag **5.** Towel **6.** Tape	**1.** Place infant with head in slightly extended position; may place towel under infant's shoulders. **2.** Introduce laryngoscope at the right corner of the mouth. **3.** Advance laryngoscope 2 to 3 cm while rotating it to midline and moving tongue to left. **4.** When tip of blade is between the base of the tongue and the epiglottis, a slight elevation of the blade will expose the glottis (sometimes a gentle compression of the external larynx by an assistant will more easily expose the glottis). **5.** Insert the endotracheal tube at the right side of the mouth and through the vocal cords, being sure you can easily see the tube; (the tube must be small enough to allow an air leak—i.e., there should be room around it; this space ensures easy expiration and reduces the risk of tissue damage). **6.** Suction secretions if needed. **7.** When the endotracheal tube is inserted, hold it firmly but gently in place and withdraw the laryngoscope slowly. **8.** Attach the endotracheal tube to the adapter on the bag. **9.** Ventilate with oxygen by bag; assistant should check for adequate ventilation of both lungs with stethoscope.	**1.** If you have difficulty with the procedure, remove laryngoscope and ventilate with mask; try again in 2 min. **2.** If tube is passed too far into the airway, it enters into the mainstem bronchus and breathing sounds on the left decrease. If this occurs, withdraw the tube slowly until breath sounds on the left increase. **3.** If tube is left in place, suction as necessary with a sterile suction catheter when excess secretions are detected (possibly every 30–60 min).

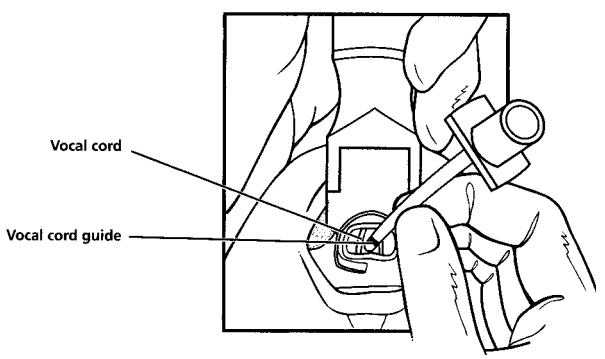

FIGURE 38-7 Insertion of endotracheal tube between vocal cords.

Some caregivers like to use a stylet in the ET tube to serve as a guide for the flexible tube. If a stylet is used, its tip must not extend too far past the end of the ET tube because of the danger of the stylet perforating the trachea. The stylet will be removed as soon as the tube is below the vocal cords.

The ET tube (with or without stylet) should be placed into the right side of the mouth and advanced into the glottis until the black line on the lower part of the tube is at the level of the vocal cords (see again Figure 38-7). Once the tube has been inserted, breath sounds should be checked. Tubes that are advanced too far will deviate into the right mainstem bronchus and can be slightly pulled back. They must then be taped securely in place (see Figure 38-9).

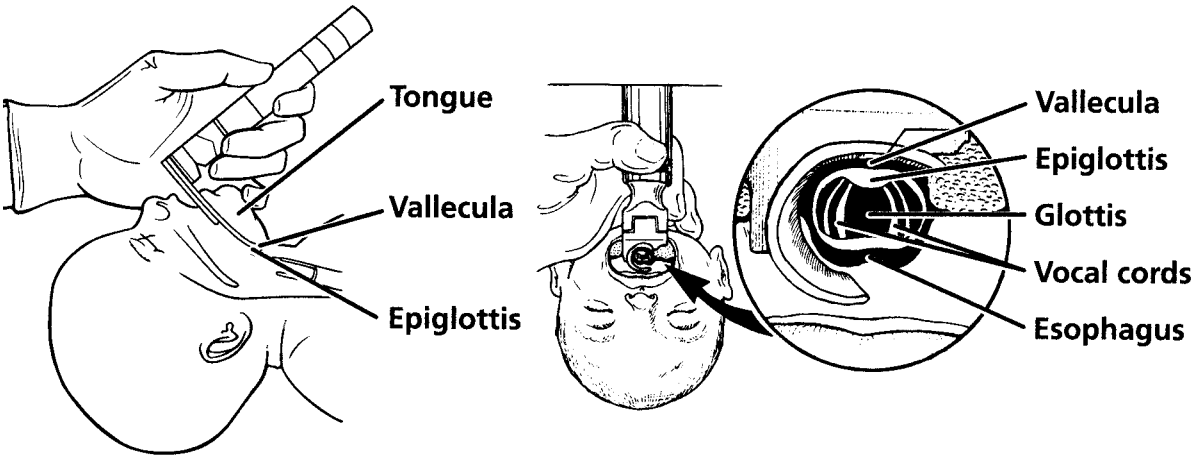

FIGURE 38-8 Identification of landmarks before placing endotracheal tube through glottis.

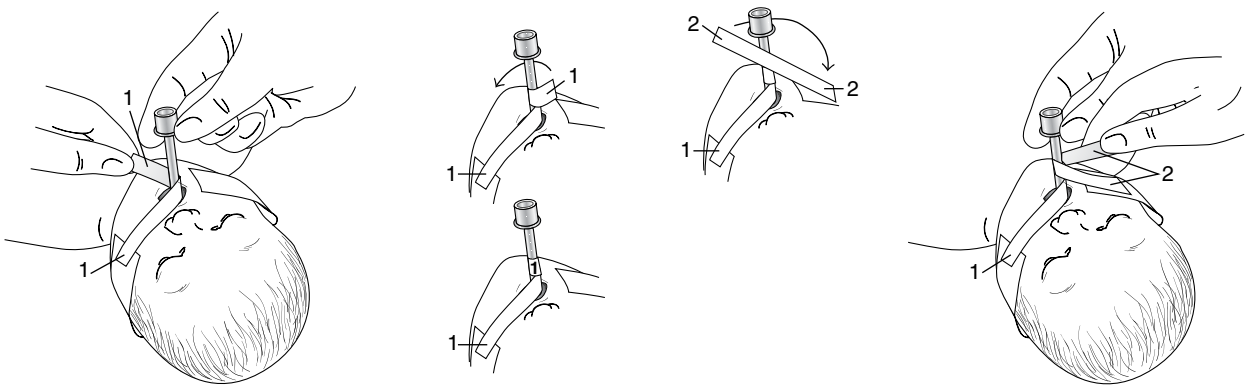

FIGURE 38-9 Taping an endotracheal tube. The cheeks and sides of the face are painted with tincture of benzoin. (Some neonatal intensive care units currently do not use benzoin because of its absorption and potential toxic effects.) Wide pieces of elastic tape are placed over the sides of the face and pinnae. With the tube pulled to the right side of the mouth, a thin piece of tape (1) secures the tube on the left side of the face. Another piece of tape (2) then secures the tube on the right side of the face in a similar fashion.

Use of Resuscitation Medications by the Midwife The use of neonatal resuscitation medications by midwives is an area of advanced practice and will depend on the midwife's training and the policies at the site of practice. If the standard of practice in the hospital or birth center includes the use of medications by the midwife, special theoretical and clinical education is required. To be effectively administered, most emergency medications need to be given through the umbilical vein. Intramuscular or subcutaneous medications will not be effectively transported through the newborn body in situations of hypotension or decreased peripheral circulation.

Some medications can be given in a noninvasive manner through the ET tube (see Figure 38-10). This technique is valuable for the midwife to know and master. In order to use this route of administration effectively, the midwife must place the ET tube in the trachea correctly. A very small volume of medication will be used. Therefore, it is recommended that this medication be diluted with 1–2 mL of normal saline, thus increasing the chance that most of the medication will actually reach lung tissue rather than adhering to the walls of the ET tube. Alternatively, the midwife may thread a small feeding tube into the ET tube and push the medication and diluent through the feeding tube. Regardless of which method is used, the midwife must give the medication and then use PPV to ensure distribution of the medication throughout the lungs.

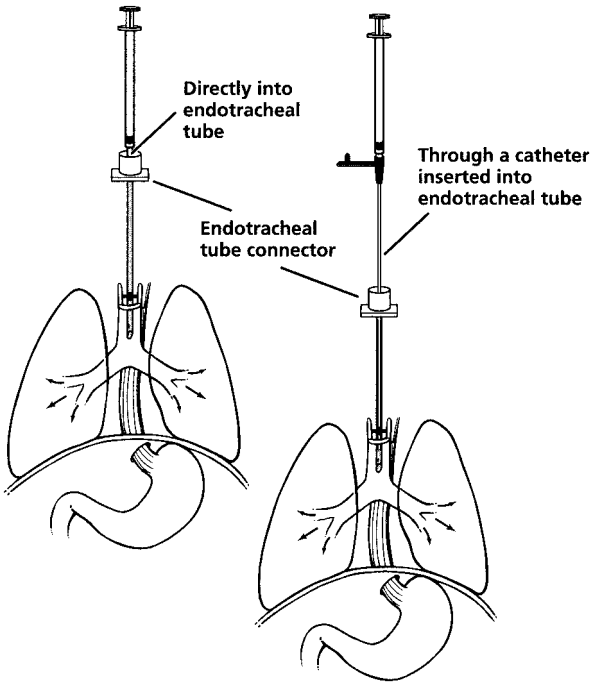

FIGURE 38-10 Medication (epinephrine) may be administered directly into the endotracheal tube (left) or through a catheter inserted into the endotracheal tube (right).

Source: From Kattwinkel, J. *Textbook of Neonatal Resuscitation*, 4th ed. Elk Grove Village, IL: American Heart Association and American Academy of Pediatrics, 2000, p. 6-5. Reproduced with permission.

If there is a high likelihood that resuscitation medications will be needed, they should be drawn up into labeled syringes prior to the birth. This saves valuable time. (If the medications are not needed, the financial consequence is small.)

One medication that can be administered in this noninvasive way is epinephrine. Epinephrine is a potent cardiac stimulant, a catecholamine with vasoconstrictive properties. Epinephrine will increase the newborn blood pressure, thereby increasing perfusion to the heart [10]. Epinephrine can be administered through an endotracheal tube; the recommended dose is 0.1–0.3 mL/kg of a 1:10,000 concentration [8]. Note the lower concentration used for neonates. Therefore, a term infant who weighed 3 kilograms would require a dose of 0.3–0.9 mL of 1:10,000 epinephrine (diluted in 1–2 mL saline). Epinephrine should be used if a newborn has no heartbeat or if the heart rate remains less than 60 bpm after 30 seconds of PPV and cardiac compressions.

Another medication that can be administered by ET tube is naloxone hydrochloride (Narcan), a narcotic antagonist that should be used if the mother received narcotics in labor that could cause newborn respiratory depression. It should never be used in a newborn whose mother is a narcotic (opiate) addict because of the possibility of causing abrupt narcotic withdrawal syndrome. Naloxone hydrochloride should be given in the dosage of 0.1 mg/kg [8]. A 3-kilogram infant would therefore receive 0.3 mg (diluted in 1–2 mL of saline). The midwife needs to know what concentration of this medication is available in a particular institution since it can be packaged in concentrations of 0.4 mg/mL or 1.0 mg/mL.

Special Situations in Neonatal Resuscitation

Care of the Neonate Born in Meconium-Stained Amniotic Fluid

Between 10 and 30 percent of fetuses pass meconium prior to birth that is retained in the amniotic fluid. The passage of meconium prior to birth is directly related to increasing gestational age. Many researchers and clinicians have tried to assign meaning to the passage of meconium [11]. Theories include (1) that it is a maturational event of no significance; (2) that it is a symptom of chronic hypoxia during the fetal period; or (3) that it is a symptom of acute hypoxia during labor that stimulates a vagal response.

Regardless of the reasons for the passage of meconium, the fact remains that meconium can damage the newborn lungs in one of two ways: it can act as a chemical irritant causing pneumonitis or it can cause direct blockage of the airways. The type of damage inflicted by meconium is related in part to how deeply meconium is inhaled into the lungs.

The goal of care for the meconium-exposed newborn is prevention of aspiration. This is best accomplished by a thorough, deep suctioning of the baby's head as it rests on the perineum and prior to the chest recoil that occurs with the birth of the newborn body. With chest recoil, a negative pressure is established that can suck upper airway fluid lower into the lungs.

The midwife needs to convince the woman giving birth not to push the newborn body out until this suctioning can be accomplished. This discussion should occur as early in labor as possible, before the discomfort of late labor distracts the mother. Suctioning can be done manually or with wall suction. Use of wall suction (less than 100

mg/Hg) attached to a meconium aspirator will allow a thorough suctioning. The mouth and posterior pharynx should be suctioned first.

The newborn should then be placed on the resuscitation surface for observation and evaluation. Recommendations about care have recently changed. The international guidelines, adopted by the AAP/AHA [9] recommends no special care for a vigorous newborn. Results of a multicenter international collaborative trial involving 2094 neonates with expectant management led to the same outcomes as aggressive management in vigorous, full-term newborns [12].

In nonvigorous newborns, aggressive care is instituted whenever possible. This includes either intubation and suctioning of the cords with a meconium aspirator attached directly to the ET tube or direct suctioning with wall suction while observing the cords. In a home birth, aggressive management would include direct DeLee suctioning after visualization of the cords by laryngoscope. Most authors agree that intubation and suctioning are warranted in a very depressed newborn. The midwife should discuss with her or his pediatric colleagues the standard of care in the local community and a particular institution.

Care of the Newborn with Possible Diaphragmatic Hernia

A newborn born with an initially vigorous respiratory effort who then quickly decompensates may have a diaphragmatic hernia. Some, but not all, of these infants will present with an abdominal contour that is unusually flat or concave (scaphoid). With a diaphragmatic hernia, part of the abdominal contents is above the diaphragm and in the chest cavity. The degree of the symptoms is related to the severity of the displacement.

There are two problems with this condition. The most serious issue is whether there has been any lung development during the fetal period. If the herniation occurred early and is extensive, there is little lung development. Many of these newborns die, even with aggressive resuscitation and surgery. The second problem occurs as a by-product of the first attempts at resuscitation. As the midwife tries to ventilate these newborns with a bag and mask, the air that is necessarily pushed into the stomach and bowel as a side effect of bag and mask ventilation causes swelling that takes up even more room in the chest. This limits the ability of existing lung tissue to become expanded.

The inability to successfully resuscitate with bag and mask will lead to a decision to intubate. If the midwife suspects this problem, the newborn should be immediately intubated and an orogastric tube should be passed to vent air in the stomach and intestines.

Quality Assurance and Risk Management

The birth of an infant who is sick or damaged is stressful and heartbreaking for all involved. Unfortunately, some newborns will need expensive ongoing medical and supportive care throughout life. This reality, combined with the grieving and anger at having a damaged child, can lead parents to seek redress through the legal system.

Each midwife should accept the challenge of preparing oneself and the birth environment for effective, high-quality, well-documented resuscitation efforts. If the midwife has the proper system in place to provide this type of resuscitation and has been formally trained in techniques of neonatal resuscitation, she or he will know that every possible effort was exerted to ensure the well-being of the newborn.

The midwife should develop a collegial relationship with the local pediatric providers who will be accepting the care of sick newborns. If written midwifery guidelines are required by state law, pediatric providers should be asked to review and comment on them. If written guidelines are not required, the midwife should still consider the merits of such a document, which can delineate clearly the proposed scope of the midwife's involvement with newborns.

If a newborn needs resuscitation, it is critical that an ongoing accurate record of the resuscitation be maintained [13]. This can be done by designated support personnel. A summary note, although also needed, will not adequately reflect the timing and sequence of actions during resuscitation. Figure 38-11 illustrates a brief but comprehensive flow sheet that adequately reflects the sequence of activities during resuscitation.

The midwife should make sure that the roles and responsibilities of the personnel attending a birth are clear. In a birth center or home birth environment, this can be discussed at staff meetings. In a hospital setting, the midwife should explore this issue with the nursing staff during orientation to the facility.

CHAPTER

39

Examination of the Newborn

MARY KATHLEEN MCHUGH, CNM, MSN

Structuring the Newborn Examination

Components of the Newborn Examination

The complete newborn examination is composed of three parts: (1) a newborn history, (2) the gestational age assessment, and (3) the physical examination. From the results the midwife will ascertain the newborn's level of wellness and identify potential or existing problems. A plan of care appropriate for that newborn and family can then be developed. This chapter discusses the components of a complete exam. Chapter 80 provides an extensive guide to the content and findings of the newborn physical exam and should be reviewed in detail by the student midwife.

Appreciation for the role of the newborn history and the gestational age assessment has grown in recent years. With increased knowledge of genetic inheritance, fetal development, and the effect of maternal conditions on fetal well-being, we know that birth is merely a continuation of a life already influenced by many variables. An accurate history of these variables becomes a critical piece in the midwife's full assessment of the newborn.

The development of gestational age assessment procedures in the 1960s revolutionized neonatal care. Prior to the development of these procedures, gestational age was determined by maternal recollection and newborn birth weight. The clinical implications were enormous: Small newborns might be treated as preterm even though they could be suffering from intrauterine growth retardation at advanced gestation. Preterm infants of diabetic mothers might be classed as term and normal because their birth weight was large. With the ability to determine gestational age accurately came the ability to predict risk based on the relationship between gestational age and birth weight.

Approach to the Newborn Examination

The midwife's goal in examination of the newborn is to maximize the amount of information gathered while minimizing upset to the newborn and parents. Parents usually show appropriate concern about any handling or examinations that cause their child to cry. The midwife is well advised to examine the newborn approximately 1 hour after a feeding, when the baby is most likely to be content.

Prior to starting a physical examination and gestational age assessment, the midwife should review the maternal prenatal records, the labor and delivery records, the record of immediate newborn transition, and the interval newborn history.

The examination must be done in an environment that provides proper lighting, cleanliness, and warmth. The midwife should gather the equipment needed for the examination: gestational age and physical exam forms, measuring tapes, stethoscope, and ophthalmoscope. Prior to any physical contact with the newborn, the midwife should perform a 3-minute scrub of hands and forearms with a bactericidal soap.

The midwife should explain to the mother and/or father the goal and purpose of the examination and approximately how long it will take. During the exam or immediately after the midwife can offer feedback to the parents on the strengths and attributes of their newborn and any significant findings. As part of this exchange, the midwife can provide the parents with information and further assess their readiness for parental responsibilities.

The midwife's ultimate goal is the integration of examination and commentary. An experienced midwife can perform a comprehensive newborn examination in the presence of the family and provide appropriate feedback about the newborn's attributes and any significant findings during the examination. However, for the learner, the presence of family members can distract from the learning experience and the performance of a smooth, comprehensive examination that is as brief as possible. You are strongly encouraged to examine the newborn when the mother is preoccupied by self-care activities like showering. With the mother's permission, the newborn can be temporarily taken to the nursery or, in a birth center, to the newborn resuscitation area.

Newborn History

The newborn history is gathered through chart review and interviews with the mother and (if possible) the father of the newborn. As the information is gathered, the midwife develops a mental list of areas of concern, including environmental, genetic, social, maternal medical, perinatal, and neonatal factors.

Environmental and Genetic Factors Environmental factors influencing the newborn can include prenatal exposure at the mother's workplace to hazardous materials such as x-rays, other radiation, solvents, infectious agents, fumes, or gases. In the home environment factors that can cause fetal or neonatal damage or illness include unsafe drinking water, paints or solvents, infections transmitted by house pets, poorly ventilated heaters, excess maternal intake of certain freshwater fish, and living near a hazardous waste site.

The genetic history should include information about any family members, alive or deceased, with physical or mental defects and/or inherited diseases. The midwife should note the names of any family members with unexplained multiple pregnancy losses. The midwife should also note whether the newborn's parents, siblings, and second degree relatives (aunts, uncles) are alive and well.

Social Factors The social history includes information on the mother's place of residence, pattern of prenatal care, and socioeconomic status. The midwife should note how the family supports itself, who lives in the home, and who will be the primary caregiver to the newborn. The midwife should ask the mother to clarify if a current male partner is the father of the newborn or her other children. If the mother is in a lesbian relationship, the midwife should inquire whether the biological father is known to her or her partner and what role (if any) he will take in the child's life. It is important to understand whether the mother's relationship with her current partner is stable or disintegrating because it will affect the mother's ability to focus on her maternal tasks. The midwife should try to ascertain who is the decision-maker in the household (mother, father, partner, grandmother, foster parent) so he or she may be included for certain discussions.

If the mother has other children, the midwife should note whether they live with her and, if not, why not. The midwife should inquire about the health and well-being of the children, paying particular attention to any accident pattern that may indicate abuse or neglect. One key question that may indicate proper attention is whether her children are up to date on their immunizations.

The midwife should make every effort to ascertain any substance abuse by the mother and members of the newborn's household. Newborns and small children exposed to passive smoking have a much higher incidence of respiratory illness. Newborns living in an environment where there is regular substance abuse may be vulnerable to neglect if the mother forgets to care for them or uses up the household money on purchases of drugs or alcohol. The possibility for exposure to violence, direct or secondary, is also increased.

Maternal Medical and Perinatal Factors The midwife should note the maternal age, last menstrual period, and expected date for delivery. The number of prenatal visits is noted along with any prenatal problems. All lab work and prenatal testing, including ultrasound reports, should be reviewed.

There are many maternal medical, prenatal, and intrapartal conditions that can significantly affect the newborn's health and well-being. The midwife must know the sequelae of certain medical and perinatal situations. Table 39-1 lists maternal medical conditions and indicates the possible fetal and newborn implications.

Neonatal Factors Valuable data from the immediate neonatal period include the Apgar scores at 1 and 5 minutes. The midwife should note the type and duration of any resuscitation efforts carried out at birth. Any information that indicates newborn asphyxia is important, as is evidence of hypothermia/hyperthermia and hypoglycemia.

The midwife should review the notes of the nurse or birth assistant regarding vital signs and the newborn's behavior in the time since birth. Positive

TABLE 39-1 Medical and Perinatal Factors and Neonatal Impact

Factors	Possible Implications for the Newborn
Maternal Medical Factors	
Cardiac disease	Chronic intrauterine hypoxia
Diabetes	Large for gestational age; trauma; hyperbilirubinemia; stillbirth
Kidney disease	Prematurity, IUGR
Hypertension	Growth retardation; prematurity; abruptio placentae
Sexually transmitted diseases	Perinatal transmission
Substance abuse	Neonatal withdrawal syndrome
Rh or other isoimmunization	Anemia; jaundice; hydrops fetalis
History of prior pregnancy losses	Genetic syndromes
Prenatal Factors	
No prenatal care	Maternal substance abuse; lack of social supports
Bleeding during pregnancy	Placental defects; placenta previa
Size-dates discrepancy	Growth restriction; large newborn; trauma
Pregnancy-induced hypertension	Growth restriction; prematurity
Gestational diabetes	Macrosomia; birth trauma
Polyhydramnios	Neonatal kidney problems, inability to swallow
Oligohydramnios	Amniotic band defects; dehydration syndromes, neonatal kidney/bladder abnormalities
Infection	Perinatal transmission
Perinatal Factors	
Preterm/postterm labor	RDS; asphyxia
Prolonged labor	Neonatal trauma
Drug use in labor	Neonatal respiratory distress
Fetal distress	Asphyxia
Elevated maternal temperature	Perinatal transmission of infection
Abnormal presentation or position of fetus	Neonatal trauma
Meconium-stained fluid	Meconium aspiration pneumonia
Prolonged rupture of membranes	Perinatal transmission of infection
Excess bleeding in labor	Newborn hypovolemia; hypoxia
Prolapsed cord	Asphyxia
Maternal hypotension	Asphyxia
Fetal acidosis	Newborn acidosis

behaviors include sucking, the ability to feed, alertness, voiding, and passage of meconium. Behaviors of concern include jitteriness, lethargy, poor or absent sucking, and unusual cry.

Any lab tests performed in the birthing room should be noted on the history. Typically these include peripheral glucose samples, hematocrits, or blood gases. The midwife should carefully note the site from which the sample was obtained.

Recording the Newborn History Some institutions have forms for record-keeping involving the newborn. These forms may not allow the collection of the social or environmental information that is integral to midwifery care. The midwife can make use of a blank progress note to record these pertinent areas of the history.

As the midwife begins the examination of the newborn, she or he should recall any areas of concern from the newborn history that may manifest themselves in physical characteristics or deviations.

The Art of Observation Of the four techniques of physical assessment, observation is particularly powerful and useful in newborn assessment. Judicious use of observation minimizes the handling of the newborn—so newborn, parents, and midwife are all less upset. If the newborn is sick, less turning and handling allows the baby to conserve oxygen and glucose.

The experienced examiner begins with a thoughtful, thorough period of observation. The midwifery tenet of "hands off the breech" can be extended here to "hands off the newborn." Key components of both the gestational age assessment and the physical exam can be achieved by observation alone (see Table 39-2).

TABLE 39-2 Information Gathered by Observation

Gestational Age Assessment	Physical Assessment
Skin attributes	Central and peripheral body color
Genital maturation (female)	Muscle tone
Posture	Characteristics of cry
Lanugo	Characteristics of respirations
	Body proportions and formation of visible body parts
	Abdominal contours
	Presence of hair, fingernails, toenails
	Symmetry of eyes; movements of mouth, arms, legs
	Presence of normal external genitalia
	Straight, intact spine

Gestational Age Assessment

Scales for Gestational Age Assessment

Standardized forms of gestational assessment have been in use in this country since the 1960s. They achieved a wide level of use after research published by Dubowitz in 1970 described the Dubowitz exam [1]. The Dubowitz exam combined assessment of both physical and neurological characteristics. In 1979 Ballard published a simplified method for assessing gestational age [2]. The Ballard Scale, based on the work of Dubowitz and others, involves less handling of sick newborns and relies less on a quiet, rested newborn for accurate results. The scale has been revised to accurately assess extremely premature newborns and provide more accuracy with term newborns [3]. It is now known as the New Ballard Scale (NBS).

The NBS (Figure 39-1) can date newborns of gestational ages as low as 20 weeks. Very premature newborns should be assessed soon after birth because of rapid changes in their skin and overall condition. The NBS and other scales are accurate within a range of 2 weeks. The test is standardized and performed most accurately by a trained examiner. Recent studies have found that prior knowledge of the obstetric assessment of gestational age does not bias the examiner performing the NBS [4]. The student midwife should be validated by a preceptor during several gestational age assessments on babies with different gestational ages.

Technical competence in performance of the NBS is critical to an accurate outcome. The proper procedure for the neuromuscular evaluation is as follows:

1. *Posture:* With the infant supine and quiet, score as indicated on Figure 39-1.
2. *Square window:* Flex the hand at the wrist; exert pressure sufficient to get as much flexion as possible.
3. *Arm recoil:* With the infant supine, fully flex the forearm for 5 seconds, then fully extend by pulling the hands, and release.
4. *Popliteal angle:* With the infant supine and the pelvis flat on the examining surface, the leg is flexed on the thigh and the thigh fully flexed using one hand; with the other hand, the leg is then extended.
5. *Scarf sign:* With the infant supine, take the infant's hand and draw it across the neck and as far across the opposite shoulder as possible; assist the elbow by lifting it across the body.
6. *Heel-to-ear maneuver:* With the infant supine, hold the infant's foot with one hand and move it as near to the head as possible without forcing it; keep the pelvis flat on the examining surface.

The proper procedure during assessment of physical maturity includes the following:

1. Check lanugo on the back with a direct light in order to get a clear view.
2. Palpate the entire pinna of the ear for presence of cartilage.
3. Palpate to accurately assess breast tissue.

Because the NBS is a standardized tool, it is important for the midwife to record findings as the assessment is made and not to rely on memory. The NBS takes approximately 2 or 3 minutes to perform and should be recorded directly on the standardized form found in most nurseries. After scores for each category of physical and neuromuscular maturity have been assigned, they are added and the aggregate score is plotted to obtain gestational age.

Application of Gestational Age Assessment

When applied to the maturity rating on the NBS form, the gestational age assessment score yields a gestational age accurate within a range of 2 weeks.

NEUROMUSCULAR MATURITY

	–1	0	1	2	3	4	5
Posture							
Square window (wrist)	 > 90°	 90°	 60°	 45°	 30°	0°

FIGURE 39-1 The New Ballard Scale (NBS).

Source: From Ballard, J. New Ballard Scale, expanded to include extremely premature infants. *J. Pediatr.* 119:417, 1991. Reproduced by permission.

The newborn will then be considered to be in one of the following categories [5]:

1. *Preterm:* gestational age of less than 38 weeks
2. *Term:* gestational age of 38 to 42 weeks
3. *Postterm:* gestational age of more than 42 weeks

It is possible to estimate risk based on gestational age. However, a more sophisticated relationship is that between gestational age and birth weight [6]. Within each of the three categories of gestational age there will be some newborns who are larger and some who are smaller. These patterns of accelerated or diminished growth are associated with certain newborn problems and predispositions.

In order to establish the birth weight/gestational age relationship, the midwife must have ac-

cess to both an accurate birth weight and an accurate gestational age. It is important to note that birth weights vary in accord with altitude, race, country of origin, and socioeconomic class. Thus there is no international standard of birth weight.

The older charts that graphed weight in relation to gestational age are limited because they determined gestational age based on the menstrual history alone. More recent studies have studied birth weight in comparison to a gestational age assigned by Ballard scores and ultrasound [7]. It is important that the midwife use a table that contains anthropomorphic data appropriate to her or his region.

Having charted birth weight in relation to gestational age, the midwife will now characterize the newborn as being in one of three categories:

1. Small for gestational age (SGA)
2. Appropriate for gestational age (AGA)
3. Large for gestational age (LGA)

Combining the gestational age categories (preterm, term, and postterm) with the weight/gestational age categories, the midwife can then classify the newborn as being in one of the following nine categories:

1. Preterm, small for gestational age
2. Preterm, average for gestational age
3. Preterm, large for gestational age
4. Term, small for gestational age
5. Term, average for gestational age
6. Term, large for gestational age
7. Postterm, small for gestational age
8. Postterm, average for gestational age
9. Postterm, large for gestational age

After accurately categorizing the newborn, the midwife can develop a plan for potential problems related to that newborn's birth weight and gestational age. The work done by Lubchenco in the 1960s (see Figure 39-2) expanded our horizons to include this type of newborn management [5, 6]. The midwife can expect that the term AGA newborn will experience the fewest neonatal problems. The immediate care of postterm, SGA, and LGA newborns is discussed in Chapter 41.

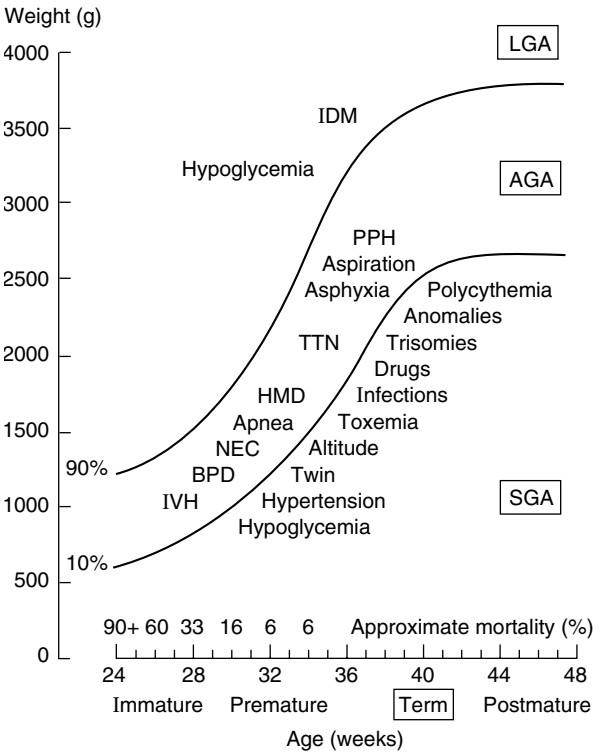

FIGURE 39-2 Conditions associated with birth weight/gestational age categories. Specific clinical conditions frequently encountered in the three major developmental channels: (1) large for gestational age (*LGA*); (2) appropriate for gestational age (*AGA*); (3) small for gestational age (*SGA*). Expected approximate overall mortality is indicated on the abscissa.
IDM, Infant of a diabetic mother; *IVH*, intraventricular hemorrhage; *BPD*, bronchopulmonary dysplasia; *NEC*, necrotizing enterocolitis; *HMD*, hyaline membrane disease; *TTN*, transient tachypnea of the newborn; *PPH*, persistent pulmonary hypertension or persistent fetal circulation.

Physical Examination of the Newborn

Basic Approach to the Exam

During examination of the newborn, the midwife will utilize the four basic techniques of physical examination: (1) inspection, (2) palpation, (3) auscultation, and (4) percussion. The value of observation has been discussed above. The complete examination will involve three types of evaluation: (1) anthropomorphic measurements, (2) evaluation of organ systems, and (3) neurological evaluation.

The physical exam of the newborn is designed to screen for physical variations and malformations and the overall state of health of the newborn. There are many differences between components of an adult physical examination and that of a newborn. There are also many minor newborn physical and behavioral variations that are within normal. Chapter 80 includes an extensive guide to the content and findings of the newborn exam and discusses variations (both minor and serious).

Learning how to conduct a newborn exam is somewhat like learning a foreign language. There are many unique terms and names, and many eponyms used in deference to the person who first described the finding. It is advisable to start with a medical dictionary. If a midwife is unfamiliar with the characteristics of normal newborns, extra observational experiences should be arranged. When writing notes, the midwife should properly name any variations present and avoid use of the nondescript phrase "within normal."

Most textbooks and physical examination records assume an exam that proceeds from head to toe. The midwife should feel free to modify this progression. If the newborn is quiet or sleeping, many examiners start their hands-on exam with auscultation of heart and bowel sounds and palpation of the femoral pulses. In an awake alert newborn, the examiner may check the red reflex first. A crying newborn presents the opportunity for inspection of the mouth and throat. The midwife should curb any nervous impulses that lead to excessive handling and thus overstimulation of the newborn. This is a common mistake, similar to the excessive touching by an inexperienced midwife performing a cervical exam. Many times the newborn can be calmed during an exam by being given a pacifier or finger to suck on.

Anthropomorphic Measurements

The midwife may be responsible for measuring the infant's length and chest and head circumference. The newborn body has a unique appearance. Normally, the head circumference is larger than the chest circumference, the abdomen is protuberant, and the tone is flexed (Figure 39-3). Measurements must be done in a standardized fashion. The newborn length is most accurately assessed if the head of the newborn is flush against a firm surface. The legs can then be extended and a mark made on the examining table paper. After the newborn is moved, the midwife can then measure the distance in centimeters.

The newborn head circumference is measured from the occiput around the head just above the eyebrows. This measurement may change in the first week of life as swelling from birth recedes (see Figure 39-4). Chest circumference is measured under the armpits and across the nipple line. The baby's weight should be assessed on a scale with a drape between the newborn and the metal. The scale should be calibrated to account for the weight of the drape. This prevents heat loss and infection from cross-contamination.

FIGURE 39-3 Normal newborn body proportions.

FIGURE 39-4 Swelling of newborn head caused by cephalohemotoma.

Table 39-3 lists mean birth weights, lengths, and head circumferences of term newborns (38–42 weeks) born in the United States. Dombrowski et al. established the means by studying 38,818 live infants (born between 1984 and 1991) whose gestational age was determined by obstetrical age and confirmed by ultrasound [7].

Assessment for Birth Defects and Genetic Disease

The midwife who examines a newborn is in a unique position to note physical variations that may be indicative of more serious underlying problems. Although no caregiver wishes to bear bad news to parents, the midwife must make sure to let parents know about any potential problems and to refer them to a physician for more extensive evaluation.

Many parents believe that a normal prenatal test provides assurance that their fetus is normal.

TABLE 39-3 Mean Birth Weights, Lengths, and Head Circumferences of Term Newborns

Gestational Age (weeks)	Weight (g)	Length (cm)	Head Circumference (cm)
38	3050	48.3	33.6
39	3225	49.0	34.0
40	3364	49.5	34.3
41	3501	50.2	34.7
42	3598	50.5	34.9

Source: Adapted from Dombrowski, M., Wolfe, H., Brans, Y., Saleh, A., and Sokol, R. Neonatal morphometry: relation to obstetric, pediatric and menstrual estimates of gestational age. *Am. J. Dis. Children* 146:852 (July) 1992. Reprinted by permission.

Unfortunately, all prenatal tests have limitations. Our ability to diagnose genetic disease prenatally remains limited to a few major chromosomal disorders. Ultrasound is valuable for major physical defects but is limited in its ability to reveal cardiac and musculoskeletal defects [8].

Variations in physical appearance may be due to inconsequential human variation or familial traits. However, the midwife should remember that many genetic disorders can be diagnosed based on the newborn's physical appearance. Approximately 3 to 4 percent of live births involve some congenital defect—some serious, some minor. The presence of three minor malformations is suggestive of a major underlying malformation [9]. Among the common minor malformations are the following:

- Large fontanel
- Epicanthal folds
- Hair whorls
- Widow's peak
- Low posterior hair line
- Preauricular tags and pits
- Minor ear anomalies: protruding, rotated, lowset
- Darwinian tubercle
- Digital anomalies: clinodactyly (curved finger); camptodactyly (bent finger); syndactyly (webbed finger)
- Transverse palmar crease
- Shawl scrotum
- Redundant umbilicus
- Widespread nipples
- Supernumerary nipples

Early evaluation and intervention can help prevent serious sequelae of malformations, such as infection, intestinal perforation, spinal cord injury, or retardation. Table 39-4 provides a list of visual clues that the midwife may note during physical examination and the serious conditions that they may indicate.

Newborns presenting with ambiguous genitalia are a particular challenge. These newborns present with external genital characteristics of both males and females. A midwife who examines a newborn and has doubts about the genitalia should consult with a neonatal team immediately. In some instances this finding is associated with congenital adrenal hyperplasia, a condition that will cause life-threatening dehydration shortly after birth. Families should be informed of the examiner's concern and should be encouraged not to assign a sex to the newborn.

Proper assessment of an infant with physical variations should be performed by a specialized team that includes a neonatologist, a geneticist, an endocrinologist, and a primary nurse. Unfortunately it may take weeks before genetic karyotypes are complete. Extensive additional testing will be necessary to evaluate the type and extent of the malformation.

The midwife's role is to support the anxious and grieving family. It is helpful if one or two midwives from a large practice accept the responsibility for staying in touch with the family during this time of testing and waiting.

The Neurological Examination

The procedure of assessing reflexes, cranial nerves, and special senses is integrated into the overall physical examination outlined in Chapter 80. However, it is important to reflect on the neurological exam as an indicator of the integrity of the nervous system. Both diminished (hypo) and accentuated (hyper) responses are cause for concern. Diminished response can result from a congenital absence of a nerve or damage to sensory or motor pathways. Diminished or accentuated response to stimulation can also reflect a central neurological deficit.

During the neurological exam, the midwife will be making assessments of the newborn's senses. Sight, hearing, and smell can all be evaluated in a newborn. Poor or absent response to stimulation may indicate damage to the nerve itself (optic, auditory, or olfactory).

An absent or diminished response to an elicited reflex may mean a variety of things. Sometimes the reflex is partial or diminished because of newborn

TABLE 39-4 Visual Clues That Suggest Birth Defects and Genetic Conditions

Diagnosis	Visual Clues
Mendelian Inheritance	
1. Autosomal Dominant (AD)	
Neurofibromatosis I	Cafe au lait spots
Tuberous sclerosis	Ash leaf spot
Myotonic dystrophy	Myopathic facies
Multiple epiphyseal dysplasia	Bumps at end of long bones
Waardenburg syndrome	White forelock
Peutz-Jehger syndrome	Brown lip macules
Van der Woude syndrome	Lip pits
Holt-Oram syndrome	Thumb anomaly
2. Autosomal Recessive (AR)	
Tay-Sachs disease	Cherry red spot
Galactosemia	Cataracts and neonatal jaundice
Cystic fibrosis	Meconium ileus, rectal prolapse
Congenital adrenal hyperplasia	Ambiguous genitalia
Mucopolysaccharidoses	Corneal clouding, joint contracture
Meckel-Gruber syndrome	Polydactyly, encephalocele
Rhizomelia chondrodysplasia	Short proximal limbs, cataracts
3. X-Linked Recessive (X-LR)	
Fragile-X syndrome	Large testes
Duchenne muscular dystrophy	Large calf muscle
Menke Kinky Hair syndrome	Steel-wool like hair
Usher syndrome	Retinitis pigmentosa
Lesch-Nyhan syndrome	Gravel urine, self-mutilation
4. X-Linked Dominant (X-LD)	
Incontinentia pigmenti	Pigmented skin swirls
Rett syndrome	Hand wringing
Vitamin D resistant ricketts	Bowed legs
Non-Mendelian Inheritance	
1. Mitochondrial	All associated with muscle weakness, ophthalmoplegia, and recurrent episodes of acidosis
Kearns-Sayre	
Lebers disease	
MELAS	
MERRF	
2. Uniparental Disomy	
Prader-Willi	Obesity, small hands and feet
Angelman	MR, recurrent bouts of laughter
3. Gonadal Mosaicism	
Osteogenesis Imperfecta	Blue sclera, brittle bones
Teratogen	
Alcohol	Microcephaly, short palpebral fissures
Dilantin	Nail hypoplasia
Hyperpyrexia	Neural tube defects (NTD)
Tegretol	NTD
Coumadin	Flat nasal bridge
Accutane	Facial and limb anomalies

TABLE 39-4 Visual Clues That Suggest Birth Defects and Genetic Conditions (*continued*)

Diagnosis	Visual Clues
Multifactorial	
Clubfoot	Same as diagnosis in each case
Cleft lip/palate (CLP)	
NTD	
Dislocated hip	
Congenital heart	
Hypospadies	
Chromosomal	
Trisomy 21	Hypotonia, single palmar crease, prominent tongue
Trisomy 18	Finger and joint contracture,webbed neck
Trisomy 13	Polydactyly, CLP, scalp defects
45 XO	Short stature, webbed neck
Klinefelter	Small testes, gynecomastia
Cat-cry 5p(–)	Natal mewing
Sporadic Multiple Pattern Syndrome	
Cornelia de Lange	Synophrys, phocomelia
Rubinstein-Taby	Large thumbs and great toes
Williams syndrome	Elfin facies
Sturge-Weber	Nevus flammeus
VATER ASSN	TE-fistula
Congenital Defects Minor and Major Malformations	
Preauricular tags and sinus tracts	Deafness and renal disease
Nasal dermoids	Nasal sinus tract to septum and to brain in some cases
Lip pits	Cleft lip and palate
Bifid uvula	Submucous cleft
Enlarged tongue	Hypothyroidism
Two-vessel cord	Renal disease
Lumbar hair tuft	Spinal cord lesions

depression secondary to medications. The response may not be optimal because the sensory pathway conducting the stimulation has been damaged, reflecting a spinal or central nervous system lesion. Sometimes a reflex cannot be elicited because of temporary motor nerve damage that prevents the muscles in the affected area to respond to a stimulation, as with a weak palmar grasp after a breech delivery or facial nerve paralysis after a forceps delivery (see Figure 39-5). Sometimes damage is permanent, as in some brachial plexus injuries and some spinal cord defects.

The midwife's role involves the elicitation of the following reflexes as part of the physical exam:

1. *Eyes:* Pupillary reflex, red reflex, doll's eye reflex, blink reflex
2. *Upper extremities:* Palmar grasp reflex

FIGURE 39-5 Facial nerve paralysis.

3. *Lower extremities:* Patellar reflex, plantar reflex, Babinski reflex
4. *Torso:* Anal wink, tonic neck reflex

Elicitation of these reflexes (see Figures 39-6 and 39-7) is described in Chapter 80. Absent, markedly diminished, or accentuated reflexes should be noted on the physical exam form; asymmetrical reflexes should also be noted. The midwife should then consult with a pediatric provider about further testing and follow-up.

The most commonly used evaluation of the neurological status of the newborn is the Moro reflex, or embracing reflex. In normal infants the response is symmetrical and disappears by 2 to 4 months. The Moro reflex consists predominantly of abduction and extension of the arms with hands open and the thumb and index finger semiflexed to form a C. Leg movements may occur, but they are not as uniform as the arm movements. With return of the arms toward the body, the infant either relaxes or cries.

FIGURE 39-6 Plantar reflex.

FIGURE 39-7 Babinski reflex.

The midwife must take care to elicit a Moro reflex and avoid "startles." Acceptable ways to elicit a Moro reflex include the following:

1. Striking the examining table near the head of the baby
2. Allowing a semi-sitting infant to fall backward (onto the examiner's open hand) from an angle of 30 degrees
3. Jarring the table suddenly
4. Making a loud noise or handclap

Medical consultation is required if any of the following deviations is found with the Moro reflex test:

1. Absence of the reflex indicates possible intracranial lesions.
2. Asymmetrical response may indicate birth injury involving the brachial plexus, clavicle, or humerus.
3. Abnormal persistence of embrace gesture indicates hypertonicity.
4. Persistence of entire Moro reflex after 4 months indicates delay in neurological maturation.

Becoming Confident at Newborn Physical Examination

If you have little experience with the appearance and physical characteristics of newborns, it is important to increase your base of knowledge by observing as many newborns as possible and studying reference books that contain color pictures of newborn deviations [10, 11]. Observing other experienced caregivers, in person or on videotape, will help you develop that intuitive, confident recognition of normal that is the basis of midwifery practice.

CHAPTER

40

Primary Care of the Newborn: The First Six Weeks

MARY KATHLEEN MCHUGH, CNM, MSN

The Midwife's Role in Neonatal Well-Child Care

The role of the midwife during the newborn's first month of life varies markedly. In some locales, the midwife has little formal role once the newborn leaves the birthing room. In other practices, usually multidisciplinary ones, the midwife will continue care of the mother and newborn throughout the first 6 weeks after birth. These midwives work in a collegial relationship with pediatric providers and the well-child care gradually shifts to pediatric or family health care providers.

The American College of Nurse-Midwives expects nurse-midwives to be competent in the care of the well neonate. The *Core Competencies for Basic Nurse-Midwifery Practice*, revised in 2002, states that the nurse-midwife "independently manages the care of the newborn during the first 28 days of life" [1, sec. 6.2]. Regardless of the formal expectation regarding the role of the midwife, the reality is that many parents will call the midwife with questions related to the care and well-being of their newborn. The midwife, conscious of the exquisite connection between mother and child, promotes family well-being by her involvement in care and advice to both the mother and new child.

Well-Child Surveillance: The First Four Weeks

All newborns should have at least two physical examinations before being discharged from the birth center or hospital or before the midwife leaves the home after a home birth. The first exam is a screening exam that is conducted at birth, as discussed in Chapter 37. The second, more comprehensive, exam includes the gestational age assessment, as discussed in Chapter 39. If a newborn is discharged after a short stay (6 to 12 hours), most pediatric providers prefer to see the newborn again on the third to fifth day after birth. If the child was in-hospital for 48 hours, the first visit can be delayed until the baby is 10 to 14 days old. The purpose of this visit is to reexamine the newborn and to review teaching and anticipatory guidance with parents.

If metabolic screening was not done prior to the infant's discharge from the birth center or hospital, it should be done on this visit. All states currently require screening for congenital hypothyroidism and phenylketonuria (PKU). Some states require screening for other metabolic diseases [2]. It is the midwife's responsibility to understand the screening requirements of the state in which she or he practices and to be prepared to take a proper blood specimen, usually from the heel. There are many incorrect techniques; most faulty samples either under- or over-sample the blood. The midwife should carefully read the instructions regarding the technique that will optimize results. The test for PKU is accurate after an infant has had at least 48 hours of feedings; until then the damaging phenylalanine has not accumulated. Therefore, drawing these tests before an early discharge, although sometimes required by law, is inadequate. A second test should be scheduled.

The purpose of a well-child visit is threefold: (1) to identify symptoms of disease; (2) to offer screening measures; and (3) to educate and support parents [3]. When a parent brings a newborn in for a well-child visit, every effort should be made to keep the child from exposure to sick children in the waiting area. Whenever possible, the mother and father should be escorted into an exam room as soon as they arrive with their child. Sometimes the well-child visit is combined with the mother's postpartum visit. The midwife should have a plan for the initial well-child visit, which should include the following:

1. Review maternal history, birth history, immediate neonatal course.
2. Observe parents and interview regarding family adjustment.
3. Take a newborn interval history: feeding, alertness, and crying, as well as bowel, bladder, and other problems.
4. Measure weight, length, and head circumference.
5. Perform physical exam.
6. Review need for metabolic screening.
7. Provide teaching and anticipatory guidance.
8. Schedule visit in 6 to 8 weeks for further immunization and checkup.
9. Review how to reach the pediatric provider for emergencies.

The visit starts with a brief interview of the mother or father. Particular attention should be paid to unresolved issues related to the labor and delivery experience or the immediate care of the baby following birth. Parents need to be able to discuss any memories or misinterpretations they may have of that time period.

The midwife should assess the well-being of the mother and father and look for signs of depression or inability to cope with the demands of the new baby. Inquiries should be made about help in the home, sibling reaction to the new baby, and reaction of other relatives to the newborn.

Questioning should move on to the behavior and characteristics of the newborn. Particular emphasis should be paid to feeding patterns, levels of alertness, bowel and bladder patterns, and crying patterns. The midwife should ask, "Do you have any worries or concerns about the baby?" in order to elicit unspoken fears.

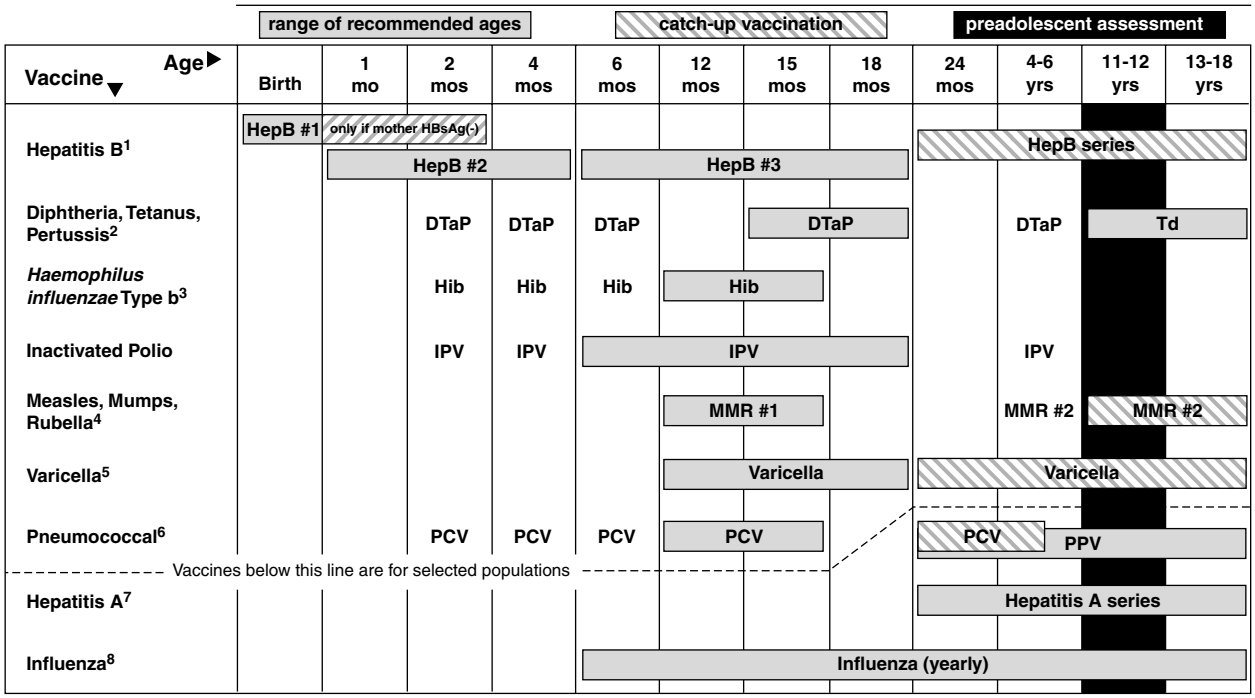
Next the midwife conducts a complete physical exam and checks the baby's reflexes. The physical exam should include a weight check and measurement of length and head circumference. Head circumference may measure slightly less than at birth if the newborn's head was swollen at delivery. During the physical exam, the midwife is looking for evidence that the newborn is hydrated and well cared for. Particular attention should be paid to level of alertness, the heart sounds, and the abduction of the hips. Many metabolic diseases present a number of days after birth, with symptoms of hypotonia or irritability, and feeding problems.

During the physical exam the midwife has an ideal chance to observe for signs of parental attachment to the newborn. This will be evidenced by the parents' use of the newborn's name and by appropriate efforts to protect and comfort the newborn. The midwife has a chance to observe whether the parents are at ease in handling the newborn. If there is an opportunity to observe a feeding, this can be particularly valuable.

The greatest part of the initial well-child visit should be spent soliciting parental concerns and offering guidance and anticipatory advice. As with all teaching, the midwife must ascertain whether the parent is able to pay attention and really hear the guidance. Parents distracted by fatigue or worried about an emergent problem may hear and retain only certain pieces of information. Written instructions can be provided to the parent on common newborn issues.

The second well-child visit usually takes place when the baby is between 6 and 8 weeks old. Parents can be told to expect that the immunization series (which began with the first hepatitis B immunization immediately after birth) will continue then [4]. Standard immunization recommendations are noted in Figure 40-1. Weight and measurement are measured again and another physical examination is conducted.

Any midwife providing well-child care should have an explicit agreement with a pediatric provider for consultation and/or referral of any newborn presenting with signs of illness or disorders. This relationship should be clear to all concerned—the parents, the midwife, and the pediatric caregivers. Depending on state law, the midwife may need to state this relationship formally, in writing.



This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2002, for children through age 18 years. Any dose not given at the recommended age should be given at any subsequent visit when indicated and feasible. ▨ Indicates age groups that warrant special effort to administer those vaccines not previously given. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations.

1. Hepatitis B vaccine (HepB). All infants should receive the first dose of hepatitis B vaccine soon after birth and before hospital discharge; the first dose may also be given by age 2 months if the infant's mother is HBsAg-negative. Only monovalent HepB can be used for the birth dose. Monovalent or combination vaccine containing HepB may be used to complete the series. Four doses of vaccine may be administered when a birth dose is given. The second dose should be given at least 4 weeks after the first dose, except for combination vaccines which cannot be administered before age 6 weeks. The third dose should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 6 months.

Infants born to HBsAg-positive mothers should receive HepB and 0.5 mL Hepatitis B Immune Globulin (HBIG) within 12 hours of birth at separate sites. The second dose is recommended at age 1–2 months. The last dose in the vaccination series should not be administered before age 6 months. These infants should be tested for HBsAg and anti-HBs at 9-15 months of age.

Infants born to mothers whose HBsAg status is unknown should receive the first dose of the HepB series within 12 hours of birth. Maternal blood should be drawn as soon as possible to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). The second dose is recommended at age 1–2 months. The last dose in the vaccination series should not be administered before age 6 months.

2. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose and the child is unlikely to return at age 15–18 months. **Tetanus and diphtheria toxoids (Td)** are recommended at age 11–12 years if at least 5 years have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 years.

3. *Haemophilus influenzae* type b (Hib) conjugate vaccine. Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB® or ComVax® [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4, or 6 months, but can be used as boosters following any Hib vaccine.

4. Measles, mumps, and rubella vaccine (MMR). The second dose of MMR is recommended routinely at age 4–6 years but may be administered during any visit, provided at least 4 weeks have elapsed since the first dose and that both doses are administered beginning at or after age 12 months. Those who have not previously received the second dose should complete the schedule by the 11–12-year-old visit.

5. Varicella vaccine. Varicella vaccine is recommended at any visit at or after age 12 months for susceptible children, i.e., those who lack a reliable history of chickenpox. Susceptible persons aged ≥13 years should receive two doses, given at least 4 weeks apart.

6. Pneumococcal vaccine. The heptavalent **pneumococcal conjugate vaccine (PCV)** is recommended for all children age 2–23 months. It is also recommended for certain children age 24–59 months. **Pneumococcal polysaccharide vaccine (PPV)** is recommended in addition to PCV for certain high-risk groups. See *MMWR* 2000;49(RR-9);1-38.

7. Hepatitis A vaccine. Hepatitis A vaccine is recommended for children and adolescents in selected states and regions, and for certain high-risk groups; consult your local public health authority. Children and adolescents in these states, regions, and high risk groups who have not been immunized against hepatitis A can begin the hepatitis A vaccination series during any visit. The two doses in the series should be administered at least 6 months apart. See *MMWR* 1999;48(RR-12);1-37.

8. Influenza vaccine. Influenza vaccine is recommended annually for children age ≥6 months with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV, diabetes, and household members of persons in groups at high risk; see *MMWR* 2002;51(RR-3);1-31), and can be administered to all others wishing to obtain immunity. In addition, healthy children age 6–23 months are encouraged to receive influenza vaccine if feasible because children in this age group are at substantially increased risk for influenza-related hospitalizations. Children aged ″12 years should receive vaccine in a dosage appropriate for their age (0.25 mL if age 6–35 months or 0.5 mL if aged ≥3 years). Children aged ″8 years who are receiving influenza vaccine for the first time should receive two doses separated by at least 4 weeks.

For additional information about vaccines, including precautions and contraindications for immunization and vaccine shortages, please visit the National Immunization Program Web site at www.cdc.gov/nip or call the National Immunization Information Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Approved by the Advisory Committee on Immunization Practices (www.cdc.gov/nip/acip), the American Academy of Pediatrics (www.aap.org), and the American Academy of Family Physicians (www.aafp.org).

Newborn Behavior

Parents of newborns are particularly interested in the behavior and sensory capabilities of their children. The midwife can help the parents be realistic in their expectations during the first few weeks of life. Parents with exaggerated views of newborn abilities may become more easily frustrated.

Newborn infants are in a period of behavioral instability. By the time parents figure out a pattern of newborn behavior, the pattern will have changed. A good rule of thumb for the first month of life is, "There is no pattern."

Sleep-Wake States

Newborns have two major categories of behavior: periods of waking and periods of sleeping. Although many researchers have further characterized these two categories, Brazelton developed the most common classification scheme, noting six behavioral states of the newborn [5]. The waking states include crying, considerable motor activity, alert, and drowsy. The sleep states include active (light) sleep and deep sleep.

Knowledge of infant behavioral states is helpful to both midwife and parent. The newborn's abilities to feed and connect visually with the environment are most pronounced in the alert state. This is also the optimal time to check for some reflexes. However, term newborns spend only approximately 15 percent of their daytime hours in the alert state.

The crying state is the most perturbing to parents. Parents of a newborn have not yet learned to decode the cries of their newborn. Midwives can help parents try to gauge whether the cry expresses a need to be fed, to be held, to be stimulated, to suck, or to sleep. Crying is inevitable, but prolonged and frequent crying has physiological sequelae that include increased heart rate and blood pressure, oxygen depletion, aerophagia, and increased cortisol levels [6]. The experienced midwife realizes that some of these physiological parameters also change in the stressed caregiver of the crying infant. Occasionally, crying expresses pain [7]. A newborn who cries excessively may cause a negative interaction with caregivers and can be the source of family conflict. Many parents are focused on not spoiling even very young infants. A discussion of the child's primal needs may give parents the permission they need to spend time calming their newborn.

The two types of sleep appear very different to the observer. In active (light) sleep the newborn may exhibit varying depths and rates of respiration. The variation can concern parents. Motor movements are frequent and the infant can startle while sleeping. In deep sleep the infant has few motor movements. Respirations are deep and regular and the infant appears peaceful.

During the first month of life the percentage of time spent in each of these states changes. Healthy newborns spend up to 60 percent of their time sleeping. However, much of this sleeping is in short naps. As the first month of life progresses, infants shift away from active (light) sleep and toward more deep sleep. Similarly, there is a shift in the waking states toward an increase in alertness. Infants who are crying begin to be able to remain alert to the environment while crying.

Newborn Reflexes

The newborn has two categories of reflexes: proprioceptive and exteroceptive. The exteroceptive reflexes are best evoked when the baby is quiet and alert, since they are stimulated by light touch. They include the rooting, grasping, plantar, and superficial abdominal reflexes. The proprioceptive reflexes include gross motor reflexes such as the Moro reflex. This can be checked at any time. Complete absence of any of these reflexes is a cause for alarm. However, there are frequent instances of an incomplete elicitation of a reflex. This condition can be caused by neurological depression secondary to medication. The loss of a previously strong reflex in the first month of life is a cause for alarm and should be reported to a pediatric provider.

Parents can be involved in a discussion of the self-protecting nature of some reflexes. As they gain an appreciation of a newborn's innate ability to root, suck, latch on to or withdraw from stimuli, and are shown evidence of prewalking behavior, they will come to appreciate their newborn as a competent person.

Sensory Capabilities

Research during the last 30 years has shown that the newborn's ability to use the five senses is more highly developed than previously suspected [8]. Sensory capabilities are strongly related to gestational age. There are dramatic increases in the sensory stimulation just after birth that can lead to neonatal exhaustion, exhibited in fussiness or aversion. The midwife should teach the parents how to "read" the neurobehavioral clues of the newborn (see Table 40-1).

TABLE 40-1 Infant Neurobehavioral Cues

Distress/ Disengagement Cues	Stability/ Engagement Cues
Bradycardia, apnea	Facial gaze
Rapid heart or respiration rate	Smiling
Grunting	Vocalization
Stooling	Feeding posture
Mottled skin	Flexion of arms and legs
Dusky color	Eyes alert
Cyanosis	Stable heart rate
Tremor	Stable respiratory rate
Finger splay	Smooth movements
Fingers interlaced	Hand to mouth
Arching	Finger folding
Hyperalert face	Smooth state transitions
Facial grimace	Sucking and mouthing
Limb extension	Consolable
Gaze aversion	"Ooh" face
Eyes closed	Alert
Slack jaw	Eye-to-eye contact
Open mouth	Grasping
Tongue thrusting	
Sighing	
Regurgitation	
Jittery	
Flaccid	
Vomiting	
Hand to ear	
Worried face	
Rapid state change	
Eyes floating	
Staring	
Hyperextension	
Glassy eyed	
Tongue protrusion	
Flushed	
Hiccough	
Startle	
Yawn	
Flaccidity	
Sneezing

At term the newborn shows an ability to fix on and track objects visually. Many studies have shown a strong newborn preference for patterns of stripes. During the first month of life, newborns become preferentially interested in patterns with contours that resemble the human face. The ability to see in color is limited at first, so newborns prefer black and white patterns or strong colors like red. Newborns in the alert behavioral state will spend some minutes staring at patterns. Within the first two weeks, newborns also show an ability to mimic human facial expressions.

The newborn has the ability to discriminate among distinctive odors. A newborn can discriminate the odor of its mother's breast pad from the odors of the breast pads of other nursing women. Newborns react strongly to variations in taste and show a strong preference for sweet liquids. They suck longer and with an increase in heart rate when presented with a sweet liquid in a bottle.

Newborns have acute hearing and are able to localize sound in the environment. They can discriminate finely among sounds and show a preference both for real voices as opposed to synthesized voices and for the mother's voice. By the end of one month, newborns prefer sound with a pattern similar to speech.

Prior to birth, the fetus experienced touch in the shifting of the amniotic fluid. At birth the newborn is dry for the first time and is subject to many and varied forms of touch. The ability of the newborn to respond to touch is well demonstrated with the elicitation of the various exteroceptive reflexes such as rooting, grasping, abdominal reflexes, and spinal curving.

Regulation of Behavior

Each infant shows a unique ability to react to stimulation presented by the environment and its own bodily functions. Infants vary in their ability to cope with these stimuli. Within a short period of time parents and caregivers characterize newborns as "quiet" or "active," terms related to characteristics of behavior described by Brazelton [5]. The newborn learns best in the alert state. Therefore, the ability of the newborn to regulate itself so as to spend more time in the alert state is critical. At times, parental intervention in the form of rousing the baby or decreasing environmental stimuli may be essential if the newborn is to achieve the alert state.

On occasion a midwife may recommend to parents that their newborn be given the full Brazelton Neonatal Behavioral Assessment Scale (NBAS). This is especially indicated if the midwife is aware that the parents are having trouble coping with a newborn. This test is standardized and can only be reliably given by a trained examiner. However, every midwife should learn the components tested on the scale. The NBAS starts with the newborn in a sleeping state. Both behavioral and neurological

responses (reflexes) are tested. Repeated stimulations are offered and the examiner observes how the newborn adjusts to the stimuli. The behavioral parts of the NBAS assesses the infant's ability to do the following tasks:

1. Organize behavioral states.
2. Decrease motor activity to cope with sensory input.
3. Become alert and oriented to auditory and visual stimuli.
4. Interact with a caregiver through cuddling.
5. Able to console self.
6. Habituate to repeated stimulation.

The abilities to quiet down and focus, to smile and cuddle with a caregiver, and to ignore extraneous stimulation are key to coping in the world. Midwives can utilize the results of an NBAS to work with parents who need to understand the unique features of their child. Testing that indicates the newborn has trouble calming, cuddling, or habituating to stimuli should be discussed with parents, with emphasis on the parents' support of their newborn's special needs.

Developmental Milestones in the First Six Weeks

Term infants should reach certain developmental milestones during the first 6 weeks of life. Of the various methods of developmental screening available, only the Denver II is accurate in early infancy. The Denver II, a revision and restandardization of the Denver Developmental Screening Test, is based on more testing on various ethnic groups and population mixes. (The Denver II materials are available from DDM, Inc., PO Box 371075, Denver, CO, 80237-5075.)

Within the first 2 months of life, term newborns should progress in all four areas tested on the Denver II. Personal-social skills should include spontaneous and responsive smiling and attentiveness to a face. Some infants will attend to their own hands. Fine motor movements will include visual following to midline and progress toward visual following past midline. In the language area infants will vocalize spontaneously and respond to a bell. Gross motor capabilities include symmetrical movements and lifting the head, occasionally to 45 degrees. Knowledge of these normal developmental milestones should shape the advice a midwife gives to new parents.

The Denver II is a growth chart of development, not a test that a child passes or fails. Findings of any significant developmental difference need to be weighed against other information such as previous developmental patterns and the degree of delay [9].

Psychological Tasks of Early Infancy

During the first months after birth, a profound psychodynamic develops between the young infant and the principal caregiver (usually the mother). The infant is performing the psychological task of differentiation: seeing himself or herself as a separate being in relation to other beings. Human infancy and childhood, unlike that of other species, is lengthy and full of dependence. Young infants must be able to trigger their caregivers to feed, clothe, and shelter them—otherwise they will die. They trigger these protective reactions in adult humans by their sweet, curved physical appearance, their cuddliness, their cries, and their social smiles. A growing body of research implicates the maternal hormone oxytocin in the initiation and maintenance of human attachment behaviors [10, 11]. The brain is a target organ for oxytocin activity, known to contain oxytocin receptors. In animal research, nonpregnant animals given oxytocin suddenly initiate maternal behaviors including grooming, feeding, building nests, and defense of young animals [11].

As the first few months of life progress, the infant and mother form a psychological attachment to each other. First described by Ainsworth and Bowlby in the 1950s, attachment theory has profoundly shaped our knowledge of healthy caregiver-child interaction. Ideally the baby develops secure attachment, fostered by predictability on the part of the mother who responds to and accurately interprets the cues of the baby. The psychological dance of the mother-infant pair is a significant determinant of well-being later in childhood and establishes patterns that can influence attachments throughout life [12]. Infant attachment is best facilitated by caregiver sensitivity, which can be defined as (1) emotional availability, (2) sensitive responses and appropriate stimulation, and (3) consistency over time.

Infants who form a secure attachment with the mother consider the mother as a secure base from which it is safe to foray into the greater world (see Figure 40-2). In the first year of life, secure infants

FIGURE 40-2 Mother as secure base: Susan, Riley Clay, and Shelby Elizabeth (in utero).
Source: Photo ©1982 Gabrielle Beasley; used with permission.

will venture out, crawling or toddling in a strange environment. They return often to the mother, usually for a quick nursing, a pat, or a cuddle. The mother is a safe harbor, predictable in her availability and response.

Mothers and infants who do not form a secure attachment do form other types of attachment. Researchers have characterized two types: insecure attachment and avoidant attachment [13, 14]. In both, the key determinants are the inability of the mother to interpret infant cues successfully and to respond in a predictable way. Infants showing evidence of insecure attachment are anxious and cope poorly with changes or distance from the mother. Their behavior may show extremes of fussiness or other attention-getting behaviors. These infants seem to feel that mother's attention is best gained by a negative display. The mother may be distracted, tired, or too young to know how to play well with an infant. She will, however, respond to screaming or other negative displays. Reinforcement, even negative attention, is enough to encourage the infant.

Infants showing evidence of avoidant attachment seem detached from the mother—as though her lack of predictable response had caused them to shut down emotionally. Babies born to women with significant mental illness or substance abusers may show evidence of avoidant attachment. The effects of the substance abuse can change the mother's personality unpredictably. One day the mother may be tense, one day stuporous, one day nervous from drug withdrawal. The infant receives inconsistent messages that cause emotional shutdown.

The ability of mother and baby to form a secure attachment is key to preventing many other problems of childhood. Longitudinal studies begun when subjects were infants have shown a high correlation between insecure or avoidant attachment in infancy and patterns of school problems and delinquency [15].

The midwife can help the new parents understand the importance of forming this secure attachment. Some mothers need validation of their desire to spend time with their babies. The midwife can explain to both parents the critical importance of parental response to infant cues. This advice can help shape the parents' response to crying and the infant's attempts to communicate through smiling and eye contact. Mothering capability and desire to build this attachment can be undermined by failures at soothing or feeding. Mothers who *perceive* themselves as successful develop a feeling of confidence and competence. Midwives must take the time to talk with the mother about her perception of herself as a caregiver, and help to reframe expectations that may be unrealistic [16]. Although most of the literature discusses maternal-infant attachment, the midwife should be cognizant of other possible "secure bases" for infants, including fathers and grandmothers [17].

Some women never experienced quality mothering when they were children. They have no memory or imprint of a secure attachment. The task of mothering may seem overwhelming to these women and they are at high risk for frustration during the early months of motherhood. Whenever possible the midwife should attempt to refer these women to a counselor or parenting group during the weeks immediately after birth.

Parents need to understand that to a young infant, the whole world is represented by the parent. If the infant is to learn the basic human emotion of trust, it is imperative that attempts to communicate receive an appropriate response.

Physical Care of the Newborn

Parents have many concerns regarding the physical care of their newborn. Overall, they should be reassured that there is more than one right way to approach many physical aspects of their child's care.

An infant does not need a full bath daily. Newborns need to have their heads and diaper areas sponged whenever those areas are dirty. This "tops and tails" routine should be done with a mild, nondeodorized soap and the areas should be well dried. A full bath can be given occasionally when the parent has the time to make it a relaxing event for the newborn. Parents must be urged never to leave a newborn unattended in the bath. The soap, towels, shampoo, and clean clothes should all be organized before starting the bath. Slip-proof bath mats are inexpensive and help prevent the infant from slipping.

Care of the umbilicus starts immediately after birth. As noted in Chapter 37, "dry care" of the umbilicus is sufficient. There is no need to ask the parents to use alcohol on the cord at home. The cord should continue to dry and will most likely fall off in 2 weeks. Cords with a strong odor can be cleansed with hydrogen peroxide. Parents should call the midwife if the cord oozes pus or red streaks appear on the abdomen near the umbilicus.

Care of the skin covered by the diaper is essential if diaper rash is to be prevented. Skin care should start with regular diaper changes and a thorough cleansing of the skin with soap and water or a commercial diaper wipe. There is no need to use powder or cream on a regular basis. Use of a barrier cream containing zinc oxide (e.g., Desitin) can sometimes stop diaper rash at the earliest stages.

Parents frequently have strong feelings about what type of diaper to use: paper disposable or cloth. Disposable diapers present environmental issues related to paper/plastic waste. On the other hand, commercial diaper services often use large amounts of bleach and the delivery trucks create pollution. A few parents will choose to wash their own diapers. They must carefully pre-soak diapers (in bleach and detergent) and wash them twice in very hot water in order to ensure that bacteria are destroyed. It is important that the washer not be overloaded so that adequate rinse water can circulate.

Parents are frequently encouraged by family members to dress babies in excessive layers of clothing. A general rule of thumb is to clothe the infant with as many layers as other persons in the room are wearing, plus one layer. Because babies cannot sweat effectively, symptoms of overheating are mainly a red skin color, irritability, and body warmth. Eventually the overheated infant will appear lethargic. Newborns also cannot cope well with cold winds. They will rapidly cool through inspired cold air. Infants taken outside on windy, cold days should have a nonrestrictive covering near their face while they are outdoors.

From the earliest moments at home with a newborn, parents should be scanning for environmental hazards that present safety risks. In the first months of life these risks are mainly related to falling (from a changing table or baby seat) or getting stuck between crib bars. Parents using hand-me-down baby equipment need to check the reliability of safety straps and measure that the space between crib bars is less than $2^{3}/_{8}$ inches and that the mattress fits tightly into the crib. Parents of newborns should also think about hanging mobiles out of reach and removing soft pillows and toys that may lead to suffocation.

There is strong evidence that infants should be positioned for sleep in the supine position (on their backs). This position helps to minimize the risk of sudden infant death syndrome (SIDS). The American Academy of Pediatrics Task Force on Infant Sleep Position and Sudden Infant Death Syndrome first recommended the change from a prone to a supine sleep position in 1992. Since then, the deaths from SIDS have dramatically decreased (see Figure 40-3). Research continues on other factors that contribute to SIDS. Association has been noted with soft sleep surfaces, loose bedding, maternal smoking, bed sharing (especially with multiple family members), overheating, and preterm birth [18, 19]. The midwife is in an ideal position to speak with the family members about the sleeping arrangements, and to urge that no one smoke in the house where the baby resides. Current data do not support the widely held belief that newborns must be positioned on their abdomens in order to prevent aspiration of regurgitated food. Infants consistently placed in the supine position for sleep may have delays in reaching the developmental milestone of rolling over, previously expected by four months of age [20].

All parents using a car for transportation need to have a child safety seat. Small infants should be placed in the backseat of the car, facing the rear of the car. Some states have car seat loaner programs for indigent families. Parents who are buying a new seat should be encouraged to look for infant car seats that double as baby seats in the home. These

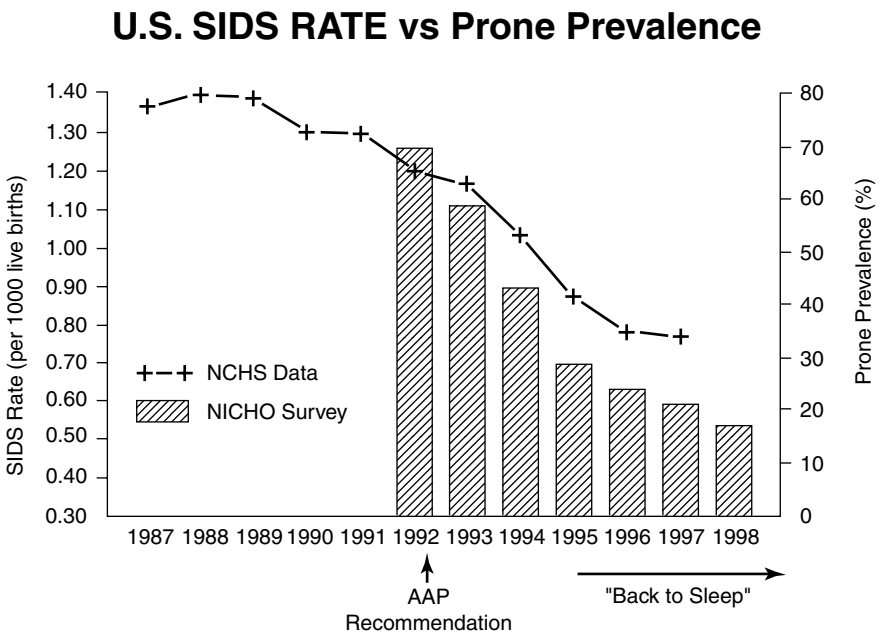

FIGURE 40-3 Change in incidence of SIDS since encouragement of the supine sleeping position.

will have the adequate harness that will prevent infant falls within the home.

The Circumcision Decision

In the United States, circumcising male newborns became prevalent in the 1950s. A complex web of religious, cultural, and family traditions surrounds each family in this decision. Certain religious traditions (Jewish, Muslim) have practiced male circumcision for centuries.

The procedure of circumcision involves the cutting of adhesions and retraction of the foreskin covering the glans of the penis. This procedure is customarily done in the hospital or during the first month of life as a religious ceremony. Complications from circumcision are unusual but can be serious. The most frequent complications are local infection and bleeding, seen in only 0.2 to 0.6 percent of infants [21]. Although the foreskin of newborns is rarely able to be retracted, by age 3 the foreskin can be retracted on 80 to 90 percent of male children.

The contemporary medical rationale for circumcision is a source of controversy. Proponents of circumcision maintain that because the circumcised penis can be kept clean more easily, circumcised males experience lower incidence of medical problems including cancer, urinary tract infection (UTI), and sexually transmitted disease (STD). Cancer of the penis is a rare cancer, especially in the cooler climates of the Northern Hemisphere. The relationship between circumcision and UTIs seems clear: all studies that have examined the association between UTI and circumcision status show an increased risk of UTI in uncircumcised males, with the greatest risk in infants younger than 1 year of age [22]. The relationship between circumcision and STDs remains complex. A number of studies have found a positive correlation between men who were uncircumcised and incidence of STDs, including HIV. However many other contributing factors such as socioeconomic class and sexual practices have clouded the association. Routinely circumcising newborns prevents the small percentage of men with phimosis (inability to retract the foreskin) from developing problems with edema and inflammation of the glans.

Opponents of circumcision maintain that modern sanitary conditions in the United States eliminate the need for this procedure. They believe that the procedure is a painful violation of an unconsenting infant to get rid of a functional body part. The American Academy of Pediatrics makes the fol-

lowing statement: "Existing scientific evidence demonstrates potential medical benefits of newborn male circumcision; however, these data are not sufficient to recommend routine neonatal circumcision" [22]. The Academy further recommends that if circumcision is performed adequate analgesia be provided via a dorsal penile nerve block or an anesthetic cream [23].

Parents choosing not to circumcise should be taught the normal anatomy of the penis and its development. As the child matures, he should be taught to retract the foreskin gently while bathing in order to clear any collection of smegma. Parents must be urged not to retract a foreskin forcefully, since the resultant irritation and edema may cause further adhesions.

In some areas, midwives have added circumcision to their practice [24]. Since this is not a core competency taught in midwifery educational programs, the midwife must utilize the ACNM *Guidelines for the Incorporation of New Procedures into Nurse-Midwifery Practice*. This is a procedure that must be carefully taught by an experienced preceptor who can observe the midwife as she or he learns the new skill. The technique of circumcision is described in Chapter 81. Whether midwives can add this skill to their clinical practices depends on state regulation regarding circumcision in midwifery practice. All midwives, regardless of their personal position on the subject, must be prepared to present the pros and cons of circumcision to parents.

Nonnutritive Sucking

Each family will have its own preference regarding thumb sucking or the use of pacifiers with newborns. Developmentally, nonnutritive sucking serves many functions. Newborns use sucking as a calming activity and are better able to regulate to an alert state when they suck on a thumb or pacifier. There is some evidence that use of a pacifier is associated with a lower incidence of SIDS [18]. Some fetuses start sucking their thumb in utero and continue postnatally with this preference.

Many families use pacifiers to help calm newborns. If parents choose to use a pacifier, they should be advised to clean it regularly and check for signs of dirt or mold. Most pacifiers today have a design that promotes proper development of the muscles of the mouth. Pacifiers should never be placed on a string around the baby's neck because of the risk of strangulation. Some newborns never accept a pacifier and parents must devise other methods to help the newborn become calm (walking the baby, distracting the baby, encouraging thumb sucking).

When a baby is left sucking on a bottle for a prolonged period of time, the residual sugars from the milk or juice may contribute to childhood dental caries, or "baby bottle mouth." The accumulation of milk in the back of the oropharynx may also lead to ear infections. Therefore, prolonged bottle-feeding should never be used to calm an infant.

Feeding

The decision to bottle-feed or breastfeed a newborn is one full of emotion for many parents, especially mothers. Midwives are, by and large, strong advocates of breastfeeding. This choice and its attendant benefits and management are discussed in Chapter 43. Whenever possible, the midwife should express strong support for breastfeeding. However, there are some situations in which the decision to bottle-feed an infant is a logical, prudent choice.

The decision to bottle-feed is logical when the woman's preference is overwhelmingly in this direction. Some women or their significant others are repulsed by the process of breastfeeding. Other women, because of life demands, will share child rearing with other family members or partners and will not be available to breastfeed. Heavy smoking or substance abuse by the mother makes bottle-feeding a safer choice for the infant. Women experiencing certain infections such as HIV or women on certain medications may not safely choose breastfeeding.

Commercial formula is usually heat-treated, nonfat cow's milk to which vitamins, minerals, fats, and sugars have been added (see Table 40-2). Some formula preparations are based on soy products. All are protected by standards set by the Food and Drug Administration (FDA). Commercial formula preparations in the United States come in three types: ready-to-use, concentrated, and powdered. The midwife should become familiar with all three types. In most states only concentrated liquid formula can be purchased with the Women-Infant-Children (WIC) coupons. Parents must be instructed to pay attention to the difference in formula types. Newborns receiving overdiluted formula will fail to gain weight, and newborns fed undiluted formula will receive an osmolar load that will eventually be dangerous to the kidneys.

TABLE 40-2 Comparison of Human Milk, Cow's Milk, and Formula

Nutrient (Unit)	Minimum Level Recommended[1]	Mature Human Milk	Typical Commercial Formula	Cow's Milk (Mean)

[1] Committe on Nutrition, American Academy of Pediatrics

[2] Protein of nutritional quality equal to casein

[3] Includes 300 mg essential fatty acids

Source: From Hambridge, K., and Krebs, N. Normal childhood nutrition and its disorders. In Hay, W., et al. *Current Pediatric Diagnosis and Treatment*, 12th ed. Norwalk, CT: Appleton and Lange, 1995, p. 273. Reprinted by permission.

Parents who are unable to afford commercial formula may choose to make formula. They must be carefully instructed not to use plain cow's milk for an infant younger than 1 year old. Cow's milk has a very high protein content, mainly of hard-to-digest casein. It also contains a high solute load that adds a renal burden and is inadequate in vitamins and iron. If the midwife learns that a family cannot afford commercial formula, the use of an evaporated milk formula may be helpful. Formula can be prepared as follows:

1. Measure 15 ounces of hot water into a pitcher.
2. Add 1 level tablespoon of table sugar.
3. Add 10 ounces of evaporated milk. (Wipe the lid before opening the can.)
4. Yield is 25 ounces of formula at 20 calories/ounce.

The heating process in the preparation of evaporated milk helps to make the protein more digestible. Babies on evaporated milk formulas should receive a multivitamin with iron preparation daily; this can be given orally with a dropper.

There is variable iron storage by the fetus. The American Academy of Pediatrics recommends that

infants who are not breastfed or are partially breastfed should receive an iron-fortified formula (containing between 4.0 and 12 mg/L of iron) from birth to 12 months [25]. Iron in fortified formula is inefficiently absorbed and is helpful only if the newborn receives it routinely. Many caregivers use the iron-fortified formula from birth onward. However, some fear gastrointestinal upset, including constipation from iron-fortified formula. The midwife needs to check with the family about any barriers to use of the iron-fortified formula, carefully explaining the benefits.

Breast milk has very low concentrations of iron, calcium, and zinc. However, all of these elements are extremely bioavailable and, therefore, efficiently absorbed. Breastfed babies will not need iron supplementation until 4 to 6 months of age, when the prenatal stores are used up because of rapid growth.

When using ready-to-use formula or when using unfluoridated water to prepare formula, it is recommended that fluoride supplement be given; the fluoride can be given orally by dropper. Fluoride is a trace element that strengthens the enamel of the tooth and makes it more resistant to acids. Although it is currently recommended that breastfed babies receive fluoride after 6 months of age, some dental caregivers believe that supplementation should start earlier. The introduction of fluoride into public drinking water has caused a dramatic decrease in dental caries in the United States. Each midwife should make inquiries regarding the availability of fluoridated water in her area of practice.

Some families will give a baby water from time to time. This is unnecessary except in very hot weather. Any water given to an infant should be unsweetened. If, for cultural reasons, parents insist on sweetening the water, they may use $^1/_2$ teaspoon of table sugar in 4 ounces of water. Parents should be urged never to use honey or corn syrup as sweeteners because of the risk of contamination with botulism spores of the bacillus *Clostridium botulinum*.

In most areas of the United States there is no need for parents to sterilize bottles, nipples, or water for formula. Cleaning these items with a bottle brush and soapy hot water or in a dishwasher is adequate. However, parents using well water or any uncertain water supply may need to sterilize bottles and formula. This can be accomplished by setting cleaned bottles filled with formula in a large pot and boiling them for 25 minutes. The nipples and bottle caps should only be screwed on loosely during the boiling process. They can be tightened after the entire pot has cooled and is safe to touch.

The most important instruction for parents is to refrigerate formula promptly once it is mixed. Parents who are traveling can use powdered formula with peace of mind.

Parents should be strongly encouraged to hold and cuddle a newborn during a feeding. One of the major benefits of breastfeeding is the comfort of being cuddled. Newborns who are fed from propped-up bottles cannot be observed properly for choking and the need to burp. They also are being deprived of several hours of visual, olfactory, and auditory stimulation each day.

Newborns who are bottle-fed should be held in a position comfortable for both the infant and the mother. Some mothers prefer a semisitting position with the baby resting in the curve of the arm, as when breastfeeding. Stroking the baby's lip with the nipple allows the baby to root for the nipple and grasp it, which is more relaxing than forcing the nipple into the mouth. The bottle should be held so that the milk is in the nipple and neck of the bottle (see Figure 40-4). This keeps the infant from swallowing any more air than necessary.

An infant who has cried for a period of time before the feeding may have swallowed enough air to need burping prior to feeding or after taking a swallow or two of formula. Burping or bubbling can be done several ways and the mother should use the method most comfortable to her and the baby. She can place the baby over her shoulder, set the baby upright in her lap while supporting the chest and jaws with one hand, or lay the baby over her legs while patting or rubbing the back to bring up the bubble of air (see Figure 40-5).

FIGURE 40-4 Technique of bottle-feeding.

FIGURE 40-5 Methods of burping the newborn.

Hiccups are common and are more annoying to the mother than to the infant. They are due to spasmodic contractions of the diaphragm caused by irritation from regurgitation of gastric contents. Usually a few swallows of water to wash down the irritating material will help the contractions stop quickly. Some babies are more prone to hiccups than others.

The average amount to feed a term infant during the first 2 weeks is 30 to 60 milliliters every 2 to 3 hours. During the first 2 weeks of life, the newborn should be wakened to feed at least every 4 hours. After that, if the infant is gaining weight, longer sleep periods (especially at night) can be allowed.

There is no medical reason for a young infant to be fed anything other than breast milk or formula. Infants are developmentally ready to transfer food to the back of the tongue for swallowing at approximately 4 to 6 months of age. This coincides with an ability of the gastrointestinal tract to digest other foods. If parents insist on giving their infant another food before this age, they should restrict themselves to rice-based cereal in small amounts.

Common Variations in the First Six Weeks

There are certain variations among infants that are of concern to parents and caregivers alike. In each case the midwife must stay alert for signs and symptoms that point to a more serious underlying problem.

Diaper Rash

Most diaper rash is a reaction of the skin to the ammonia in urine and the bacterial contamination from fecal material. It is important to note the location and distribution of the problem and note whether there is generalized redness, a rash, or both. Simple diaper rash of the irritant variety presents as flat, reddened areas without too much skinfold involvement (Figure 40-6[a]). The affected skin should be cleaned with mild soap and tepid water. The infant will be in distress when the area is cleaned. Whenever possible, the diaper area should be left uncovered so that air can circulate. If diapers must be used, frequent diaper changes are necessary. Most diaper rash will rapidly clear up with this regimen. In the early stages of irritation a zinc oxide barrier cream (e.g., Desitin) may prevent further skin problems.

Infants presenting with pronounced erythematous confluent lesions, skinfold involvement, and "satellite lesions" at some distance from the perineum and anus may have a fungal diaper rash caused by *Candida albicans* (Figure 40-6[b]). This is best treated with a topical antifungal preparation such as topical nystatin, miconazole, or clotrimazole; fungal diaper rash will resist most other treatments. Babies with fungal diaper rash will be in pain. A 1% hydrocortisone cream may help lessen the inflammation and can be used concurrently with the fungal preparation [26]. Frequent diaper changes and sponging with tepid water will also assist healing.

A newborn must be evaluated if the parent reports peeling skin, vesicles, or an exudate. Sometimes

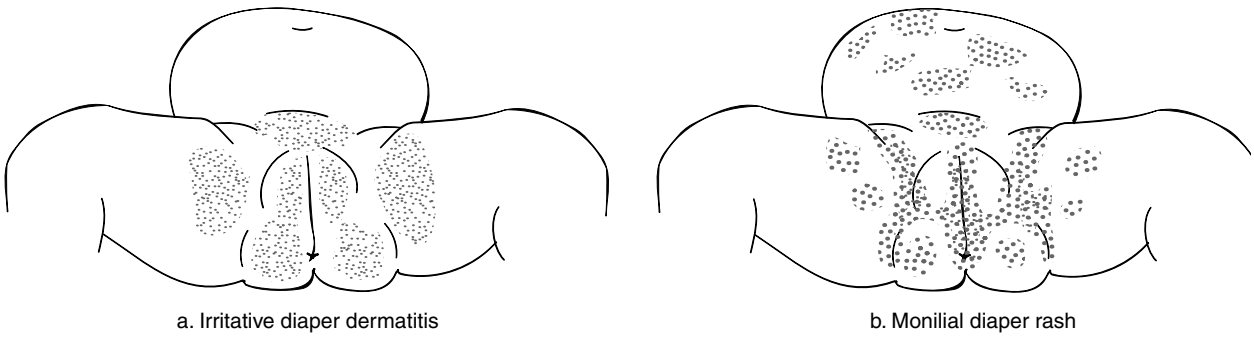

FIGURE 40-6 Diaper dermatitis.

Source: From Liptak, G. Diaper rash. In Hoekelman, R. A., Adam, H. M., Nelson, N. M., et al., *Primary Pediatric Care*, 4th ed. St. Louis, MO: Mosby, 2001, p. 1458. Reproduced by permission.

a simple diaper rash can be secondarily infected with staphylococcus or streptococcus, leading to impetigo. In rare cases, herpes simplex virus or histiocytosis—a seborrhea-like condition—can cause a diaper rash. When infants present with frequent diaper rash, the midwife should try to assess whether the parents are following hygienic practices. Parents on limited incomes may not change diapers often because of the cost of disposable diapers.

Cradle Cap

Some infants collect a seborrheic exudate on their scalp that becomes adherent. This cradle cap is only of cosmetic concern. It can be loosened by a gentle scalp massage with vegetable or olive oil and removed by shampooing and use of a very fine-toothed comb. It usually does not return if shampooing is part of the bath.

Mouth Thrush

Parents who complain that their baby starts to eat but then pulls away from the breast or bottle while crying should be instructed to inspect the infant's mouth. Infant thrush, caused by *Candida albicans*, appears as adherent white plaquelike clumps on the tongue, gums, and hard palate. These infants will need to be treated with an oral antifungal preparation or gentian violet. Occasionally, breastfeeding mothers will get a fungal infection of their nipples from an infected infant. Symptoms will include very itchy nipples. This problem can be treated with an antifungal cream used after breastfeeding.

Noisy, Irregular Breathing

Parents frequently are concerned about noises that infants make while breathing. This concern is usually intertwined with a concern about irregularities in the respiratory pattern. Parents should be advised that the upper airways of infants are narrow and any slight nasal swelling can produce some noise. The common parental practice of frequent suctioning of the nares with a bulb syringe should be discouraged because it produces trauma and swelling, making the situation worse.

If an infant seems to have a crusted nasal discharge, parents can purchase some saline drops and insert one or two drops into the nares to loosen the discharge. Routine use of a home humidifier is controversial because humidifiers are breeding grounds for fungus and molds that are then circulated in the air.

The periodic breathing of the newborn must be distinguished from apnea. Direct observation of the newborn is critical in order to see the pattern of respiratory effort. Periodic breathing occurs most frequently during REM sleep and is defined as pauses in respiratory movement that last for up to 20 seconds alternating with breathing [27]. Pauses more frequent than that need to be evaluated, especially if they are accompanied by other signs of respiratory compromise like tachypnea (>60 breaths per minute), nasal flaring, retractions, color changes, or grunting. Periodic breathing should not be associated with a drop in heart rate.

The Fussy Baby

A frequent cause of parental desperation in the newborn's first 2 months is the fussy, inconsolable baby—often known as "high-need" or colicky babies. The midwife needs to take a careful history of the crying and fussing patterns in order to help devise a plan of care. Parents should be interviewed regarding their expectations of the newborn's sleep/wake patterns and ability to self-comfort. Occasionally, mothers who are depressed will com-

plain about the newborn's behavior while masking their own serious depression. Any discussion of the fussy baby must include questions about the mother's well-being and her recent history.

The reasons that some infants become fussy and cry excessively are not known. A baseline physical examination should be done to rule out infections, milk intolerance, and gastrointestinal blockage. During this visit, a weight check will be done. An organic cause for fussy behavior is rarely pinpointed. One theory regarding these babies is that they have a very low threshold for stimulation and frustration. They appear to get overwhelmed quickly and to rapidly cycle through various behavioral states to full crying.

The approach currently in favor in pediatric circles involves education of the parents to a wide repertoire of calming techniques [28, 29]. Among the suggested ones are the following:

1. Try to feed the baby.
2. Hold the baby; try different holds that provide abdominal support.
3. Swaddle the baby.
4. Give the baby a pacifier.
5. Talk to the baby face-to-face; use low, rhythmic sounds.
6. Reduce sensory stimulation in the room.
7. Walk the baby around the room.
8. Take the baby outside for a walk or a car ride.

Parents are encouraged to go through the repertoire, trying each technique for only 5 minutes until the baby calms. A variety of holding positions can be utilized, including the cradle hold, flexion over the adult shoulder, football hold, or draping over the adult knee. Many of these positions have in common some firm support to the infant's abdomen.

Evaluation of crying is particularly difficult because of the lack of a standardized definition of excessive crying [30]. Parents can be urged to keep a record of their interventions and the time the baby actually spends crying. Modest successes can thus be highlighted and patterns identified. Any parental success should be framed by the midwife as examples of how well the parents are understanding and helping their high-need child. Most importantly, the midwife must urge the parents to discuss their frustration and anger at the situation. A very fussy baby can provoke violent responses from a sleep-deprived parent. Parents should get a clear message to call the midwife if they feel themselves getting out of control. They should also be reassured that most extremely fussy babies settle considerably by the third month of life.

Eating Patterns and Weight Gain

Many parental anxieties are focused on weight gain and eating patterns in the first few weeks of life. Some of this is culturally determined in families who believe that maternal competence is reflected in infant weight gain. When a parent calls with concerns about intake, the midwife must set aside time to take an adequate history.

Among the factors to be considered are history of the birth and immediate postnatal course, birth weight and length, current age, interval illness or problems, method of feeding, primary caregiver, and current family stress level. The parental level of comfort with infants and infant feeding should be assessed. The parents should be asked why they are concerned. Is there a specific reason they feel that the infant's eating patterns are problematic? Most parents will express concerns about vomiting, amount of milk ingested, or the infant's lack of interest in eating.

The midwife presented with this problem during a phone call will need to decide whether the baby should be brought in for an office evaluation. Parents will be most reassured after a weight check; therefore it can be worthwhile to arrange an appointment. On occasion the midwife may be concerned enough by the history that she feels an immediate office visit is critical. The factors listed in Table 40-3 would warrant immediate evaluation.

A midwife who is reassured by the absence of any critical indicators during her phone conversation with the parent can offer some information.

TABLE 40-3 Factors in Feeding History Requiring Immediate Evaluation

Regular projectile vomiting
Bile-stained vomit
No stools since birth
No urination since birth
Poor muscle tone—"spread-eagle posture"
Inability to rouse infant
Inability of infant to suck
Rapid respirations over time (greater than 60 per minute)
Marked color changes during eating
Taut, swollen abdomen
More than six stools per 24 hours
Bloody or excessively watery stools

Healthy term newborns who were of average weight of gestational age can be expected to gain 1 ounce per day in the first 3 months. Breastfed babies may gain slightly less than 1 oz per day. Over the course of the first year, birth weight trebles and birth length doubles [31]. During the first 3 to 5 days of life, newborns may lose from 5 to 10 percent of their birth weight, with breastfed babies experiencing the larger weight loss. This weight should be regained by the tenth day of life. The weight and length of infants born in the United States are evaluated on growth charts. These national norms were recently revised by the CDC and more accurately reflect the diversity of the population and the weight gain patterns of breast-fed infants [32]. Nonetheless, the 2000 CDC charts compare a child to all the children in the United States—a heterogeneous population. It is possible that midwives working exclusively with certain ethnic groups might find slightly differing patterns of growth.

Parents need to distinguish regurgitation from vomiting. Regurgitation ("spitting up") is reflux of stomach contents through the immature lower esophageal sphincter and is normal in newborns. The amount is usually small and the spitting up is rarely forceful. Overfeeding with the bottle contributes to regurgitation. Regurgitation should not interfere with weight gain. Regurgitated milk will not be bile- or blood-stained.

Babies who are being fed adequately will produce both urine and feces in a regular pattern. Anxious parents should be asked to check the diaper prior to a feed for evidence of urine. Superabsorbent disposable diapers may be hard to evaluate, so parents may need to diaper the baby in cloth in order to observe the presence of urination. Six voids a day indicate adequate hydration.

Infant interest in feeding changes with time. During the first 48 hours of life infants may show minimal interest in feeding. Their intake may be only 1 ounce, but they should be offered a chance to feed regularly. Infants are usually hungry every 2 to 3 hours and during the first month feeding should be offered at least every 4 hours. As the first month continues, the infant's stomach will enlarge and feedings of 2 to 4 oz will become the norm.

Physiological Jaundice

Up to 50 percent of newborns become jaundiced to a level that is visible. Visible jaundice indicates a bilirubin level of at least 5 to 7 mg/dL. As discussed earlier, there are many physiological reasons for the development of jaundice during the first week after birth.

Management of jaundice depends on whether the jaundice is determined to be within the norm for physiological jaundice or indicative of a pathophysiological process. The midwife should learn to distinguish these two processes (see Table 40-4) and should encourage infant care practices that enhance clearance of jaundice.

Physiological jaundice is more common in some situations. Asian babies have a high incidence of jaundice and African-American babies a low incidence [33]. Breastfed babies have a higher incidence of physiological jaundice than bottle-fed babies.

The criteria listed in Table 40-4 for possible pathological jaundice do not amount to a firm diagnosis. Other factors need to be considered, including the race and sex of the baby, method of feeding and gestational age. Because most U.S. newborns are discharged from the hospital early, there has been an increasing emphasis on predicting which neonates will experience excessive jaundice. Some hospitals are screening all newborns with serum total bilirubin (STB) levels at one day of age. A level less than 5 mg/dL is very predictive of infants who will not need treatment for subsequent severe jaundice. Higher levels indicate newborns who should be followed closely, even if discharged to home, for STB rising to pathological levels [34, 35].

TABLE 40-4 Types of Jaundice

Physiological Jaundice	Possible Pathological Jaundice
Not visible in first 24 hours	Visible during first 24 hours
Rises slowly and peaks at day 3 or 4 of life	May rise quickly: >5mg/dL/24 hours
Total bilirubin peaks at less than 13 mg/dL	Total bilirubin greater than 13 mg/dL
Lab tests reveal predominance of unconjugated bilirubin	Greater amounts of conjugated bilirubin
Not visible after 10 days	Visible jaundice persists after one week

All parents should be given advice about the high frequency of jaundice in the newborn. They can be advised to feed the infant frequently during the first days of life in order to promote the passage of meconium. As discussed earlier, meconium has a high bilirubin content and delayed passage promotes reabsorption of bilirubin as part of the enterohepatic shunt. Parents can be taught to assess the newborn in a well-lighted room or near a sunny window by blanching the skin to reveal the underlying color. The icterus will start on the head and face and move downward to the trunk and extremities. If a home visit is planned the neonate can be evaluated with an icterometer or transcutaneous jaundice meter [36].

A newborn with pronounced physiological jaundice can be treated with phototherapy. The following symptoms may indicate that the jaundice is not physiological and the newborn needs a more extensive medical evaluation: vomiting, lethargy, poor feeding, hepatosplenomegaly, excessive weight loss, apnea, temperature instability, tachypnea, dark urine or urine positive for bilirubin, light-colored stools, persistent jaundice for more than 3 weeks [37].

Increasingly, phototherapy can be offered in the home and supervised by a pediatric provider. Home phototherapy is contraindicated when the bilirubin level is greater than 18 mg/dL or when pathology is suspected [38]. Many mothers prefer home phototherapy but some are too tired or nervous to accept the extra responsibility for monitoring the newborn [39]. Pathological jaundice is discussed in Chapter 41.

CHAPTER

41

Recognition and Immediate Care of Sick Newborns

MARY KATHLEEN MCHUGH, CNM, MSN

The Midwife's Roles and Responsibilities

Occasionally the midwife is confronted with a newborn who exhibits signs and symptoms that may indicate a deviation from health. The role of the midwife includes recognition of abnormal signs and symptoms, provision of adequate supportive care, and parent education. The midwife's early recognition and referral will be of key importance in the newborn's recovery. The role of the midwife is limited but critical, consisting of either independent management or transfer to pediatric care. Midwives do not co-manage the care of sick newborns. Midwifery management roles are defined in Chapter 2.

In order to be effective in verifying the normality of the newborn and consulting on abnormal findings, the midwife must be willing to accept the inevitable fact that not all newborns are healthy and normal. Faced with signs and symptoms that are abnormal, the midwife follows the steps of the management process related to data collection. The midwife also initiates a consultation with the pediatric team. As discussed in Chapter 38, each midwife establishes a relationship with pediatric providers who provide consultation and accept transfers. On occasion, the midwife may need to start basic supportive care while awaiting a transport team from the pediatric facility.

This chapter is meant to supplement texts on pediatric medicine and will focus on recognition of possible illness and the appropriate midwifery response. It will not provide an exhaustive description of the pathophysiology or treatment of newborn illnesses or deviations.

Frequently the midwife will be in the position of having to explain to worried parents that a certain sign or symptom is abnormal. This chapter will help support those explanations and guide the midwife in educating the parents of a newborn with abnormal signs and symptoms.

This chapter is organized around signs and symptoms that may indicate newborn illness. Symptoms consist of subjective evidence of illness perceived by the patient or, in the case of a newborn, interpreted by the parent. One of the particular challenges in providing care to the newborn is the interpretation and validation of a parent's reports of symptoms—subjective information. Signs of illness include objective evidence perceptible to the midwife during the physical exam of the newborn. Signs and symptoms can be corroborated by additional data gathered by the caregiver, such as laboratory results, vital signs, imaging studies, ultrasounds, etc. Final diagnosis will be based on the signs, symptoms, and additional data and will usually be made by the pediatric team.

The chapter also discusses baseline validating data and describes midwifery management plans for certain newborn situations. It is important to emphasize that the midwife's involvement will continue only until the newborn can be transferred into the care of the pediatric team. Thus, the management plans outlined here will emphasize stabilization and transfer of the newborn.

The Sick Newborn

Overlapping Signs and Symptoms

One of the great challenges facing the midwife caring for newborns is the nonspecificity of certain signs and symptoms in the newborn. It is critically important for the midwife to realize that some of the most common abnormal signs can represent a variety of illnesses or conditions. In particular, respiratory signs can denote many different types of illnesses that are nonrespiratory in nature. Differential diagnoses of common abnormal physical signs are outlined in Table 41-1. Because of the nonspecific nature of some of these signs and symptoms, the midwife must perform a careful history and physical exam (including vital signs) in order to gather the maximum amount of data to report to pediatric caregivers.

Signs of Respiratory Disease

Respiratory signs are the most common abnormal finding in newborns (Table 41-2). The cardinal signs of respiratory compromise include tachypnea (more than 60 respirations per minute), nasal flaring, and retractions of the intercostal muscles located between the ribs. In severe cases of respiratory compromise there will be retraction of the sternum. If the lungs are wet, rales and rhonchi may be heard with auscultation of the lungs. If air is trapped within the lung, audible grunting is heard. The level of cyanosis noted will depend on the degree of hypoxia, although the visibility of cyanosis will be decreased by hypovolemic states.

There are many pulmonary and nonpulmonary causes of respiratory compromise in the newborn (see Figure 41-1). They include sepsis and congenital anomalies that cause upper or lower airway obstruction or pulmonary obstruction. In preterm infants respiratory distress syndrome (RDS) is caused by the absence or deficiency of surfactant. Midwives are most likely to deliver term infants; the most common pulmonary causes of term neonatal respiratory distress are pneumothorax, aspiration of meconium, neonatal pneumonia, and transient tachypnea of the newborn.

TABLE 41-1 Nonspecific Signs of Illness in the Newborn

Abnormal Physical Sign	Possible Etiology
Tachycardia (heart rate greater than 170 beats/min)	Overheating Infection Anemia Shock Cardiac defect
Tachypnea (respirations greater than 60/min after transition)	Overheating Pulmonary disease Metabolic acidosis Cardiac disease Congenital defects of ribs, airway, lungs
Pallor	Cold stress Shock Anemia
Jaundice	Infection (prenatal or postnatal) Hemolytic disease Congenital defects of liver, biliary tract Abdominal obstruction
Abnormal cry	Central nervous system abnormalities Congenital defects of upper airway
Jitteriness	Hypoglycemia Hypocalcemia Drug withdrawal Normal variation
Feeding difficulties	Neuromuscular problems Infection Cardiac disease Respiratory disease Drug withdrawal

TABLE 41-2	Signs of Respiratory Compromise
Visible Signs	**Audible Signs**
More than 60 respirations/min	Rales or rhonchi heard on auscultation
Cyanosis around face and trunk	Stridor heard with inspiration
Nasal flaring	Grunting heard upon expiration
Retractions of the intercostal muscles	
Retractions of the sternum	
Apnea	

A pneumothorax occurs whenever air from the lung is pushed outward from the alveoli into an atypical place, usually the tissue of the interstitial space of the lung. The alveoli rupture as a result of overdistention. Although newborns who are mechanically ventilated are at high risk for pneumothorax, many spontaneous pneumothoraxes occur without an obvious antecedent event. Some pneumothoraxes are so small that there are few if any symptoms. With a larger pneumothorax, the midwife will note the signs of diminished breath sounds on one side, cyanosis, and perhaps overdistention of the chest on the affected side. A large pneumothorax can be a true emergency. The responsibilities of the midwife include emergent referral to a pediatric team and supportive respiratory care.

Meconium aspiration can lead to a serious chain of events in which the chemical inflammation and the obstruction from meconium particles lead to pneumonitis, air trapping, hypoxia, air leaks, persistent fetal circulation, respiratory failure, and persistent pulmonary hypertension. These term newborns will rapidly decompensate in the first hours after birth and may need support from a respirator and occasionally ECMO (extracorporeal membrane oxygenation), a type of heart-lung bypass [1]. Signs of meconium aspiration syndrome include uneven breath sounds, a barrel-chested appearance, rales and rhonchi, and cyanosis.

Pneumonia may be acquired in the intrauterine period or during the passage through the birth canal. Symptoms of pneumonia include the respiratory signs noted above plus hypothermia, color changes, and apnea. Infections can be caused by bacteria, viruses, or other organisms (chlamydia, fungi, and mycoplasma) and may vary in intensity.

A more benign condition is transient tachypnea of the newborn (TTN). In transient tachypnea,

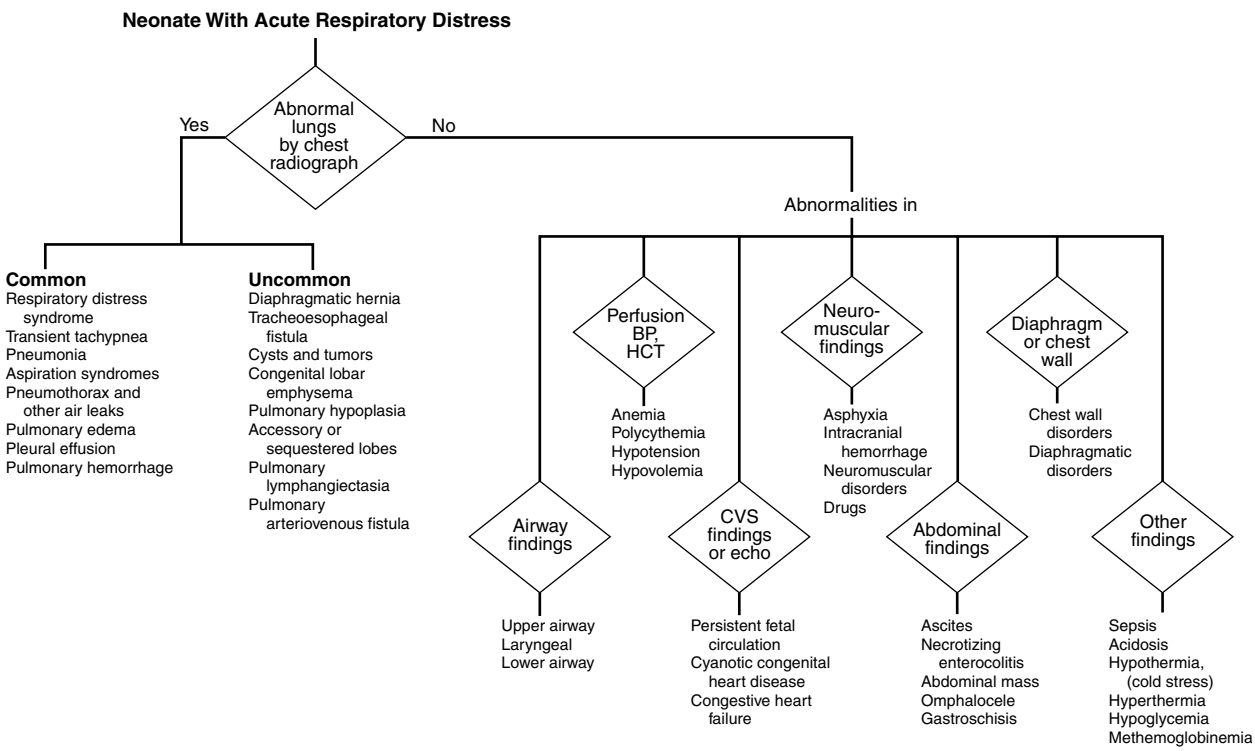

FIGURE 41-1 Neonate with acute respiratory distress.

Source: Reprinted from Kenner, C., Lott, J. W., and Flandermeyer, A. A., *Comprehensive Neonatal Nursing: A Physiologic Perspective*, 2nd ed., 258, © 1998 Elsevier Inc., with permission from Elsevier.

there is inadequate absorption of lung fluid after the birth. Newborns with TTN take longer than most newborns to make a transition from fluid-filled to air-filled lungs. Newborns born by cesarean section, especially elective surgery, are at particular risk for TTN. This is probably because of the lack of lung stimulation from prostaglandins during labor [2]. The principal signs of TTN include tachypnea, rales or rhonchi on auscultation, and sometimes nasal flaring or intercostal retractions. Transient tachypnea lasts only 48 to 72 hours. However, during that period the newborn may need assistance with feedings and extra oxygen.

The Midwife's Involvement The midwife caring for a newborn with signs of respiratory distress provides supportive care while awaiting the pediatric team. Central cyanosis (of the trunk, lips, tongue, and oral mucous membranes) is a sign of serious compromise of the neonate's hemoglobin oxygen saturation. Care includes delivery of oxygen via hood (starting at 40 percent) to relieve cyanosis and to help decrease the work of obtaining oxygen. If cyanosis is not rapidly relieved, the midwife should increase the percentage of oxygen delivered. The midwife should carefully review the mother's prenatal, intrapartum, and postpartum history for evidence of infections.

The newborn should be continuously monitored for heart rate and respiratory rate. If possible, blood pressure is checked. Temperature is monitored and oral feedings are withheld because of the risk of aspiration and the extra oxygen demands of feeding. In a remote site the midwife may be asked to obtain a chest x-ray, CBC with differential, and a blood sugar while awaiting the pediatric team.

The midwife practicing far from a pediatric inpatient facility should become familiar with techniques for starting a peripheral intravenous line in the neonate (see Figure 41-2). If the neonate's condition deteriorates, it will be more difficult to find a vein. Therefore, if there will be any delay in transferring the neonate, the intravenous line should be started.

Oxygen levels can be assessed with capillary blood obtained from a heel stick but this is frequently inaccurate, especially in a poorly perfused neonate. Most hospitals will have equipment available to monitor blood gas tensions noninvasively. There are two primary methods: transcutaneous measurement of partial pressure of oxygen and continuous pulse oximetry. In continuous pulse oxime-

try a small probe is attached to one of the neonate's fingers or toes. This method computes arterial oxygen saturation (SaO_2), with an acceptable level being 92 to 95 percent [2]. The use of continuous pulse oximetry is growing in popularity because, unlike transcutaneous monitoring of the partial pressure of oxygen, the continuous pulse technology does not need calibration, cannot cause skin damage from heat, does not need frequent position changes, and is accurate even in the presence of edema [3]. The midwife should become familiar with the type of equipment present in the practice environment.

Signs of Possible Infection

Congenital Viral and Parasitic Infections

The newborn who has acquired an intrauterine viral infection will present with signs that may include early jaundice, hepatosplenomegaly, petechiae, and palpable lymph nodes, and be small size for dates. Depending on the virus, there may also be cataracts, limb or cardiac defects, microcephaly, rash, or vesicles. Thrombocytopenia may be present on a complete blood count (CBC). The visible effects of infection will vary according to the severity of infection and the timing of fetal exposure. Newborns who acquire infection during labor will not have the same signs at birth as the fetus infected transplacentally.

Midwifery actions may include the isolation of the newborn from other newborns and pregnant health care workers until the virus is identified. Cord blood should be saved for further testing. The presence of IgM antibodies in the cord blood will help to confirm a suspected viral infection.

Bacterial Infections

Bacterial infections in the newborn are commonly caused by *Group B beta-hemolytic Streptococci* or *E. coli*. Bacteria can be acquired in utero or during the birth process. Other infections are caused by *Staphylococcus aureus* and *Staphylococcus epidermidis* acquired in the hospital. Many infants who are colonized with bacteria from the mother do not become ill. Those who do become ill warrant immediate attention.

If a mother has antenatal or intrapartal risk factors for early onset Group B Streptococcal disease, the currently accepted algorithm is to treat in labor with penicillin: two doses 4 hours apart. Some women will give birth prior to receipt of the two doses. In this situation the Centers for Disease Control recommends the following for newborns of greater than 35 weeks' gestation: CBC with differential, blood culture, and chest x-ray (for any pulmonary symptoms) [4].

Early onset bacterial infection (birth to 6 days) can be severe and life threatening. Respiratory distress is common and signs may include tachypnea, labored breathing (nasal flaring and intercostal retractions), and poor color. There may be apneic episodes. Vital signs may indicate temperature instability (fever or hypothermia) and hypotension. The newborn will often not feed well.

Midwifery actions include immediate consultation and provision of a supportive environment. The newborn is continuously monitored for respiratory rate and heart rate. If possible in the site, check the newborn's blood pressure and conduct noninvasive oxygen monitoring. Warm, humidified oxygen is administered via hood at 40 percent or greater. These newborns should not be fed orally because of the risk of aspiration. In a remote setting, the midwife may be asked to obtain a chest x-ray, CBC, blood sugar, and cultures of the blood and urine. Intravenous access should be established.

Signs of late-onset bacterial infection (7 days to 3 months) will become evident after the newborn has been discharged home. These signs include problems with feeding such as a disinterested suck, lethargy, color changes, occasional apnea, and temperature lability.

The most important action the midwife can take with late onset bacterial infection is to acknowledge that there is a problem. This is a particular challenge if the symptoms are being reported by telephone. Denial or "wish management" may lead the midwife to give false reassurance to the parents with potentially serious sequelae for the untreated newborn. These newborns will need treatment as in-patients.

Acquired Immunodeficiency Syndrome

A newborn can be infected with HIV transplacentally, during the birth process and after the birth. As discussed earlier, all pregnant women should be encouraged to be tested for HIV during pregnancy so aggressive antiretroviral therapy can be started during gestation and continued after birth for a number of weeks. Testing for HIV in the newborn needs to be repeated at least three times, up to 15 months of age. By then maternal antibodies are no longer present.

At birth, the HIV-infected neonate will not have any specific signs of illness. If the mother is found to be HIV positive during her intrapartum stay, the newborn can be treated with postexposure prophylaxis. Newborns of HIV-infected women should not be breastfed. Overall transmission of HIV from infected mother to a breastfed child can be as high as 25 percent, a rate recently confirmed with a multicenter meta-analysis [5].

Signs of Possible Heart Disease

Cardiac problems in newborns result from a variety of causes. They mimic a number of other problems, especially respiratory disease and sepsis. Some newborns will quickly demonstrate signs of an underlying congenital defect. These are usually structural in nature and may affect the heart itself or major vessels leading to and from the heart. The primary signs of heart disease include central cyanosis and/or tachypnea and/or pallor. Depending on the defect, pulses may be bounding or diminished. Pulses can vary in intensity from upper to lower extremities. Depending on the defect, a loud murmur may be present at birth or may not be heard for 1 to 2 weeks after birth. The cyanosis of heart disease is seen over the entire body, and this differentiates it from the peripheral cyanosis of normal newborns.

The most common heart defect in newborns is a ventricular septal defect, accounting for 30 to 50 percent of defects in various populations. If large enough, the defect involves left to right shunting whereby oxygenated blood crosses over the opening in the septum and recirculates through the lungs. Therefore this is not a cyanotic defect. The murmur may not be heard until two or more weeks of age as the compensatory measure of increased pulmonary vascular resistance diminishes and more blood flows from left to right. This is characteristic of a large defect and may be associated with a subtle onset of congestive heart failure evidenced by tachypnea, feeding problems, and failure to thrive. The midwife may elicit troubling symptoms during a postpartum visit with the mother or during calls about breastfeeding problems. In the smaller ventricular septal defects the systolic murmur is heard soon after birth but will not lead to congestive heart failure.

Some newborns will not make the transition from intrauterine to extrauterine circulation. In some infants, the pulmonary resistance remains so high that blood flow through the newborn lungs is decreased. This results in persistent pulmonary hypertension (formerly called persistent fetal circulation). Frequently, these are newborns who experienced significant asphyxia in utero (see Chapter 36). Signs include tachypnea, nasal flaring, and intercostal retractions. Because of the high level of resistance from the lungs, the ductus arteriosus and the foramen ovale may stay open to provide right-to-left shunting. In this case, peripheral pulses will be bounding, the precordium will be active, and a murmur will be heard.

Midwifery management of newborns with acute signs of heart disease includes immediate consultation with the pediatric team and supportive care for the resulting respiratory distress. The newborn is constantly monitored for heart rate and respiratory rate. If possible in the site, the newborn's blood pressure is checked and pulse oximetry is performed. If heart disease is suspected the blood arterial oxygen saturation of an upper extremity can be compared to a lower extremity. In persistent pulmonary hypertension the saturation is lower in the descending aorta [6]. Warm, humidified oxygen is provided via hood at high concentrations. When there is a cardiac problem even high concentrations of oxygen may not yield normal results. If the newborn is tachypneic, oral feedings are withheld. The metabolic demands of respiratory distress will predispose the newborn to hypoglycemia. Peripheral blood samples for glucose are obtained regularly, and an intravenous line should be placed.

Signs of Birth Injuries

Most birth injuries occur during a long, protracted labor or a difficult birth. Birth injuries may occur in situations in which the fetus is large or the fetal presentation or position is abnormal. However, there are cases in which injury occurs in utero.

Cephalhematomas and Skull Fractures

Injuries to the head include cephalhematomas and skull fractures. A cephalhematoma is a collection of blood under the periosteum. Cephalhematomas may be singular or bilateral. The blood does not cross the suture lines of the newborn skull, because the bleeding is under the periosteum. Cephalhematomas may cause tenderness. Some cephalhematomas occur with linear skull fractures, most of which heal well. A clear sign of a skull fracture is a depressed area of fetal skull, particularly over the parietal bones. An

area of skull depression increases the possibility that fragments of skull bone have penetrated through the dura, the covering of the brain. Midwifery care includes careful positioning of the newborn on the side opposite the affected area and consultation with the pediatric team, who will order imaging tests.

Facial Palsy and Brachial Plexus Injuries

Injuries to the face include bruising from forceps or facial palsy caused by either forceps or pressure from the maternal sacrum. The signs of facial palsy include asymmetry of the face. One eye may remain open. Midwifery actions may include consultation for the use of an eye patch and lubricating eye drops. The paralysis is temporary.

Injuries to the brachial plexus may occur prenatally or during a birth when traction is applied to the neck. Such injuries can occur during breech births or births involving shoulder dystocia. The newborn with a brachial plexus injury may be fussy and in pain. The manifestations of the injury will depend on the nerve root that was injured and the degree of the injury. Nerve roots involved can include the cervical roots C5 and C6 (Erb-Duchenne paralysis), roots C8 and T1 (Klumpke's paralysis), or both. The physical signs of Erb-Duchenne paralysis include a generalized loss of movement in the affected arm with an adduction of the lower part of the arm. This leads to the characteristic "waiter's tip" sign involving an internal rotation of the lower portion of the arm with the finger and wrist flexed. The grasp reflex is intact but the Moro reflex is weak on the affected side. In Klumpke's paralysis the grasp reflex is absent and the infant's hand is kept in a clawlike posture.

Midwifery management will include referral for splinting of the affected arm close to the body and consultation with the pediatric team. Parents should be encouraged to handle the affected extremity as little as possible for the first week because of the pain involved. Parents can be reassured that in the vast majority of cases paralysis disappears in 3 to 6 months, with initial improvement evident within a few weeks. Physical therapy is helpful after the first swelling subsides.

Injuries to nerve roots higher in the brachial plexus (C3-C5) can lead to signs of significant respiratory compromise because of paralysis of the phrenic nerve and diaphragmatic compromise. Newborns with this type of nerve injury take very shallow breaths with limited respiratory excursion and need aggressive respiratory support at birth.

Bone Fractures

Pressure and manipulation during the birth process may lead to fractures of bones. Occasionally there are intrauterine fractures. The bones most frequently affected include the clavicles, the arms, and the legs. Signs of bone fracture include swelling, skin discoloration, lack of movement, abnormal positioning, and pain with movement. Crepitus can sometimes be elicited on palpation. The Moro reflex will be asymmetric.

Midwifery management includes splinting of the arm if a clavicular or arm fracture is suspected; obtain pediatric consultation. Parents can be assured that newborn bones heal well and quickly.

Signs of Neurological Disease

The most common sign of neurological compromise in the newborn period is seizure activity. The most frequent reason for seizures in the neonatal period is hypoxic-ischemic encephalopathy (HIE). The newborn who experienced distress in labor may have the cluster of criteria for the diagnosis of perinatal asphyxia: (1) cord blood pH <7.1, (2) Apgar score of 0–3, (3) seizures, and (4) multiple organ system dysfunction in the early neonatal period [7].

Other reasons for neonatal seizures include metabolic disturbances such as hypoglycemia or hypocalcemia, and infection. In the older newborn, seizures can be an indicator of an inborn error of metabolism.

Newborns may evidence various types of seizure activity. The most common is the subtle seizure. Signs of subtle seizures include sucking motions, chewing, bicycling of limbs, drooling, apnea, deviation of the eyes, and eyelid fluttering. These seizures are evidenced as short, repetitive bursts of activity. The midwife will notice these repetitive behavioral patterns during a careful newborn exam.

Other types of seizures (multifocal, focal) are less common in newborns. The signs of these seizures include movement of one limb with progression to other limbs or movement of both limbs on one side of the body.

Because of the risk of apnea, the newborn with possible seizure activity is moved to the nursery for more intensive observation, including monitoring of heart rate and respiratory rate, until the pediatric team arrives. The midwife orders a peripheral glucose sample because of the association between hypoglycemia and seizure activity.

Signs of Surgical Emergencies

There are numerous types of congenital defects that are corrected by surgery on the newborn. The possibilities include both defects that are immediately visible and defects that are hidden from view. These will be discussed separately.

Visible Congenital Defects

Certain types of congenital defects cause quick deterioration in the newborn and may lead to significant morbidity and mortality if not properly managed. Of these, abdominal wall defects and spinal cord defects pose particular challenges. Abdominal wall defects are subdivided into gastroschisis and oomphalocele. Gastroschisis is a condition in which the eviscerated abdominal organs are not covered by a sac. In an oomphalocele, the abdominal organs are external but are covered by a sac. In both cases the potential is great for hypothermia and dehydration because of the large surface area that is exposed. Infection is highly likely.

Midwifery management includes an immediate call for pediatric assistance and transport to a tertiary pediatric hospital. The newborn is placed in a radiant warmer in as sterile an environment as possible. Sterile, warmed saline is applied to the eviscerated abdominal contents via sterile gauze pads [8, 9]. The infant's torso is then wrapped in sterile gauze to keep the saline in place. No feedings are given; a feeding tube is inserted and any stomach contents are aspirated. The neonate has an acute need for intravenous fluids.

Newborns with open spinal cord defects pose similar problems. The two common neural tube defects are meningocele and meningomyelocele. Meningocele is a bony defect of the spinal cord. With meningomyelocele, the vertebra is defective and the spinal cord and spinal roots are externally located in a sac. Meningomyeloceles are commonly found in the lower spine, lumbar, and sacral areas.

The principles for treatment of spinal cord defects are similar to those described for abdominal wall defects: application of a sterile, warm saline dressing with a dry sterile overwrap, thermoregulation, and fluid maintenance. In addition, the infant is positioned prone and fecal contamination is scrupulously avoided [9].

Nonvisible Congenital Defects

Tracheo-esophageal fistula and esophageal atresia are not visible on physical exam. However, signs of excess salivation, respiratory distress, swallowing problems, and abdominal distention will be present. The midwife will be unable to pass a sterile feeding tube more than 10 centimeters.

Midwifery management includes positioning the newborn in a prone position with the head elevated. No oral feedings are given. Aspiration of the esophageal contents by feeding tube attached to a syringe helps to minimize the chance of aspiration into the lungs.

Diaphragmatic hernias are surgical emergencies in the newborn because of the herniation of abdominal contents into the chest cavity. These hernias are usually unilateral on the left. The degree of respiratory distress is directly related to the amount of lung tissue that has been compromised. In some newborns, the herniation is so severe that there has been practically no lung growth on the affected side. The signs of diaphragmatic hernia include decreased left-sided breath sounds, heart sounds on the right, and severe respiratory distress at birth secondary to persistent pulmonary hypertension. Depending on the degree of the defect, the abdominal contents may be in the chest cavity, which causes a concave (scaphoid) abdominal contour.

Midwifery management is emergent and includes endotracheal intubation in the birth room. Use of bag and mask ventilation will only worsen the situation. A feeding tube, preferably attached to low suction, should be passed and taped in place to vent the stomach of air [10]. The pediatric team should be requested immediately.

A variety of congenital defects can lead to intestinal obstruction in the newborn [8, 9]. Among these are malrotation and mid-gut volvulus, meconium plugs, meconium ileus, Hirschsprung's disease, and imperforate anus. With all of these defects, the major diagnostic signs are bile-stained emesis and failure to pass stool. Significant abdominal distention will be present with meconium ileus, meconium plug, and Hirschsprung's disease.

The midwife may receive reports of these symptoms during a home visit or a postpartum phone call. Newborns with these signs should be evaluated immediately by a pediatric caregiver. No oral feedings should be given if there is bile-stained emesis. If neglected, all of these defects can lead to intestinal perforation.

Signs of Drug Exposure in the Newborn

The term drug exposure, when used in reference to a newborn, covers a wide variety of substances and situations, ranging from the most casual exposure to daily, repetitive in-utero exposure. Many at-

tempts have been made to quantify the effects of substance exposure on the fetus and newborn. Most of these studies have had equivocal results or results that were contradicted by other studies.

A large part of the problem in the study of substance exposed fetuses and newborns stems from the reality that few women use only one substance while they are pregnant. Most women are polydrug users, combining various substances in various doses [11]. Also, many substance-using women combine their substance use with other lifestyle patterns that can cause fetal compromise. Factors such as poor nutrition, lack of prenatal care, lack of vitamin supplementation, chronic stress, and environmental exposure to teratogens all affect the fetus.

There are four signs that the newborn may have been significantly exposed to a drug during pregnancy: (1) low term birth weight, (2) dysmorphic physical characteristics, (3) neonatal irritability, and (4) neonatal withdrawal symptoms (see Table 41-3).

Source: From D'Apolito, K., and Hepworth, J. T. Prominence of withdrawal symptoms in polydrug-exposed infants. *J. Perinat. Neonatal Nurs.* 14(4):49, 2001. Reprinted by permission.

Neonatal withdrawal covers a wide spectrum of physiological and neurobehavioral symptoms. The most predictable symptoms occur in the neonate exposed to heroin or methadone.

Newborns who have been exposed to nicotine during the fetal period may be of low birth weight. This results from the effects of both carbon monoxide (leading to relative fetal hypoxia) and nicotine (leading to placental vasoconstriction). The effect on the fetus is dose-related and can be reversed if the mother stops smoking during pregnancy.

Newborns born to alcohol-abusing mothers can suffer serious and permanent damage. Because ethanol readily crosses the placenta, the amount of fetal exposure is high. Damage is on a continuum, and two terms are used to describe the damage: fetal alcohol syndrome (FAS) and fetal alcohol effect (FAE). Newborns exhibiting signs of FAS will have both physical and cognitive damage. Physical damage includes dysmorphic features that are congruent with a midline defect, which occurs early in fetal life. The manifestations of FAE are more subtle and will become obvious when the child is older and has trouble with school or socialization.

The dysmorphic features of the newborn with FAS are primarily facial and include narrow forehead, flat midface, low nasal bridge, short nose, thin upper lip with indistinct philtrum (indentation between top lip and nose), epicanthal folds, and micrognathia. Other signs include palmar creases and low birth weight. These newborns may exhibit behavioral signs including irritability, poor feeding, tremors, and hypersensitivity to stimuli.

The signs of FAS may or may not be obvious during the newborn period. Damage varies with timing and dose of exposure. The midwife who notices physical or behavioral signs that are possibly indicative of FAS should discuss the situation with the pediatric team. These newborns need careful follow-up for failure to thrive. Their behavioral characteristics may make them difficult babies and thus vulnerable to abuse by the mother or other caregivers.

Maternal use of cocaine has been suspected as a cause of many fetal problems, most of them related to the intense vasoconstrictive properties of cocaine, which lead to placental and cord accidents. The known effects of cocaine exposure include behavioral problems related to central nervous system irritability [11]. Cocaine-exposed newborns may be irritable, tremulous, and hard to comfort. They may favor a rigid, hyperextended posture. In short, they will be high-strung newborns who may be difficult to mother. The manifestations of cocaine exposure are related to the amount, duration, and timing of fetal exposure. Third trimester use is more likely to result in residual behavioral effects.

The use of heroin in pregnancy is associated with a clear pattern of neonatal withdrawal called neonatal abstinence syndrome. Heroin is a derivative of morphine, which is extracted from the opium poppy. This opiate is very addictive, and the lives of many pregnant heroin users revolve entirely around finding their next high. Thus fetal exposure to heroin tends to be regular and in increasing doses. The fetus becomes addicted in utero and shows evidence of severe intrauterine withdrawal symptoms if the mother stops using the drug during pregnancy. Rather than stopping use during pregnancy, women are urged to join methadone programs that provide uniform, regular doses of methadone and supportive health care services.

At birth, most newborns born to heroin-addicted women exhibit withdrawal symptoms [12]. These start in the first few days after birth and can persist for many weeks. Because heroin use is often intravenous, these newborns are also at high risk of infection with the hepatitis and HIV viruses.

The symptoms of neonatal abstinence syndrome are multiple and involve many neonatal systems. They include central nervous system irritability, tremors, excess hunger and salivation, sweating, yawning, sneezing, fist sucking, and temperature regulation problems. Some infants progress to seizures and profuse vomiting and diarrhea. These newborns need to be managed by the pediatric team during an in-patient stay. Some management considerations include providing a quiet, nonstimulating environment, a possible increased need for calories and fluids, and potential need for pharmacotherapy to control symptoms [12].

The Midwife's Involvement

A midwife who suspects that a neonate has been drug-exposed should order a urine or blood toxicology screen on both newborn and mother. Some laboratories can also do toxicology screens on newborn hair or meconium. Meconium testing is particularly attractive because of the ease of specimen collection from the diaper. If the sample is frozen, the drugs are stable in the meconium for up to 9 months [13]. The results of the screen will help to guide pediatric management. In some states and localities, a positive toxicology screen must be reported to child welfare officials.

The midwife working with a substance-using woman and her newborn faces a particular challenge. The midwife has to sensitize the new mother to the special needs of her substance-exposed new-

born. Yet being labeled as a drug user may cause the mother to avoid further contact with health care providers. The midwife needs to adopt a nonjudgmental approach as she discusses the substance use with the new mother. The following are of particular concern to the midwife:

1. Does the level of substance use impair the mother's ability to care for the baby?
2. What is the pattern of substance use? Daily, or only on weekends? At home or elsewhere?
3. Are there other responsible adults in the extended family who can become involved in care of the newborn?
4. Is the mother receptive to learning about the special needs of her newborn?

The midwife should help the mother understand that the central nervous system irritability of newborns caused by alcohol, cocaine, and heroin will eventually pass. In this situation a visit from a community health nurse after discharge can be very helpful [14]. These newborns need an environment that is not too stimulating. The mother should be taught the swaddling and calming techniques that were outlined in Chapter 40, page 1025. The midwife has a particular obligation to help the mother identify resources she can rely on if the newborn's fussiness starts to wear on her. If she feels her anger building, the mother should be urged to call the midwifery practice, the pediatric practice, or a hotline number before the newborn is abused.

The midwife should discuss with the mother her readiness to accept treatment. If the mother is not ready, the midwife should encourage her to think about change in the future. The mother should be urged to use adequate contraception.

Infants of Diabetic Mothers

Infants of diabetic mothers (IDM) are at risk for birth injuries and for hypoglycemia. The hypoglycemia results from a hyperinsulinemia characterized by accelerated use of exogenous glucose and diminished endogenous glucose production [15]. This disorder is temporary in the newborn and is lessened if the mother had good diabetic control during pregnancy. These infants may be macrosomic or growth restricted, depending on the severity of the diabetes. For women who were diabetic prior to pregnancy, the infants are at increased risk for cardiac and skeletal birth defects.

Many pregnant women are routinely screened for diabetes as part of their prenatal care. Unfortunately, some women receive inadequate prenatal care and their gestational diabetes is undiagnosed when they present in labor. The midwife looks for the following signs that may indicate an IDM: birth weight greater than 4.0 kilograms, tremors, early jaundice, or unexplained respiratory distress. Lab tests may reveal polycythemia (hematocrit greater than 65 percent).

Newborns who may be IDM need to be carefully screened for hypoglycemia. The midwife should screen these newborns hourly until a value of greater than 36 mg/dL (if asymptomatic) and 45 mg/dL if symptomatic has been consistently obtained for a few hours in succession [16]. Any value of 36 mg/dL or lower is immediately verified by drawing a central sample. The midwife will notify the pediatric team if there are any abnormal blood sugar levels. The pediatric team will need to order intravenous fluids containing dextrose.

Signs of Intrauterine Growth Restriction

Newborns whose weight is below the tenth percentile for gestational age are considered small for gestational age (SGA). Although some of these infants have no underlying reason for being SGA, the majority of them have some underlying cause for their intrauterine growth restriction (IUGR).

Term newborns who suffer from IUGR are subdivided into two categories. Some will show signs of symmetric growth restriction, including both reduced birth weight and reduced head circumference. The symmetrically growth-restricted newborn is affected early in gestation. Some common causes for symmetric growth restriction include chromosomal abnormalities, perinatal infections, and exposure to drugs or environmental teratogens.

Other newborns are considered to have asymmetric growth restriction. These newborns suffered compromise late in fetal life, typically in the third trimester. Asymmetric growth restriction can be caused by any condition that causes decreased placental blood flow or decreased oxygenation of the fetus. Their weight is below the tenth percentile but their head circumference is above the tenth percentile.

Besides weight and head circumference changes, newborns affected by IUGR show signs of subcutaneous tissue wasting. The midwife will be able to gather large skin folds, particularly around the shoulders and upper back. The skin is dry and there is frequently meconium present. These newborns have a characteristic overalert appearance.

Their eyes are very prominent, their skulls firm. Laboratory tests might reveal a compensatory polycythemia.

The Midwife's Involvement

A midwife who suspects that a fetus is SGA must monitor the fetus adequately during labor. These fetuses suffer an increased incidence of fetal distress. Many of them have suffered from chronic hypoxia, which can be made catastrophically worse by the normal hypoxia of labor. At birth, supportive care is given for transition to extrauterine life. The midwife should perform a quick physical examination to look for signs of congenital anomalies or active infection and complete a gestational age assessment. The midwife needs to remember that some of the physical characteristics of the Ballard Scale may be inaccurate because of the intrauterine skin changes of the IUGR newborn. The midwife should rely more heavily on the neurological components of the New Ballard Scale.

Because of the prenatal wasting, these newborns are prone to hypoglycemia and hypothermia. Their glycogen stores may be almost exhausted prior to birth. The midwife should emphasize early feedings. The midwife should screen these newborns hourly until a value of greater than 36 mg/dL (if asymptomatic) and 45 mg/dL if symptomatic has been consistently obtained for a few hours in succession [16]. Any value of 36 mg/dL or lower is immediately verified by drawing a central sample. A neutral thermal environment should be created for the newborn. Some IUGR newborns need an exogenous heat source. Others may stabilize with double wrapping in warm blankets and hats. The midwife should order frequent temperature checks.

The placenta should be saved for possible pathology examination. Cord blood should be saved for possible testing for congenital infections.

PART

VII

Postpartal Care

This page intentionally left blank

CHAPTER

42

The Normal Puerperium

The postpartal period is the time from the delivery of the placenta and membranes (marking the end of the intrapartal period) until the return of the woman's reproductive tract to its nonpregnant condition. Note that this change is to the nonpregnant condition—not the prepregnant condition, as is often said. The prepregnant condition of the organs is gone forever—most strikingly so after the first pregnancy and childbirth experience but also with each subsequent pregnancy.

This period also is called the puerperium, and the woman progressing through the puerperium is called a puerpera. The period of postpartum recovery lasts approximately six weeks.

Database for the Puerperium

The components of the database for determining the well-being of the postpartal woman are as follows:

1. Continuing evaluation of any significant findings or developments during the antepartal and intrapartal periods
2. Evaluation of the physiological and anatomical changes of the puerperium
3. Evaluation of the woman's vital signs and other physical signs, symptoms, and changes
4. Evaluation of the mother's and father's response to their baby and their preparation for caretaking
5. Evaluation of the woman's behavioral changes and psychological responses to childbearing
6. Continued screening for signs and symptoms of obstetric or medical complications (see Chapters 24 and 29 for the database necessary for this screening)

In order to evaluate any of the components of the database you must know how to recognize the normal parameters and expected changes in each of these aspects of the woman's life.

Physiological and Anatomical Changes of the Puerperium

Although the term *involution* has been used to refer to the retrogressive changes taking place in all of the organs and structures of the reproductive tract, it refers more specifically to the retrogressive changes in the uterus that lead to its reduction in size. For the sake of clarity, the definition of *puerperal involution* will be limited to the uterus, and what happens to other organs and structures simply will be referred to as *puerperal changes*.

Uterus Involution of the uterus involves the reorganization and shedding of the decidua/endometrium and the exfoliation of the placental site as evidenced by the decrease in size and weight and change in location of the uterus and by the color and amount of the lochia. The amount of lochia and the speed of involution are not affected by the administration of a series of ergot preparations (Ergotrate, Methergine), which have only short-term effect. However, breastfeeding will speed the process of involution. The decidua remaining inside the uterus after separation and expulsion of the placenta and the membranes consist of the zona basalis layer and a portion of the zona spongiosa layer of the decidua basalis (at the placental site) and the decidua parietalis (lining the remainder of the uterus). This remaining decidua reorganizes into two layers as the result of invasion by leukocytes: a degenerating, necrotic, superficial layer, which will be cast off as part of the lochial dis-

charge, and a healthy, functional, deep layer next to the myometrium. The latter layer consists of the remnants of the basilar endometrial glands in the zona basalis layer. The endometrium will be regenerated by proliferation of the epithelium of these glands. Regeneration of the endometrium is completed by the middle or end of the third postpartal week except at the placental site.

Complete regeneration of the endometrium at the placental site takes approximately six weeks. The epithelium grows in from the sides of the site and from the surrounding uterine lining, and up from beneath the placental site. This growth of the endometrium in effect undermines the thrombosed blood vessels at the site, causing them to slough and be cast off in the lochial discharge.

The uterus, immediately after delivery of the baby, placenta, and membranes, weighs approximately 1000 g. The uterus decreases in weight to approximately 500 g by the end of the first postpartal week, and to its usual nonpregnant weight of 70 g by the eighth week postpartum.

This rapid decrease in size is reflected in the changing location of the uterus as it descends out of the abdomen and again returns to being a pelvic organ. Immediately after delivery, the top of the fundus is approximately two-thirds to three-fourths of the way up between the symphysis pubis and the umbilicus. It then rises to the level of the umbilicus within a few hours. It remains at approximately the level of (or one finger-breadth below) the umbilicus for a day or two and then gradually descends into the pelvis, being nonpalpable above the symphysis pubis after the tenth day. Although there is individual variation of the location of the umbilicus in relation to the symphysis pubis and individual variation in the breadth of the fingers from examiner to examiner, thereby creating a range of normal in the descent and daily location of the fundal height, there is enough similarity to allow the generalization of uterine descent illustrated in Figure 42-1.

Any time the top of the fundus is above the umbilicus, the following problems should be considered: blood or blood clots distending the uterus in the early postpartal hours, or displacement of the uterus by a distended bladder at any time postpartally (especially if the uterus is also displaced to the right upper quadrant). The reduction in the size of the uterus does not decrease the number of muscle cells. Instead, each cell dramatically decreases in size as it rids itself of excess cellular material.

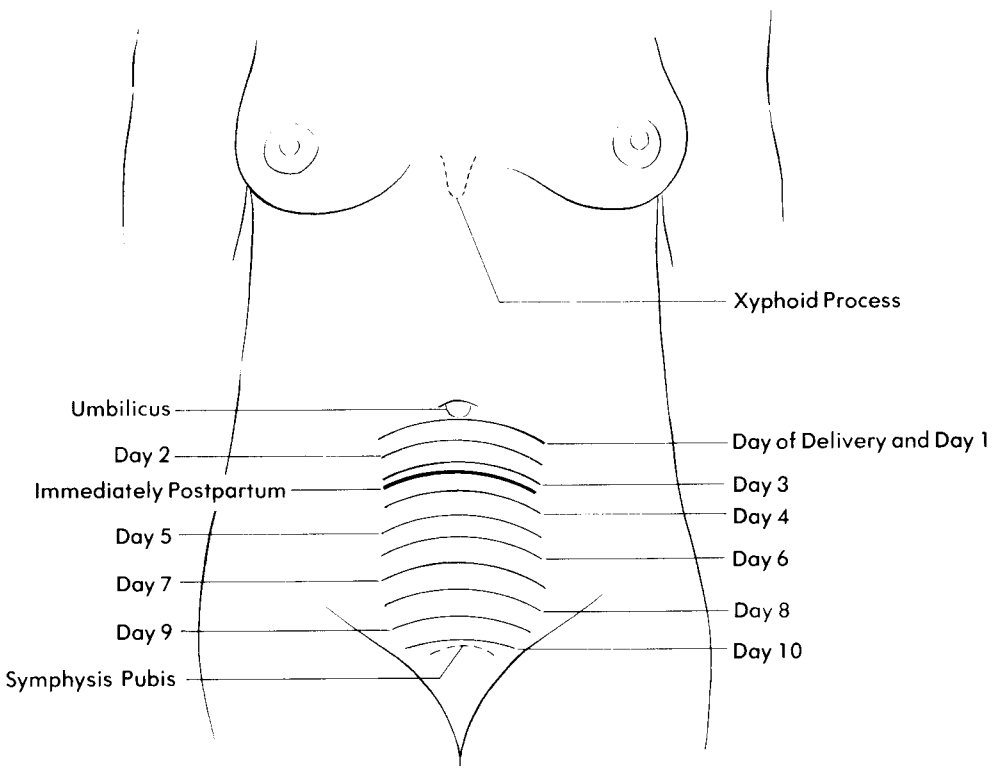

FIGURE 42-1 Fundal height and uterine involution.

The large uterine blood vessels that nourished the growing uterus and the placenta are no longer needed; the nonpregnant uterus does not have a large area that requires such a rich blood supply. These blood vessels degenerate and become obliterated. They are thought to be replaced by new blood vessels with smaller lumina.

Immediately after delivery, the cervix is extremely soft, flabby, and floppy. It may be bruised and edematous, especially anteriorly if there was an anterior lip in labor. It looks congested, reflecting its great vascularity. It assumes a loose form and readily admits two to three fingers. It regains some of its form within the first day and becomes less soft. The cervix continues to admit two fingers for about a week but thereafter admits one finger with difficulty, and even that is stopped now at the internal os. The external os has assumed its nonpregnant form by the fourth postpartal week. This form is determined by parity and the presence of lacerations.

The broad and round ligaments, which stretched to accommodate the uterus during its increase in size, are now lax. This accounts for the easy displacement of the postpartal uterus by the bladder. By the end of the puerperium, the ligaments have regained their nonpregnant length and tension.

Lochia Lochia is the name given to the uterine discharge that escapes vaginally during the puerperium. As it changes color, its descriptive name changes; lochia is rubra, serosa, or alba. Lochia rubra is red because it contains blood. It is the first lochia that starts immediately after delivery and continues for the first two to three days postpartum. Lochia rubra contains primarily blood and decidual tissue.

Lochia serosa starts as a paler version of lochia rubra, serous and pink. It ends approximately seven to eight days later as a pink, yellow, or white color as it makes the transition into becoming lochia alba. Lochia serosa contains primarily serous fluid, decidual tissue, leukocytes, and erythrocytes.

Lochia alba starts about the tenth postpartum day and resolves over a period of two to four weeks. In some women it will still be present at the time of the postpartum examination. It is creamy white and consists primarily of leukocytes and decidual cells.

Lochia has a characteristic odor not unlike that of the menstrual flow. This odor is strongest in the lochia serosa. It is stronger if mixed with perspiration and must be carefully differentiated from a foul odor indicative of infection.

Lochia begins as a heavy discharge in the early postpartum hours. Subsequently it decreases to a moderate amount as lochia rubra, a small amount as lochia serosa, and a scant amount as lochia alba. It is common for a woman to have a small amount of lochia while lying down and to bleed more heavily or to pass small clots when she gets out of bed. This is the result of pooling in the upper vaginal vault when the woman is in the recumbent position. Pooling is associated with clotting, particularly on the first days after the birth. The average total amount of lochial discharge is approximately 8 to 9 oz (240 to 270 mL). Variation in duration of lochial flow is not uncommon. However, the daily trend should be to a lighter flow, which is changing from bright to dark red, to brown, to pink. The sudden recurrence of bright red vaginal bleeding is not a normal finding and requires evaluation. Causes include excessive physical activity, retained placental or membranous products, and uterine atony.

Vagina and Perineum Immediately post delivery the vagina remains stretched open, may have some degree of edema and bruising, and gapes at the introitus. Over the first one to two days postpartum, it regains enough tone that it does not gape so widely and is no longer edematous. It is now smooth-walled, larger than usual, and generally lax. Its size decreases with return of the vaginal rugae by about the third postpartal week. The vaginal space will always be a little larger than it was prior to the first childbirth. However, perineal muscle tightening exercises will restore its tone and enable the woman to deliberately tighten her vagina. This can be accomplished by the end of the puerperium with daily practice.

Abrasions and lacerations of the vulva and perineum heal readily, including those needing repair (see Chapter 79).

Breasts Lactation is initiated in all women by the hormonal changes of childbirth. Whether a woman chooses to breastfeed or not, she may experience engorgement over the first few postpartum days as her body prepares to nourish the infant it just bore. Women who breastfeed respond to the stimuli of the nursing infant with further hormonal release and stimulation of the milk producing alveoli. For women who choose to formula feed, involution of the breast tissue occurs with avoidance of stimulation. Chapter 43 discusses the breast changes asso-

ciated with breastfeeding and the options for infant feeding in detail.

Assessment of the breast in the early postpartum period includes appearance and integrity of the nipples, bruising or irritation of breast tissue from the infant's position at breast, presence of colostrum, whether the breasts are filling with milk, and any evidence of clogged ducts, engorgement, and signs of potential mastitis.

Vital Signs and Other Physical Signs, Symptoms, and Changes

Blood Pressure Immediately following delivery, many women experience a transient rise in both systolic and diastolic blood pressure, which resolves spontaneously to the prepregnancy baseline over several days. The midwife is responsible for assessing the risk of postpartum preeclampsia, a relatively rare but serious complication, when the blood pressure elevation is significant.

Temperature The maternal temperature returns to normal from its slight elevation during the intrapartal period and stabilizes within the first 24 hours postpartum.

Pulse The pulse rate, elevated during late labor, resolves over the first few hours postpartum to its normal level. Hemorrhage, fever during labor, and acute or persistent pain may affect this process. Any pulse rate above 100 during the puerperium is abnormal and may be indicative of infection or delayed postpartal hemorrhage (see Chapter 44).

Respiration Respiratory function resolves to the woman's normal range during the first hours postpartum. Shortness of breath, rapid respirations, or other changes warrant evaluation for conditions ranging from fluid overload, to an asthma exacerbation, to pulmonary embolus.

Renal System Changes The renal pelves and ureters, which were stretched and dilated during pregnancy, return to normal by the end of the fourth postpartal week.

Immediately postpartum the bladder is edematous, congested, and hypotonic, which may result in overdistention, incomplete emptying, and excessive urine residual unless care is taken to ensure periodic voiding. Rarely is the urethra obstructed, but it may be insensitive as a result of prolonged labor with the fetal head in the pelvis. Unless the woman develops a urinary tract infection, the effects of labor on the bladder and urethra diminish within the first 24 postpartal hours.

Approximately 40 percent of postpartal women have nonpathological proteinuria from immediately postdelivery up to the second day postpartum. The specimen must be obtained as a clean-catch or from catheterization, as lochial contamination will also produce proteinuria. Benign proteinuria can be assumed only in the absence of signs and symptoms of a urinary tract infection or preeclampsia.

Diuresis begins shortly after delivery and lasts up to the fifth day postpartum. The urine output may be more than 3000 mL per day. Diuresis is the body's primary route for discarding excess interstitial fluid and excess blood volume. This is also the explanation for a rather profuse perspiration that may occur during the early postpartum days.

Weight Loss Women lose an average of 12 lb at the time of delivery. This loss represents the accumulated weight of the baby, placenta, and amniotic fluid. Another 5 lb may be lost during the first postpartal week as a result of fluid loss. One study has found that the majority of women approach their prepregnancy weight by 6 months postpartum. The single greatest determinant of postpartum weight loss was pregnancy weight gain, with those who gained the most losing the most. However breastfeeding, commonly reported to influence weight loss after childbirth, did not have a significant effect in this study. On average, multiparous women lost less weight [1].

Gastrointestinal Changes Women may be hungry and ready for a meal an hour or two after delivery. Barring complications of delivery, there is no reason to delay feeding healthy postpartum women longer than it takes to make an initial assessment.

Constipation may be a problem in the early puerperium due to a lack of solid foods during labor and self-restraint in defecation. The woman may practice self-restraint because her perineum is sore or because she lacks knowledge and is afraid she will rip open or tear out her stitches if she has a bowel movement.

Abdominal Wall The abdominal striae are never eradicated completely but they do change to fine, silvery-white lines over a period of several months.

The abdominal walls are flabby after delivery because of their stretching during pregnancy. All puerperal women have some degree of diastasis recti—the separation of the rectus muscles of the ab-

domen. How severe this diastasis is depends on a number of factors, including the woman's general condition and muscle tone; whether the woman exercises to regain her abdominal muscle tone and close the diastasis after each pregnancy; her parity (regaining complete muscle tone becomes increasingly difficult with increasing parity); the spacing of her pregnancies (whether she had time to regain her muscle tone before another pregnancy); and whether her pregnancies have overdistended her abdomen (e.g., multiple gestation). These factors also determine how long it will take her to regain her muscle tone. It takes longer to regain muscle tone from a diastasis that is five fingerbreadths wide than it does from a diastasis that is two fingerbreadths wide. In the latter instance, it is possible to have closed the diastasis by the end of the puerperium. (See "Postpartal Abdominal Examination" in Chapter 53, for a discussion of evaluating and measuring diastasis recti and how to motivate a woman to exercise.) If abdominal wall muscle tone is not regained, the space between the rectus muscles fills in with peritoneum, fascia, and fat. The woman then does not have good muscle support in subsequent pregnancies, which accounts for the pendulous abdomen often seen in a multipara. This condition may lead to extreme back pain for the woman and difficulties with engagement of the fetal presenting part at the time of labor and delivery in the next pregnancy.

Hematological Changes Leukocytosis, which elevated the white blood cell count to 15,000 or above during labor, continues with an elevated WBC for the first two days postpartum. The white blood cell count may further increase to 25,000 or 30,000 without being pathological if the woman had a prolonged labor. However, infections should be ruled out in the presence of significantly elevated WBC.

The hemoglobin, hematocrit, and erythrocyte count vary widely in the early puerperium as a result of vacillating blood volume, plasma volume, and red cell volume levels. These levels are affected by the woman's current state of hydration, the volume of fluids she had during labor, and her normal reduction in total blood volume from its elevated state during pregnancy. These factors render the hematocrit less effective as a measure of blood loss for at least two to four days postpartum. However, if the hematocrit in the first day or two postpartum is lower by two or more percentage points than the hematocrit done upon entry into labor, there has been a significant blood loss. Two percentage points is roughly the equivalent of a unit (500 mL) of blood loss. There is a reduction of approximately 1500 mL in total blood volume during delivery and the puerperium. Not all of this is blood loss; there is a reduction in volume as the accumulated fluid load of pregnancy is lost through diuresis, increased perspiration, and a return to the normal nonpregnant function of the renal system. Of the total, approximately 200 to 500 mL of blood may be lost during delivery, another 500 to 800 mL of volume during the first postpartal week, and the last 500 mL over the remainder of the puerperium. Lochia itself makes up less than a quarter of the total loss.

Normal nonpregnant levels for all the constituents of the blood are reached by the end of the puerperium.

The Mother and Father's Response to Their Baby and Preparation for Caretaking

The response of each mother and father to their baby and to their experience in childbearing is different and covers the entire spectrum of reactions and emotions, from the heights of boundless joy to the depths of despair and grief. The scenarios are endless and reflect individual circumstances in life. The midwife enters into the joy in situations that meet expectations or are happy or quietly satisfying. When the response is not joyful, the midwife needs to understand what is occurring and to facilitate a healthy process of working through the response for the well-being of each parent, baby, and family. It helps to keep a few basic thoughts in mind:

1. Attachment does not begin at birth. The mother nurtures her baby throughout pregnancy. Both the mother and the father fantasize about their baby during (and often before) pregnancy.
2. Birth is a moment in the continuum of the mother's bond with her baby.
3. The relationship between a mother and her baby is symbiotic; each needs the other.

Early Attachment and Bonding It has long been known that animals demonstrate a pattern of behavior in accepting their newborn and that certain intervening variables alter this pattern and end in rejection of the newborn. The description of this behavior as species-specific reflects the fact that the pattern of attachment behavior differs from species to species.

How a human mother and father behave toward their newborn is influenced in part by internal factors, which they bring into the situation, and in part by external factors, which occur at the time. The internal factors include how the individuals were cared for by their own parents; their genetic endowments; internalized cultural practices, mores,

and values; relationships with each other, families, and significant others; previous pregnancy and bonding experiences; the identification work done during this pregnancy (identifying themselves as parents, identifying the baby as theirs, fantasizing parenthood, etc.); and the effect of the course of the pregnancy on this work. The external factors include the care received during labor, delivery, and postpartum; the attitudes and behaviors of attendants; the responsiveness of the infant; the newborn's condition; the practices of the attendants and institutions; and whether the parents are separated from the baby during the first hours or days of life.

There are basically three sequential time periods during which attachment and bonding between parents and baby develop and take place, each encompassing a series of events: (1) the prenatal period; (2) the time of birth and immediately following birth; and (3) the postpartal and early caretaking period. Delineating these three time periods does not negate the influence of the prepregnancy period, both in shaping parental attitudes and role anticipation from birth to present parenthood and in the formation of the thoughts and dreams that go into planning a pregnancy; nor does it negate the continuing reciprocal responses, strengthening of bonds, and changing roles occurring throughout life after the postpartal period.

The Prenatal Period It is during the prenatal period that the woman accepts the fact of pregnancy, delineates her mothering identity as separate from that of her own mother's, verifies the pregnancy and identifies the baby as an individual separate from herself, dreams and fantasizes about the baby, and makes preparations for the baby. These psychological processes and events are discussed in Chapter 21. The father experiences a similar sequence of events.

The Time of Birth and Immediately Following Birth This period starts with labor because what happens during labor directly affects the attachment process at birth. The most obvious factor from labor that can affect attachment and bonding during this period is medication. Attachment processes are thwarted if both mother and baby are "sleepy" from medication. The mother's active participation and involvement during labor sets the stage for taking-in and reception of the baby at birth (Figure 42-2). The bonding between the mother and father that results from the power of the shared labor experience strengthens and facilitates postbirth family bonding.

Figure 42-2 Mother receiving her baby at birth.

The actual taking-in and touching of her baby may begin with the mother's touching her baby's head at the introitus shortly before birth. Even when the baby is placed in a skin-to-skin total body contact position on the mother's abdomen immediately after birth or when the mother has reached out for her baby, there is a definite sequence in her touching of the baby. The speed of this sequence may vary. The basic direction is from peripheral actions and position inward to central actions and position. This touching sequence starts with the mother's fingertips touching the baby's extremities in an exploratory, questioning manner; progresses as she places the palms of her hands on the baby's trunk and then encircles the baby's trunk with both hands; and ends when she encloses and encompasses the entire baby within her arms.

Other attachment and bonding behaviors in the immediate postbirth period include establishing mutual eye contact and spending time in the *en face* position, talking to the baby in a high-pitched voice, comparing the baby to the baby fantasized and dreamed of during pregnancy (this comparison usually starts with the sex of the baby), and using the baby's name.

These behaviors mesh with the unmedicated newborn's capabilities. This meshing enables a responsiveness that establishes a reciprocal and rein-

forcing two-way interaction between parent and child. The capabilities of the newborn are facilitated because the baby is in a quiet-alert state during the first hour after birth. This makes the baby receptive to stimuli and constitutes a sensitive time for the baby corresponding to a sensitive time for the mother during the first hour postpartum. The baby can see at birth and is able to follow a moving object visually at an optimal distance of 10 to 12 in. This corresponds to the distance the baby is usually held in the *en face* position and results in reciprocal eye contact and mutual gazing. The high-pitched voice the mother uses corresponds to the baby's ability to hear especially well in the high-frequency range.

The attachment behaviors of the father also follow an orderly progression. Unlike the mother, who may be in constant intimate contact with her baby, the father is peripheral to the central interaction between mother and baby. This is evidenced in the series of behaviors that bring him to the same touching sequence described for the mother and into his own central interaction and bonding with the baby. This series of behaviors starts with a hovering posture over the baby. In this position he visually latches on to the baby with an intensity that is only briefly and infrequently diverted during the first few minutes immediately after birth. The father's hands and fingers may be positioned in readiness toward the baby and he gets as close as possible to a face-to-face position with the baby who is in an *en face* position with the mother. He establishes fingertip contact with the baby, leading to palm contact. When he holds the baby he positions himself *en face* for eye contact and mutual gazing (see Figure 37-2).

The Postpartal and Early Caretaking Period A relationship develops over time and depends on the participation of both parents in the relationship. Reciprocity and reinforcement from circular communication lead to learning what to expect from each other and to the development of trust. Caretaking ability resulting in a healthy, responsive baby inspires fulfillment, confidence, and feelings of competence and success within the caretaker. The satisfied, loved baby learns the feeling of self-worth and gains the confidence to learn and to adapt. Early learning has a direct relationship to early caretaking.

The mother and father go through a process in making the transition into parenthood. The process starts before pregnancy with the anticipation of someday being a parent and visualizing themselves in this role. This anticipation intensifies during pregnancy as they start to make decisions that will affect their baby and their childbirth experience—for example, choosing a health care provider and locale of birth; attending preparation for childbirth and parenthood classes; the woman's second trimester evolution from a care receiver from her mother to a caregiver, preparatory to being a mother; and seeking role models for how to mother or father.

A study of participants in childbirth classes found that many parents-to-be expressed concern over their ability to parent, or their partner's ability to parent, or how they would cope with parenting [2]. Women were more likely to report concern about postpartum physical appearance, while the fathers expressed concern about the infant's effect on work and personal time. Men also were concerned about whether the women would be "bored or lonely" while at home with a newborn. While these results cannot be generalized to all pregnant couples, they suggest that prenatal interventions that support bonding and preparation for the realities of parenting may support the transition.

The observational work of Kennell and Klaus has emphasized the importance of a labor support person to healthy newborn interactions [3, 4]. While human mothers do not have a set window of time for bonding with their infants, early receptiveness is certainly a way to facilitate the sort of relationship in which stressors such as establishing breastfeeding can be better tolerated. Peterson and Mehl surveyed new mothers and reported that the length of mother-infant separation, birth experience, length of labor, and prenatal expectations all affected how quickly mothers became attached to their children [5].

When the baby is born, parents undergo a period of learning the behaviors of and cues from their baby. For first-time parents, it also is a time of awkwardness and insecurity in the skills of caretaking as well as beginning to grasp, and cope with, the responsibilities and functions of the parental role. Caretaking behaviors are largely under the influence of others and, especially for the mother, may be determined by how others want her to function. This period may last several weeks until the parents have learned appropriate responses to their baby's cues and have begun to develop their own style of parenting, individually and as a team. Klaus and Kennell cite the work of Winnicott to describe what he termed "primary maternal preoccupation," a pe-

riod of heightened maternal awareness of the newborn's needs, lasting for several weeks [6]. The need for nurturing, protective behaviors from those around the mother to allow her this time of awareness was emphasized.

The end point is attainment of the parental role, the time at which the role is accepted and internalized and the parents are comfortable both with the role and with their own style of parenting, which may not occur until four to six months following the birth.

Behavioral Changes and Psychological Response to Childbearing The mother experiences extensive physical and physiological changes: she has made enormous adjustments of both her body and her psyche, has undergone extraordinary stimulation and excitement, is in the process of exploration and assimilation of the reality of her baby, is under pressure to absorb quickly the learning necessary for her to get to know and care for her baby, and feels the awesome responsibility she has assumed now made real and the demands placed on her to "mother." Small wonder that she may have a few behavioral changes and at times feel a bit overwhelmed by it all. It is a time of vulnerability and being open to guidance and learning; at the same time the new mother may be frustrated by not feeling competent and in control. All women experience these changes, but their intensity and how well a particular woman copes with them may vary depending on her locale when they are taking place. In the home, a woman learns and makes adjustments in the security and comfort of her own environment where she can exert control. In the hospital, these supports are lacking, and the feelings of frustration and vulnerability may develop into what has become known as the postpartum blues.

Grief is the other end of the continuum of the intense emotions possible in childbearing. The most intense grief comes with death of the baby, no matter when in the pregnancy. Fetal death is sudden and unexpected. A midwife must understand a mother and father's psychological response in order to help them grieve in a healthy way.

Postpartum Blues (Baby Blues) The phenomenon of early postpartum or baby blues is a common sequela of childbirth, occurring in up to 70 percent of all women [7]. Various causes have been proposed, including an unsupportive birth environment, rapid hormonal changes, or insecurity in a new role. None of these has been demonstrated to be a consistent underlying cause. It is possible that all of these, plus the inevitable sleep deprivation experienced by new mothers, play a role in this process.

In any event, postpartum blues typically begin a few days after birth and resolve by 10 to 14 days. Characteristics include weepiness, feeling let down by the experience of birth, agitation or restlessness, mood swings, distancing, and negative reactions to their child or family. Because birth is portrayed as a "peak" experience, the new mother may perceive herself as inadequate or as not having been properly cared for, if her imagined birth does not match her experience. She may also feel ignored if her family suddenly focuses attention on the new baby.

The key to supporting a woman through this period is consistent support from family and caregivers, reassurance that she is not "going crazy," and opportunities for increased rest. Additionally, positive reinforcement of her successes in parenting the newborn can help restore her confidence in her abilities.

Among the purposes of early postpartum telephone contact by the midwife or early clinical visits is the assessment of maternal mood. Baby blues, by definition, are self-limiting. Persistent depressed mood past the first few weeks postpartum requires assessment for postpartum depression.

Grief Grief is a psychological response to loss. The grief process consists of the identified stages or phases of this response. Grief work, a term coined by Lindemann [8], refers to the task of moving through the stages of the grief process to a resolution of the grief in the formation of new significant relationships. Grief is normal, and grief work is essential to keeping grief normal. Failure to do grief work, usually because of a desire to avoid the intense pain and distress of grief and its full emotional expression, often leads to a morbid, or pathological, grief reaction.

Grief varies considerably, depending on what the loss is and the individual's perception of and involvement with whatever is lost. "Loss" may run the gamut from the cancellation of a planned-for event (for example, a picnic, trip, or party) to the death of a loved one. How severe a loss is depends on the perception of the individual who has suffered the loss. The degree of loss to the individual is reflected in the response to the loss. For example, a death may induce a small or large grief response, depending on an individual's relation and involvement with the person who has died.

Maternity losses include those experienced by women with infertility problems (women who are unable to become pregnant or unable to maintain a pregnancy); those that involve losing the baby

(through abortion, miscarriage, stillbirth, giving the baby up for adoption); those that have a viable baby but have a loss of expectations (because of prematurity, congenital deformities/abnormalities); and the losses discussed as causative factors of postpartum blues (loss of internal intimacy with the baby, loss of attention). Another important loss (which is sometimes overlooked) accompanies the change from the exclusive relationship between the father and mother to a threesome involving mother-father-child.

The manifestations and feelings of grief in adults are quite uniform and the process follows a definite pattern. There is, however, considerable movement between the stages of grief, with the intensity of the first and second stages diminishing as a person does grief work and moves toward resolution. The time line for movement through the stages of grief varies for each individual based on the nature of the relationship and the intensity of the loss.

The first stage of grief is shock, which is the individual's initial response to the loss (Figure 42-3). Behavioral manifestations and feelings include denial, disbelief, despair, anger, fear, anxiety, guilt, emptiness, aloneness, loneliness, sadness, isolation, numbness, crying, introversion, irrationality, hostility, hatred, bitterness, acute awareness, lack of initiative, mechanical actions, alienation, betrayal, abandonment, frustration, rebellion, and lack of concentration. Physical manifestations include waves of somatic distress lasting 20 to 60 minutes, sighing, weight loss, anorexia, fitful sleep, fatigue, restlessness, haggard and drawn appearance, tightness in the throat, choking, shortness of breath, nagging and tormenting chest pain, internal quivering, generalized weakness, and specific weakness in the legs.

The second stage of grief is suffering, the phase of reality (Figure 42-4). Acceptance of the fact of the loss and adjustment to the realities this imposes

For Our Emily

Sweet Emily
in eager dreams,
in giddy accord
we wished for you.

In delicious tenderness,
in fiery loving
we made you.

In blossoming roundness,
in serene closeness
we grew you.

In joyous preparation,
in gladsome anticipation
we awaited you.

In unbelieving shock,
in agony of grief
we lost you.

And now, in wrenching sorrow,
in aching emptiness
we must part from you and learn to live
without you.

Lois Lake Church, mother
April 7

So much anticipation and so much joy
so much hard work and concentration
so great an effort.
Such breathing energy
such loving unity
such caring teamwork
breathing
inhale
exhale
in and out
then urgent, necessary pushing,
thrusting forth, stretching,
straining till no straw might be added.
A beautifiul and magnificent effort
finally ends; through!
Triumphant!
And lovely,
O, so lovely
but absolutely silent
and terrible.

Allan Southworth Church, father
April

Not Mine

Powdery scent, apricot-soft skin
of someone else's infant;
toddler-round cheeks and sturdy legs,
damp hair clinging in curls
to nape of neck—
child of another woman's body.
Father swooping his girl aloft,
voices bubbling, blending in glee—
not my husband, nor my child.
Babydoll sprawled on car's seat
—not my daughter's,
nor tiny dress of calico,
painstakingly smocked, lovingly pressed.
Not of my family, the long hair to braid and beribbon,
the child of my gender
to nurture to womanhood.
Mine only, the big-belly memories,
mine the not-to-be-fulfilled dreams.

Lois Lake Church, mother

occur during this period—for example, the grieving person adjusts to the environment without the presence of the loved one or accepts the fact of a deformity and makes necessary adjustments in living and plans because of it. During this time there is preoccupation with and idealization of the lost object. The events leading to and surrounding the loss are relived again and again. The why, what if, and how questions are asked repeatedly and arouse feelings of anger, guilt, and fear, respectively. The pain of loss is felt in its totality, in prolonged reality, and in the memories each day, date, and event evoke. Full expression of emotion is essential to a healthy resolution. Crying is a common form of release. The pain of suffering comes in waves—frequently or less frequently, anticipated or unexpectedly—the intensity of the pain relinquishing with agonizing slowness. During this time, the grieving person's life goes on. As the individual continues to do grief work, preoccupation with the loss gradually changes to anxiety about the future.

The third stage of grief is resolution, the phase of establishing new significant relationships. During this period, the grieving person accepts the loss, adjustment is completed, and the individual is again fully functional. This progress results from the person's reinvesting emotions in other significant relationships. Reinvestment of emotions does not mean that the lost object has been replaced. Rather, it means that the individual is once more capable of investing in and forming other significant relationships. With resolution, the person's behavior becomes again a matter of free choice, whereas during suffering behavior was determined either by social convention or by internal restlessness.

Behavioral manifestations of a morbid or pathological grief reaction include avoidance and distortion of normal emotional expression of grief, agitated depression, psychosomatic conditions, acquisition of the symptoms of the last illness of the deceased, activities that are detrimental to the individual's social or economic existence, lasting loss of acceptable patterns of social interaction, morbid attachment to the possessions of the deceased, and persistent loss of self-esteem.

When the maternity loss is the death of the baby, it is essential that the parents experience the reality of the baby's existence in order for them to be able to accept the reality of the baby's death. Otherwise, the entire pregnancy-life-death sequence becomes the subject of fantasy, imagination, and a dream-mirage type of illusion, which is difficult to grasp and even more difficult to accept and resolve. Women periodically fantasize about pregnancy, birthing, and parenting (regardless of whether they actually desire to experience them) throughout life, including long before actual conception and childbearing. Conception and recognition of the fact of pregnancy (wanted or unwanted) reawaken, activate, or accentuate these fantasies. Quickening intensifies the fantasies, as a living presence makes itself known. The fantasies now begin to include specific physical and personality characteristics of the child, dreams of parent-child interactions, and projections of the child's growth, maturity, and life. Often the family and environment are reorganized in preparation for the expected baby. Then death strikes—and there is no solace for the grief over the now-empty womb. The loss is not only the actual baby but also the loss of all the dreams and fantasies extending far into the future (Figure 42-5). There is also a real sense of loss of part of one's self, which enhances the feeling of worthlessness to which all who grieve are vulnerable. Actions that help parents experience the reality of their baby's existence and thus facilitate healthy grieving include

O Emily, we wanted to show you
the world's wonders,
but now your sweet blue eyes
will never see
the glories of the sunset,
the miracle of spring's first flowers,
your papa's loving face.

We wanted to help you know
the sounds we love,
but now your tiny ears
will never hear
a lacy fugue of Bach,
the morning song of birds,
your brother's laughter.

We wanted you to taste
all of life's flavors,
but now your rosebud mouth
will never know
the sweet milk I have for you,
a plump juicy raspberry,
the tang of ocean waves.

We wanted you to touch and try
all textures and tasks,
but now your graceful hands
will never play a note of music,
stroke a cat's fur,
slip trustingly into mine.

Our Emily, we wanted to teach you
how to love,
but you already know
the love that created you,
the joy that nurtured you,
the strength that birthed you,
And these will be yours forever.

In love and sorrow,
your mama,
Lois Lake Church

having them see, touch, and hold the dead baby; encouraging them to name the baby; giving them a set of footprints, photographs, a lock of hair; and encouraging them to have some form of funeral and burial service.

When the maternity loss is a loss of the parents' expectations of a perfect child because of deformities or abnormalities, it is essential that the parents grieve the loss of their perfect child and all the fantasies and dreams they had about their baby's appearance and potential. This grieving is essential if the parents are to be free to accept and bond themselves to their imperfect child. This is a long, painful process that takes place over time. Parents of a child with anomalies also suffer loss of self-esteem during their grief process resulting from their perception that their child's imperfection reflects negatively on them. Resolution includes acceptance of each family member's individual characteristics, development, and potential as separate from one's own.

A midwife can help the parents grieve and thus facilitate their attachment to the imperfect child by providing a safe, patient, listening, facilitative environment for ventilation of their negative feelings and hostility toward, and rejection of, their baby as well as anger toward the hospital, health care professionals, God, themselves, and others. It is important also to accept the other behavioral manifestations of grief, such as parents' need to repeatedly relive and retell their experience and feelings, and their need for full and accurate information about the causes and implications of their child's anomalies. Other actions include the health professional's acceptance of the baby, recognition of the baby's individuality and other characteristics, and genuine caring for the imperfect baby. Midwives should take cues from the parents as to their readiness to care for their infant and then ensure that their initial caretaking experiences are as positive as possible. It is important to encourage and facilitate the sharing of grief, caretaking, and open communication between the parents, and to provide information and assistance that will allow parents and siblings to cope realistically. Midwives can also help the couple identify and make good use of family and community sources of support. The parents should be referred for genetic counseling if indicated.

Siblings in the home should be told the truth about the loss so they have an honest explanation of their parent's behavior. Otherwise, they may fantasize that they are the cause of a horrible, unknown problem. Siblings need to be reassured that whatever has happened is not their fault and that they are still important, loved, and cared for.

The midwife's first major responsibility in the event of a loss is to share this information with the parents. Families may sense instantly when something is not right at birth; there is a stillness in the

room, an unnatural quietness and sadness in those attending the woman. In the event of death, there are no baby sounds. The mother has a right to as much information as we have—then, not later. Truth and reality are far more compassionate than false reassurance or concealment.

The midwife should also encourage and create a safe environment for emotional expression of grief. This means arranging privacy and taking the time to stay with the parents, to share in their grief, to cry with them, and to listen. This is a continuing commitment to the parents, and the midwife should plan additional visits to listen as they relive their experience, to provide information about the grief process and the facts pertaining to their loss, and to assess that their grieving is healthy and without manifestations of a pathological reaction.

When the loss occurs at an early stage of pregnancy, the midwife may still be called on to participate in care. Because the rituals of birth and death are less evenly offered with miscarriage, and because many otherwise supportive persons do not recognize the depth of parental loss, families may find themselves without their usual support. Grief often appears more intense, with increased sensations of guilt. There may be resurgences of grieving with future pregnancies, or around the time of the anticipated birth [9]. Additionally, when families make the decision to end a pregnancy early because of fetal abnormalities, their grief closely resembles those of women who have a spontaneous loss, and they may require assessment for postpartum depression [10]. Offering families telephone contact and the opportunity for counseling in the office during the weeks following an early loss can contribute to the healing process. Following an initial visit at the time of the loss with an opportunity to talk with one of the few people able to validate the reality of the lost child may help speed the grieving process [11].

It is always difficult for midwives who have been at a birth with a poor outcome, such as a fetal or newborn loss, or who have assisted families through the their own grief, not to question their own skills. This is a normal response, and the trust relationship that the midwife has built during a pregnancy may magnify his or her own grief. Nonetheless, the midwife must be part of the support system for the family; to avoid them at this time is to foster their fears and doubts. Reviewing care provided to be sure that it meets the standards of care is only one part of addressing one's own feelings after such an event. The midwife herself may need collegial support as she deals with her own emotions.

Although all health care providers are cautioned about not discussing the care provided when there has been an "adverse" outcome—the language used to describe a dead or injured newborn—protected mechanisms exist for review of clinical cases as well as resources for counseling.

Management Plan for the Puerperium

Management of care during the puerperium includes management of care during the early puerperium, guidance for the remainder of the puerperium, conducting or arranging for home visits as indicated, conducting the two-week postpartum visit, and conducting the four- to six-week postpartum examination. Specifically the midwife has responsibility for the following:

1. Continuing evaluation and management of care of the woman's well-being
2. Providing relief from physical discomforts
3. Providing assistance with breastfeeding
4. Facilitation of parenting
5. Assessment of the baby during a home visit, if these are offered in your practice
6. Providing anticipatory guidance and instruction
7. Continuing screening for complications of the puerperium (Chapter 44)

Management of care of the first hour postpartum was discussed in connection with the fourth stage of labor in Chapter 33. Management of the early puerperium involves the management of care of the woman while she is in the hospital after the birth and for a minimum of 1 to 2 days postpartum if she is at home.

Continuing Evaluation and Management of the Woman's Well-Being

Evaluation of the Early Puerperium During the early puerperium the midwife should see the woman at least once daily. Each visit includes the following aspects:

Chart Review Before the midwife begins a visit, she will review any part of the antepartum and birth care with which she is unfamiliar, so that she can speak with knowledge to the new mother. This includes being aware of any complications in the new-

born's health status. Reviewing the chart entries since the birth also familiarizes the midwife with the record of the mother's vital signs, laboratory results, medication use, and any comments from the nurses. Previous orders and progress notes are reviewed as well. Time elapsed since birth, in hours or days, is ascertained to identify expected physical findings.

History As the midwife begins her visit, the first topic is often the birth itself. When the woman shares her experience, she is offering information that can be validated or corrected, and providing cues for which topics are of greatest concern to her. Additional information can be requested to assess both physical recovery and the mother's progress with learning to parent her newborn.

Interval assessments for each postpartum visit include maternal nutrition, bladder and bowel function, amount of lochial flow, activity level, and pain or discomfort. If the mother is breastfeeding, this is also assessed. Whether or not the midwife is the primary caregiver for the infant, infant feeding method, information about infant behavior, and sleep-wake cycles should be collected.

If at all possible, the midwife should arrange her visit to coincide with those times when the baby will be awake and with the mother. This enables the midwife to evaluate the mother-baby interaction for normality (screening out maternal rejection) and for the mother's skill and comfort in handling her baby, which may indicate areas of learning needs.

Physical Examination The examination during the early postpartum period includes the following:

1. Assessment of vital signs, including the trend over the period since the birth
2. Breast examination (see Chapter 52), including demonstrating the presence of colostrum and management of the nipples for breastfeeding women
3. Auscultation of heart and lungs, as indicated by maternal complaints, or observed changes in appearance or vital signs
4. Abdominal evaluation for uterine involution, diastasis, bladder (see Chapter 53)
5. Evaluation for costo-vertebral angle (CVA) tenderness if indicated by maternal complaints or clinical signs (see Chapter 54, method C)
6. Perineal assessment for bruising, edema, hematoma, healing of any repair, inflammation, suppuration
7. Lochia for type, quantity, and odor,
8. Anus for hemorrhoids
9. Extremities for varicosities, edema, calf tenderness or heat, presence of Homan's sign, reflexes

Examination of the perineum requires good visualization (i.e., exposure and light). The woman should be positioned with the bottoms of her feet together, knees bent, and legs apart. Let her ease into this position. Pain while she does so is informative. A penlight is invaluable in checking the perineum and should be an indispensable item of equipment for making a postpartum visit. Another helpful item is a large mirror, which can be positioned so the woman can see her own perineum if she so desires. Part of the postpartum perineal examination is educating the woman about what to expect when she sees or touches her vaginal area, including the normal changes as well as the appearance of any trauma.

For examining the posterior end of a repair (especially a lengthy one) and the anal area for external hemorrhoids, you may be able to see best (especially if the woman is obese) if the woman turns on whichever side is more comfortable for her. Gentle separation of the buttocks then gives good exposure for visualization of the area.

Evaluation of the extremities includes checking for Homan's sign. Homan's sign is elicited by placing one hand on the mother's knee, and applying gentle pressure in order to keep the leg straight. Dorsiflex that foot. If there is calf pain with this action, the sign is positive.

Management of the Early Puerperium The midwife develops a management plan for the early puerperium that reflects both the setting in which birth has occurred and the nature of the woman's birth experience. How different the plans may be for the experienced mother resting in her own bed at home after an easy birth and the exhausted woman who has worked through a painful back labor and had a large laceration repaired. In many institutional settings, routine or standing orders for the first postpartum days may exist. It is imperative for you to consider whether these orders are the appropriate ones for the new mother and to make adjustments as indicated (for example by modifying pain management routines or planning a lactation consult). Equally, it is essential to understand which are required for the efficient management of care and should be implemented without concern (such as deleting labor orders or entering an order to discontinue IV fluids). The midwife should be certain the following issues are addressed if written orders are

prepared, or that they are included in the instructions for mothers delivering outside the hospital setting:

1. Hydration, including when and whether any IV access should be discontinued
2. Nutrition
3. Activity level
4. Any medications (such as vitamins and iron, stool softeners or laxatives, pain relievers, sleep medications)
5. Perineal care, including relief of postpartum discomfort
6. Management for inability to void
7. Breast care and support for chosen feeding method
8. Laboratory tests as needed
9. Rh screening for Rh immune globulin administration in Rh negative mothers
10. Rubella vaccine for nonimmune women
11. Contraception if being initiated prior to the first postpartum visit

Patient Teaching in the Immediate Postpartum Period

During the first few days after birth, the new mother's ability to actively absorb formal teaching is limited by her intense focus on her newborn. Rubin's classic work on the developmental stages through which new mothers proceed suggested that her time was essentially focused on the infant and her behavior was dependent (taking in) for several days, before she began to take hold, or function more autonomously [12]. A small study published in 1990 suggested that the pace of this transition had accelerated; however, the brief hospital stays now common for healthy women still limit the mother's ability to function independently with her new infant before she is on her own at home [13]. An Israeli study found transient loss of cognitive ability in the immediate postpartum period [14]. All this suggests not only that initial teaching should be focused on essentials but that follow-up contact will support the mother in learning to care for her new child.

Teaching must target essentials of self-care, including handwashing, hygiene, relief of common discomforts, and recognition of warning signs such as fever, pain, excessive bleeding, dizziness or faintness, sudden-onset headache, visual changes, or epigastric pain. Initiation of breastfeeding, including access to continuing resources or how to judge infant satisfaction if the mother is formula feeding, is included. The basics of infant care deserve particular attention, especially for first-time mothers who may have little or no experience with newborns.

Education for perineal care may seem self-evident, but handwashing, the use of a warm water rinse with voiding, wiping front to rear, patting any incision area rather than scrubbing at it, and an explanation of the various comfort measures available can make a huge difference to the new mother.

The immediate postpartum visit is also a good time to begin to encourage a return to Kegel's exercises. The originator of the exercise reported that 20 to 40 hours of progressive resistance exercise, over two months time, was necessary to completely restore tone [15].

Common Medications Prescribed in the Postpartum Period

Analgesics Most midwives have their preferred pain relief regimens for the early postpartum period. Ibuprofen 800 mg (Motrin) is generally available. The midwife may wish to write a prescription for the woman to take home, or recommend that she purchase the ibuprofen 200 mg tablets over the counter, take them initially at 800 mg doses, and titrate her dose down as postpartum discomforts resolve. Acetaminophen with codeine 30 mg (Tylenol 3) is another commonly prescribed pain reliever, as is oxycodone/APAP (Percocet). Women who have had a normal childbirth should not require anything stronger than ibuprofen by the second postpartum day. Significant pain that persists warrants an examination to identify its cause.

Laxatives Those women have who labored for many hours without eating or have experienced lacerations that penetrate the rectal sphincter may have concerns regarding either pain or the integrity of the repair that decrease their willingness to move their bowels. The prescription of a mild stool softener such as docusate sodium (Colace) 50 to 100 mg daily or twice daily will help to maintain normal function. Reassurance, education about any repair and its healing, and encouragement to increase fluid intake and eat a high fiber diet will also promote normal function.

Rh Immune Globulin (RhoGAM, BayRho-D) Rh immune globulin is a fractionated plasma product developed to prevent alloimmunization of Rh-positive infants of an Rh-negative mother. They are specific to the D antibody; thus only women who are Rh D negative, Du (weak D) negative need be treated. Although Rh immune globulin is a blood product and carries warnings about risk of transmission of viruses such as HIV and hepatitis as well as Creutzfeldt-Jakob disease, this is a highly fractionated plasma derivative. The risk of disease transmission associated with drug administration is theoretical, and the risk asso-

ciated with alloimmunization significant both for the mother and for future children. Nonetheless, women should be told that this is a blood product before it is administered [16].

As many as 75 percent of all pregnant women experience a fetal-maternal transplacental hemorrhage (TPH) during pregnancy or birth. The amount of fetal blood in the maternal circulation is less than 0.1 mL in 60 percent of these cases and less than 5 mL in over 99 percent [17, p. 738]. The risk of TPH increases with chorionic villus sampling, spontaneous or therapeutic abortion, amniocentesis, preeclampsia, external version, hemorrhage from placenta previa or abruptio placentae, cesarean section, and manual removal of the placenta. Minimal TPH may produce antibody response in some women, and the risk of the mother developing antibodies following the birth of an Rh positive infant is approximately 16 percent [18].

The action of RhoGAM is to suppress the mother's production of antibodies in response to receipt of the Rh-positive antigen. Passive immunity transmitted through immunization prevents the development of maternal antibody. The rationale for suppression of antibody production in the woman is that it is the presence of D antibodies in the mother that causes hemolytic disease of the newborn (erythroblastosis fetalis) in subsequent pregnancies. Administration of Rh immune globulin in the prescribed manner postpartum reduces risk to 1 to 2 percent, which is the risk of antepartum exposure to fetal cells.

Regardless of whether she has received Rh immune globulin during pregnancy, any postpartal woman who meets the following criteria should receive Rh immune globulin:

1. She is Rh D/Du negative.
2. She is not sensitized to Rh D antibodies based on a current screen. (The exception is that a woman who has received a 28 week injection of Rh immune globulin may have a persistent low positive value at term. She still receives the postpartum injection.)
3. The infant is Rh D positive.
4. The infant has a negative direct antiagglutination test (Coombs' test).

The standard 300 μg dose of Rh immune globulin is sufficient to treat a fetal-maternal bleed containing 15 mL of red blood cells or 30 mL of whole blood. If there is suspicion of a greater exposure, a Kleihauer-Betke test should be performed to determine the correct dose. Rh immune globulin is administered within 72 hours of birth, before antibody production begins and the woman becomes sensitized. Once the mother has become sensitized to the Rh factor, the process cannot be reversed.

If cord blood results are delayed and administration of Rh immune globulin is deferred for 72 hours, Rh immune globulin should be administered at that time. About one-third of the time, the infant will be Rh negative; however, no harm is done to the mother by administering the dose unnecessarily, and this outcome is preferable to not treating a mother at risk of Rh sensitization. In addition, prophylaxis has been demonstrated to be at least partially protective for up to fourteen days after the birth [17, p. 760].

Rh immune globulin is not administered to the newborn infant, to previously sensitized Rh negative mothers, or to Rh negative mothers whose infant is Rh negative. It is never given to Rh D positive or Du positive women.

Rubella Vaccine 0.5 mL Subcutaneous Rubella vaccine is given postpartum to women who had a rubella titer of less than 1:10 or who tested nonimmune or indeterminate for rubella immunity during the antepartal period.

Methergine Methergine 0.2 mg by mouth, every four hours for six doses, is prescribed when the mother has had significant uterine atony after giving birth, to decrease the risk of a delayed postpartum hemorrhage. It may also be prescribed based on multiparity, overdistention of the uterus as with a macrosomic infant or polyhydramnios, persistent relaxation of the uterus in the early postpartum period, or a concern about retained membranes or placental fragments.

Postpartum Follow-Up: Telephone Calls, Home Visits, and Two-Week Postpartum Visit

A midwife can use a variety of methods to stay in contact with the mother and baby between the immediate postpartum period and the four- to six-week examination. Some midwives make telephone calls, some do home visits, and some have the mother and baby return for a two-week visit. Some midwives may work with nurses or train birth assistants to make the telephone calls or do the home visits. Some midwives do a combination of these, depending on the needs of the mother, baby, and family. These activities have a number of purposes:

1. To evaluate the postpartum course and well-being of the mother
2. To evaluate the well-being of the baby
3. To evaluate progress and comfort in caretaking ability and assumption of the parental role

4. To review with the mother her labor and birth experience
5. To be accessible for questions and concerns and to establish a contact for the mother to feel comfortable calling when she has questions or concerns
6. To provide needed teaching and counseling

While there is some evidence that physical outcomes are not improved by early postpartum visits [19], many of the problems that arise postpartum may be better addressed by early intervention. For example, breastfeeding support may enable a mother to continue, rather than wean her infant to formula. Or the early onset of postpartum depression may be recognized and help sought.

Telephone calls are usually made the day after the delivery or the day after the mother goes home from the birth center or hospital and again a few days later. They are often combined with a two-week visit in the office or clinic. During the telephone call the midwife screens for problems by asking about both maternal and infant well-being.

For the mother, evaluation includes the following:

1. Her perception of labor and birth, her current coping ability, and how she is responding to the new baby.
2. Condition of the breasts, including engorgement, whether or not the mother is breastfeeding, what comfort measures she is using to reduce discomfort. In addition, if the mother is breastfeeding, questioning should include pain or discomfort with feeding, appearance of the nipples and areolae, whether colostrum or milk is present, and an assessment of the breastfeeding process.
3. Food and fluid intake, assessing for both quality and quantity.
4. Abdominal pain, cramping, bowel function.
5. Any difficulty or discomfort with urination, and whether she is diuresing.
6. The amount, color, and odor associated with lochial bleeding.
7. Perineal pain, swelling, redness, and, if there was a repair, whether the repair is visibly intact. The mother may need to find a mirror and examine herself, or have her partner check for her, if she reports any of the first symptoms.
8. Presence of hemorrhoids, and any comfort measures being used.
9. Lower extremity edema, pain, and redness.
10. Whether the mother is having enough rest, both during the day and at night.
11. Who is present to assist the new mother with household management, and how the help is perceived (i.e., useful or intrusive).
12. Current level of physical activity, in terms of newborn care, household chores, and exercise, and whether she has begun performing Kegel's exercises and abdominal tightening exercises.
13. How the family is adjusting to having the new baby at home.
14. Her current level of confidence in her ability to care for the infant.

Whether or not the midwife is responsible for the infant's care, the mother should be asked about the baby during this visit or call, including information about the following:

1. What feeding method the mother is using now. If she has switched methods, does she need any assistance with her new choice? Breastfeeding mothers are asked about difficulty with nursing, milk supply, nursing time, infant satisfaction, and sleep-wake cycles. Formula-feeding mothers should also be asked about any difficulties their infant is having with feeding, frequency, and amount taken.
2. Bladder and bowel patterns, including frequency. The shift in frequency and appearance of stools should be validated.
3. Infant color—i.e., presence of jaundice, and any circumoral cyanosis while feeding.
4. Whether the umbilical cord has come off, whether the site is clean and dry, what, if anything, the mother is applying to the site.
5. For male infants who are circumcised, the appearance of the incision site.
6. How the new infant is reacting to life. This includes whether the infant is sleeping well, appears fussy or unsatisfied after eating, is crying frequently, is alert when awake, etc.

Using a telephone call to assess the mother-baby pair's well-being, particularly if the birth has occurred in a setting where the family will be alone with their infant shortly after birth, allows the midwife to triage in a timely fashion for emergent problems that might require a trip to the office (or the pediatric nurse practitioner or physician's office), or even a visit to the emergency room. It also verifies the mother's understanding of her ability to cope with the challenges of being a new mother.

A home visit involves the same set of questions as for the telephone call but also allows the midwife to observe the following:

1. The mother's responses to the baby's needs and cues
2. The mother-baby interaction
3. The place of the baby in the home's social environment

4. The resources in the home (e.g., plumbing, water supply, refrigeration, air conditioning/heat, window screens, supplies for baby care)

A home visit may also include a brief physical examination of the mother and baby. A brief physical examination of the mother might include the following:

1. Blood pressure
2. Temperature
3. Breast evaluation
4. Abdominal assessment
5. Perineum check, including assessment of the lochia

A brief physical examination of the baby might include the following:

1. Temperature, pulse, and respiration rate
2. Check for dehydration (skin turgor, sunken fontanels)
3. Auscultation of heart and lungs
4. Cord check
5. Circumcision check (if applicable)
6. Screening for jaundice
7. Observation of responsiveness/alertness
8. Assessment of physical well-being and adequacy of caretaking

The two-week visit also involves the same set of questions as the telephone call, adjusted for expected physical, physiological, and psychological changes by two weeks postpartum. Particular attention should be paid to how well the woman is coping with these changes and her new parental responsibilities. The midwife may or may not conduct an abbreviated physical examination of the mother or the baby or both.

The two-week visit should be a mother-baby visit so the midwife can observe the mother's interaction with her baby and her responsiveness to her baby's needs and cues. Every contact with the mother is an opportunity to share with her the developmental capabilities of her baby and to discuss safety, infant stimulation, and parenting skills. This is also a good time to check that the baby either has already seen or has an appointment to see a pediatric health care professional and to discuss the need for these visits and for immunizations.

For breastfeeding mothers, the two-week visit can also be used as a time to encourage effective breastfeeding and to work on any nursing problems.

Finally, if mothers have not elected a contraceptive method during the immediate postpartum visit, the two-week visit is an excellent opportunity to review available options. Many couples will choose to begin sexual intercourse shortly after the mother's lochia resolves, if not before, and mothers who are formula-feeding may well ovulate before a routine postpartum physical is performed at six weeks.

Four- to Six-Week Postpartum Examination

Although the puerperium lasts approximately six weeks, marking the length of time it takes for the woman's reproductive tract to return to its nonpregnant condition, most experts believe it is possible to evaluate the normality and conclusion of the puerperium at four weeks postpartum. The midwife should choose the interval most appropriate to the community served, and the woman's needs, including the need for contraception.

Lydon-Rochelle and colleagues reported on a review of births in which they compared general health status of primiparous women based on mode of delivery [20]. Women with operative vaginal deliveries and those who gave birth by cesarean section were less likely to be in good general health at the end of the puerperium, indicating a potential need for careful evaluation of their ability to return to their usual activities or employment. Specific issues of concern included physical ability, and increased likelihood of postpartum blues or depression. In addition, women with forceps or vacuum births were more likely to report difficulty with bowel or bladder function and delayed resumption of sexual activity. While this is not entirely new data, the assessment of women's health during postpartum visits should take the slower recovery of this group of women into consideration, both for teaching and clinical management.

The four- to six-week postpartum examination often consists of a complete history, physical, and pelvic examination, as outlined in Chapter 2. Any available records of this pregnancy (antepartal, intrapartal, postpartal) should be reviewed. In addition, the visit includes (1) screening for contraindications to any of the methods of family planning if this has not already been done, (2) additional history regarding the period of time since the woman was last seen, and (3) additional specific physical and pelvic evaluations that relate to the return of the reproductive tract and body to its nonpregnant state. In addition to the assessment given above for use in a telephone call or at a two-week visit, this additional history includes the following:

1. Resumption of sexual intercourse—number of times, contraception used (if so, which method), dyspareunia, woman's and partner's enjoyment and satisfaction, problems

2. Family-planning method desired; previous family-planning methods used—satisfaction, side effects, length of time used, why discontinued
3. Calls to the midwife or the physician, visits to the hospital emergency room, or admission or readmission to the hospital—why, when, diagnosis, treatment, duration, and present status of problem
4. Any symptoms of fever, chills, cold, flu
5. Breasts: history of engorgement, feeding method and satisfaction, any current problems with nipples, breast care, or symptoms of mastitis
6. Bladder function, including any incontinence, any symptoms of urinary tract infection, performance of Kegel's exercises
7. Abdominal tone, persistence of a diastasis, whether the mother has begun exercising
8. Bowel function including constipation, incontinence of stool or flatus, whether the woman has used laxatives or enemas to improve bowel function
9. The resolution of lochia, including any episodes of excessive bleeding, and when or whether the menses have resumed
10. Leg cramps or pain, especially with exercise, the development or persistence of varicose veins, and signs of thrombophlebitis
11. Coping with infant needs by both the mother and the family, whether the child has been to well-child visits, growth and well-being of the child

The physical examination for a postpartum woman may be done as a complete physical evaluation, or may be limited in some settings. If only a limited examination is performed, it should include the following:

1. Thyroid
2. Lymphatics: cervical, axillary, inguinal
3. Breasts, including an assessment related to breastfeeding when appropriate as follows:
   a. Whether the breasts are adequately supported by the mother's undergarments
   b. Presence of milk
   c. Breast symmetry
   d. Nipple injury such as cracking or blisters
4. Abdominal examination, including assessment of diastasis recti
5. Perineum, including healing of any laceration or episiotomy repair, and resolution of hematomas
6. Bimanual examination, including
   a. Assessment of vaginal tone by having the mother contract her muscles around your examining finger
   b. Assessment of residual pain by applying pressure to the posterior vaginal wall at the level of the hymen
   c. Assessment for cystocele or rectocele development
   d. Assessment for estrogen depletion with decreased rugation and atrophy of vaginal tissue
   e. Uterine sizing: it may be slightly larger than the nonpregnant uterus but should be a pelvic organ. Larger than expected size for the number of weeks postpartum, boggy tone, or continued lochial oozing may be indicative of subinvolution (see Chapter 44)
7. Assessment of any residual hemorrhoids
8. Examination of the legs for varicosities, persistent edema

In addition to the history and physical examination, assessment of the postpartum woman may include laboratory assessment with CBC if severe anemia was noted at birth or following a postpartum hemorrhage, screens for sexually transmitted diseases as appropriate, and a Pap smear when indicated or part of the institutional protocol. Currently, the Pap smear is often deferred to the next annual examination, dating from the time of the initial assessment for pregnancy, or from the last annual if that Pap smear was accepted as part of the new obstetric visit assessment.

Relief from Common Discomforts

There are a number of discomforts of the puerperium. Although they are considered normal, they may cause significant physical distress. Discomforts specific to breastfeeding mothers (nipple tenderness and cracked nipples) will be discussed in the chapter on infant feeding (Chapter 43).

Afterbirth Pains Afterbirth pains are caused by the continuing sequential contraction and relaxation of the uterus. They are much more common with increasing parity and in women who breastfeed. The reason for more severe afterpains with increasing parity is a concomitant decrease in uterine muscle tone, producing intermittent relaxation. This is in contrast to the primipara, whose uterine muscle tone is good and whose uterus stays essentially contracted without intermittent relaxation. In breastfeeding women, the suckling of the baby stimulates the production of oxytocin by the posterior pituitary. The release of oxytocin not only triggers the let-down reflex in the breasts but also causes the uterus to contract.

Afterbirth pains will be relieved if the uterus remains well contracted, which requires that the bladder be empty. The new mother should be reminded that the frequent filling of her bladder as her body begins to shed excess fluid following the birth will lead to a need for frequent urination. A full bladder will displace the uterus upward leading to uterine relaxation and more painful contractions. When the bladder is empty, some women will find sufficient relief of pain by repositioning themselves to lie prone, with a pillow or blanket roll positioned under the lower abdomen. Constant uterine compression in this position can provide significant relief from cramping.

Effective analgesia for most women whose contractions are severe can be achieved with either acetaminophen (Tylenol) or ibuprofen (Motrin). Although aspirin-containing products are not recommended for breastfeeding mothers, due to the risk of decreased platelet counts and an association with Reye's syndrome, ibuprofen and acetaminophen have been shown to be safe [21, pp. 27–28, 62–63, 368–369]. In many cases, the anti-inflammatory properties of ibuprofen will make it a superior product for this purpose. Women whose pain is severe enough to require the use of narcotic analgesics following a vaginal birth should be evaluated for causes of pain other than uterine contractions.

Excessive Perspiration Postpartal woman experience excessive perspiration because the body uses this route as well as diuresis to rid itself of the excess interstitial fluid that resulted from the normal increase in extracellular water during pregnancy. Relief is simply to keep clean and dry. Care must also be taken to ensure that the woman is hydrated. Drinking a glass of water during each hour she is awake will accomplish this.

Breast Engorgement It is thought that engorgement of the breasts is due to a combination of milk accumulation and stasis and increased vascularity and congestion. This combination results in further congestion by virtue of lymphatic and venous stasis. It occurs as the milk supply increases, on approximately the third postpartal day in both breastfeeding and nonbreastfeeding mothers, and lasts approximately 24 to 48 hours.

As the milk supply comes in, engorgement is preceded by a sense of heaviness as the breasts begin to fill. The breasts become distended, tense, and tender to the touch. The skin is warm to the touch, with visible veins, and is taut across the breasts. The nipples are firmer and may become difficult for the infant to grasp. For some women, the breast tenderness becomes painful, particularly if the infant is having difficulty with nursing, or if she does not have a supportive brassiere. Although engorgement is not an inflammatory process, the increased metabolism associated with milk production may cause a mildly elevated temperature. Fever greater than 100.4° F suggests the presence of mastitis or another infection.

Relief measures depend on whether the woman is breastfeeding. For a woman who is not breastfeeding, such measures are geared toward relief of discomfort and cessation of lactation. Although in the past a variety of medications were used to attempt to suppress milk production in formula-feeding women, none was found to be without risk to the woman, nor were any completely effective. Since the Food and Drug Administration removed the indication for lactation suppression for bromocriptine (Parlodel) in 1989, no medication is approved for this use in the United States [21, pp. 87–88].

Women who choose to formula feed need to understand that they will develop a milk supply, which will cause engorgement. They need to be taught to use a bra or breast binder to firmly support the breasts, lifting rather than squeezing toward the chest wall. Women with pendulous breasts may need to add a roll underneath the breasts. A simple breast binder can be constructed using linens or a thin towel, pinned into place to provide support.

The application of ice to the breasts, using either purchased chemical ice packs or a rolled plastic bag filled with water and frozen, restricts blood flow and inhibits milk production. If the mother chooses to make her own ice packs, she should be reminded to wrap them in a layer of cloth for comfort and to reduce the risk of accidental freezing injury. The ice packs should be shifted to various parts of the breast, rather than remaining in a single location.

No attempt should be made to express milk from the breasts, either manually or by using heat (e.g., standing in a warm shower and letting the water run over the breasts), as this will only promote milk production. The application of heat dilates the blood vessels and indirectly stimulates milk production and letdown.

The use of analgesics, as described above in the section on afterbirth pains, can relieve any accompanying discomfort.

Finally, mothers should be reminded that this is a short-lived problem. Engorgement will recede as soon as the woman's body realizes that the milk is not being used and decreases production. However, the new mother can expect that her milk supply will not vanish immediately, but it will resolve over several weeks.

Breastfeeding mothers, in contrast, should be advised that the application of heat, frequent feeding, and use of mild analgesics can relieve the discomfort of engorgement. If the areolae and nipples are too firm or tense for the infant to grasp, expressing a little milk prior to placing the baby at breast can facilitate attempts to latch on (see Chapter 62). Mothers who begin breastfeeding immediately after the birth, nurse frequently on both breasts, and avoid the use of supplements or pumping to express milk for bottle feeding are less likely to engorge painfully (Figure 42-6).

Perineal Pain A number of perineal comfort measures can alleviate discomfort or pain resulting from a laceration or episiotomy and subsequent repair. Before any measures are instituted, it is essential to examine the perineum to rule out complications such as hematoma. It may also indicate which of the following measures might be most effective.

FIGURE 42-6 Breastfeeding.

Many women will also have a personal preference as to one or another of these techniques. It is often worth the time and effort to describe several different methods and allow her to choose which is working best for her.

Ice Pack or Bag as Needed. If chemical ice packs are not available, an ice bag can be made by filling an unpowdered rubber glove with crushed ice or ice chips and tying off the glove at the cuff with a rubber band. All ice bags or packs should be wrapped in a soft covering, absorbent side out, for the sake of cleanliness, and protection against an ice burn.

Ice bags or packs are applied as needed. They are most useful for reducing swelling and numbing the perineum in the immediate postpartal period. Ice should always be applied in the event of a third- or fourth-degree laceration, and when significant perineal edema is present. Optimum benefit is achieved with 30-minute applications of cold [22].

Topical Anesthetic as Needed. Examples of topical anesthetics are Dermoplast spray, Nupercaine ointment, Americaine spray or ointment, and Surfacaine ointment. If an ointment is to be used, the woman should be instructed to wash her hands before applying it. These are applied during the first few postpartum days during the period of acute healing either from a repair or if hemorrhoids are present. Women who need to continue using these after a few days should be seen to determine if another problem is present.

Sitz Bath Two to Three Times Daily. The advent of the disposable, fit-in-the-toilet sitz bath made this a simple, convenient, and comfortable procedure that the woman can use in her home. Some women will prefer to use cold water, rather than the warm—not hot—water generally prescribed.

A modification of the same idea is to pour warm water over the perineum. This can be a part of routine perineal care after both voiding and defecation. A small pitcher or container or peri-bottle facilitates this method.

The warmth of the water for either the sitz bath or for pouring should first be tested on another sensitive but nontraumatized portion of the body, such as the inside of the wrist. The warmth of the water increases circulation and promotes healing.

Ice sitz baths have also been proposed by Droegmueller [23]. It is clear that cold is the preferred therapy for the initial treatment of soft tissue injuries and inflammatory conditions in

athletics. Postpartum pain relief with the use of cold sitz baths includes the decreased response at the nerve ending as well as local vasoconstriction, which reduces swelling and muscle spasm. To administer an ice sitz bath, begin with water at room temperature and add ice until the proper temperature is reached.

Witch hazel compresses both reduce edema and are analgesic. They are concocted by pouring witch hazel over some 4 × 4 gauze squares in a small cup or basin, squeezing them out to a wet but not drippy state, folding them once, and placing them on the perineum. It is important that the hands of the person who prepares the compresses be thoroughly washed first. Tucks pads, a commercial variation of this comfort measure saturated with a mixture of witch hazel, glycerin, and water, may also be used.

Rubber Ring. Use of a rubber ring has been criticized because of its possible interference with circulation. However, properly used, it can bring safe relief when there is considerable positional pressure on the perineal area. The rubber ring should be inflated only enough to relieve this pressure. It should be a large rubber ring and positioned so that there are no pressure points in the pelvic area.

Perineal Tightening. Doing perineal tightening or Kegel's exercises increases circulation to the area and thus promotes healing. It also begins to restore muscle tone to the pelvic musculature. It is one of the most useful perineal comfort measures and often yields dramatic results in facilitating ease of movement and making the woman more comfortable.

As a comfort measure, perineal tightening is geared toward alleviation of the discomfort and pain a woman has when sitting or getting in and out of bed. In both of these instances her perineal area is subjected to direct pressure and, particularly when getting in and out of bed, her stitch area also can be scraped. Perineal tightening draws the affected area up and in, so that it does not receive direct pressure or scraping; the gluteal muscles receive these effects. The woman should tighten her perineum, drawing it up and in and maintaining this contracted state before moving in bed or lowering herself onto a chair.

Perineal tightening can have the opposite effect if the woman had a mediolateral episiotomy. Tightening the perineum in this instance pulls on the posterior end of the stitch line since the incision cuts diagonally across the muscles, and can be quite painful.

Constipation Fears may inhibit bowel function if a woman is afraid of tearing out stitches or of pain associated with the remembered bowel pressure in labor. In addition, constipation may be further aggravated by laxness of the abdominal walls and by the discomfort of a third- or fourth-degree repair.

Dietary changes to increase fiber and additional fluid intake may relieve the problem. When women have had a third- or fourth-degree laceration, the use of stool softeners and laxatives can help prevent straining. In most cases, the long-term use of a mild stool softener or laxative should be limited to women who do not resolve their problem with reassurance and diet changes, to avoid the development of dependence.

Hemorrhoids If the woman has hemorrhoids, they may be quite painful for a few days. If they developed during pregnancy, they were traumatized and became more edematous during the pushing of the second stage of labor and with pressure of the baby and distention at birth. The first three relief measures below help reduce the size of the hemorrhoids and are good for the initial 24- to 48-hours of treatment. Relief measures may be used in combination (except cold and warm during the same time span) and include the following:

1. Ice bags or packs
2. Ice sitz baths
3. Witch hazel compresses or Tucks
4. Preparation H ointment
5. Analgesic or anesthetic spray or ointment
6. Warm water compresses
7. Warm sitz baths
8. Stool softener
9. Anusol suppositories
10. Replacement of external hemorrhoids inside the rectum. A lubricated finger cot is used and the hemorrhoids are gently pushed into the rectum. Using Preparation H for the lubricant gives a double effect. After the hemorrhoids are inserted, the woman tightens her rectal sphincter both to give them support and to contain them within her rectum.

Rooming-In

The best possible structure in the hospital for facilitating mother-infant attachment, bonding, parenting, and the family unit is rooming-in (see Figure 42-7). Rooming-in is not a new concept but one that disappeared from maternity care in the United States when childbirth moved inside the hospital

FIGURE 42-7 Family in rooming-in.

and separated the mother and baby from the family and, by and large, from each other. In the mid-1940s a movement began to reverse this separation within the hospital. Opponents' fears that rooming-in would lead to increased infection have been proven unfounded. In fact, the danger is less. The most comprehensive definition of rooming-in was developed at that time at Yale University:

> The term rooming-in refers to a hospital arrangement for maternity patients wherein a mother and her newborn are cared for together in the same room. However, its meaning reaches beyond physical facilities and signifies an attitude in maternal and infant care and a general plan of supportive parental education which are based on the recognition and understanding of the needs of each mother, infant, and family. It is a plan to maintain natural mother-infant relationships, to reinforce the potentialities of each mother and infant, and to encourage the family unit. From this broad point of view, then, rooming-in is not to be viewed merely as a specific plan for space arrangement or as a particular kind of equipment or organization, but rather as an integrated, interdepartmental program of professional assistance that helps parents achieve happy family unity and warm parent-child relationships. [24]

Rooming-in does not mean that the baby has to be with the mother every minute of her hospital stay, nor does it mean that the mother assumes sole responsibility for the care of the baby. In rooming-in the nursing staff remains responsible for the nursing care of both the mother and the baby. The mother assumes care of her baby as she desires and as she demonstrates the ability to do so. The setting is ideal for a new, inexperienced mother not only to learn how to care for her baby but also to get to know her baby and how it communicates with her through body movement and vocal noises. The experienced mother also benefits from rooming-in and learning the individuality and communication style of this baby. The mother in rooming-in can rest comfortably having her baby with her, yet knowing that either she or a nurse can care for the baby, whichever she desires, so she can obtain needed rest and prevent exhaustion.

Rooming-in also is the ideal setting for breastfeeding (because the mother can respond when the baby is hungry and nurse frequently to stimulate lactation), to involve the father, and to begin parenting. The baby needs the security that comes from prompt attention to its demands and from holding, cuddling, fondling, and nuzzling. These needs must be satisfied if the baby is to be healthy and happy. An inexperienced mother and father may find it difficult both to recognize these needs and to know how to satisfy them. Baby care is a learned skill and art. It can be a shock to a new, inexperienced mother to be home suddenly with a baby she has no idea how to care for. Rooming-in makes the transition from hospital to home a gradual and natural one instead of a shock.

The importance of recognizing the baby's needs and individual behavior lies in the potential for growth when the needs are satisfied and the parents collaborate with the baby's growth and development pattern. An impersonal hospital regimen encourages a mother to believe, falsely, that her baby's behavior is automatic. Inflexible and mechanical policies condition a mother to follow rules instead of being guided by the needs of her baby. A hospital regimen does not allow her to learn that a satisfied baby cries relatively little and will settle into a fairly regular schedule of its own in two to three weeks. Growth and development are fostered when the baby is secure in the warmth and contact that comes from being held and cuddled and is free to eat, sleep, and eliminate according to internal rhythms rather than with a rigid and arbitrary regimen. Parenting begins in respect for and in response to the individuality of the baby.

Anticipatory Guidance and Instruction

This portion of the chapter provides an outline of the topics included in anticipatory guidance and instruction of the postpartal mother during the early puerperium. This is not to say that all women need instruction in all areas. It does mean that each woman should be apprised of these topics and then given instruction in those in which she feels a need. You cannot assume that because a woman is a first-time mother she doesn't know anything about these topics. She may have baby care experience through caring for a sibling or other infant relatives. By the same token, you cannot assume that because a woman is a multipara she knows all you have to offer. She may need a refresher depending on how many years it has been since her last baby. Also, most professionals who have become mothers do not like to have to rely on themselves; they want to be treated like any other new mother and be taught, if they wish, without being made to feel like they should already know everything.

The following material is presented in outline form. For the beginning midwife who is unfamiliar with infant care, a number of good resources, including those written for the lay community, are readily available. Some of these are included in the bibliography at the end of this chapter.

Mother

1. Perineal care
2. Breast care for the breastfeeding mother
3. Care of the breasts during breast engorgement
4. Abdominal tightening exercises
5. Perineal exercises
6. Activity/exercise (see Chapter 9 for information on items 4–6)
7. Nutrition
8. Rest
9. Hygiene, including tub bath or shower as preferred
10. Normality of baby blues
11. Warning signs, including
    a. Fever or chills
    b. Excessive bleeding
    c. Abdominal pain
    d. Severely painful or lumpy breast
    e. Calf pain or heat, with or without leg edema
    f. Depression
12. How to contact the midwife and other resources
13. When to return for postpartum evaluation, or when a home visit/telephone contact will be made

Baby

1. See Chapter 43 for information regarding educational needs of breastfeeding mothers.
2. If being bottle-fed:
    a. The preparation and storage of formula
    b. The care and preparation of bottles and nipples
    c. How to hold the baby during feeding
    d. How to hold the bottle during feeding
3. Burping (Figure 42-8)
4. Baby bathing, including shampooing
5. Dressing
    a. How to dress (manipulation of clothes and baby)
    b. How much clothing in relation to environmental and body temperature
6. Cleaning and care of penis of the baby, including circumcision care where applicable
7. Care of female perineum
8. Cord care
9. How to lift, hold, and carry a baby
10. Diapers—how to change them, what to do with them
11. Prevention and treatment of diaper rash

FIGURE 42-8 Teaching and learning about burping.

12. How to take the baby's temperature and how to read a thermometer
13. Pacifiers versus allowing the baby to suck on thumb or fist
14. The meaning of crying
    a. Hunger
    b. Need for a diaper change
    c. Need to be burped
    d. Need to change from an uncomfortable position
    e. Pain, for example, illness or stuck by a safety pin
    f. Need for loving—wants to be held and cuddled
    g. Clothes or blanket too tightly wrapped

    The parents should be assured that it is not possible for them to spoil their baby at this time. The first thing an infant learns is whether the world is a safe place, and whether the world responds to his or her needs.
15. Call the person providing pediatric care for any of the following:
    a. Fever
    b. Diarrhea
    c. Respiratory congestion
    d. Poor feeding
    e. Persistent restless crying
    f. Jaundice
    g. Listless behavior, not alert when awake
16. Importance of checkups and immunizations

Mother in Relation to Others

1. Sibling rivalry
2. Partner's needs and fears
3. Transitional family relationships
4. Family planning
5. Resumption of sexual intercourse
    a. Time of resumption determined by desire and comfort
    b. Alternative methods of satisfying sexual needs in the puerperium
    c. Problems of privacy, interruptions, and the letdown reflex if the woman is breastfeeding
    d. Alternative positions for sexual intercourse
    e. Use of a lubricant or hormone preparation for discomfort
6. Need for time together with partner and separate from the baby

Infant Feeding

KARIN CADWELL, RN, PhD, IBCLC; CYNTHIA TURNER-MAFFEI, MA, IBCLC
SARAH COULTER DANNER, CNM, CPNP, MSN, IBCLC

Breastfeeding—Optimal Infant Nourishment

Breastfeeding is the optimal way to nourish and nurture infants, and with the addition of complementary foods in the second half of the first year, continues to be of nutritional, immunological, and psychological significance well into the second year and beyond. Statements in support of breastfeeding have been issued by professional associations in the United States including the American Academy of Pediatrics (AAP) [1], Association of Women's Health, Obstetrical, and Neonatal Nurses (AWHONN) [2], American Dietetic Association (ADA) [3], and American College of Nurse-Midwives (ACNM) [4]. In their position statement, the ACNM:

1. Encourages efforts to inform and educate the public, health care providers and clients about breastfeeding as a normal process and as the preferred method of infant feeding.
2. Encourages health care providers to offer or arrange for a system of ongoing counseling and support for breastfeeding.
3. Promotes adoption of international, national, state, local and institutional policies that clearly support breastfeeding.
4. Encourages identification and removal of barriers to breastfeeding and opposes practices that discourage breastfeeding, and
5. Encourages the support of breastfeeding in the workplace and at school, and encourages institutions to provide optimal conditions to facilitate breastfeeding. [4]

During the last half of the twentieth century, appreciation of the uniqueness of human milk and the value of breastfeeding as a natural resource inspired government and private sector public health initiatives to promote, protect, and support breastfeeding. Priority goals and activities designed to increase breastfeeding initiation and duration are presented in documents such as those issued by the U.S. Breastfeeding Committee (USBC) [5] (Table 43-1) and the U.S Department of Health and Human Services [6] (Table 43-2).

Efforts designed to improve breastfeeding outcomes should include three features: breastfeeding promotion, protection, and support [7]. Breastfeeding promotion efforts focus on the advantages of breastfeeding to the individual baby and mother. Also included as promotion efforts are the dissemination of the advantages of breastfeeding in regard to the global ecology in decreased waste from bottles and the manufacturing process. Breastfeeding protection involves the legislated rights of women and children

TABLE 43-1 Goals of the U.S. Breastfeeding Committee

- Ensure access to comprehensive, current, and culturally appropriate lactation care and services for all women, children, and families.
- Ensure that breastfeeding is recognized as the normal and preferred method of feeding infants and young children.
- Ensure that all federal, state, and local laws relating to child welfare and family law recognize and support the importance and practice of breastfeeding.
- Increase protection, promotion, and support for breastfeeding mothers in the workforce.

TABLE 43-2 HHS Blueprint for Action on Breastfeeding

- Train health care professionals who provide maternal and child care on the basics of lactation, breastfeeding counseling, and lactation management during coursework, clinical and in-service training, and continuing education.
- Ensure that breastfeeding mothers have access to comprehensive, up-to-date, and culturally tailored lactation services provided by trained physicians, nurses, lactation consultants, and nutritionists/dietitians.
- Establish hospital and maternity center practices that promote breastfeeding, such as the *Ten Steps to Successful Breastfeeding*
- Develop breastfeeding education for women, their partners, and other significant family members during the prenatal and postnatal visits.

Source: U.S. Department of Health and Human Services, Office on Women's Health. Washington, DC, 2000.

that enable breastfeeding. These include adequate maternity leaves and appropriate child care facilities as well as the position that discreet breastfeeding in public places is not indecent exposure. Protection of breastfeeding also involves prohibiting certain marketing practices of companies manufacturing breast milk substitutes. *Support* of breastfeeding is accomplished through evidence-based hospital policies, health worker practices, and community programs that increase breastfeeding initiation and duration.

The in-hospital breastfeeding rate for the United States in 1998 was 64 percent, a rate substantially lower than the 75 percent initiation goal of the year 2000 Healthy People Goals (Figure 43-1) [6]. The five- to six-month breastfeeding rate data were released according to three racial and ethnic groups (Figure 43-2). For women identified as "Black," the rate was reported at 19 percent; for women identified as "Hispanic," the rate was 28 percent; and for women identified as "White," the rate was 31 percent. The combined six-month duration rate was estimated to be under 29 percent—less than half of the goal of 50 percent. The 2010 breastfeeding goals include an objective for breastfeeding at 12 months of 25 percent of women continuing to breastfeed. As Figure 43-3 illustrates, at

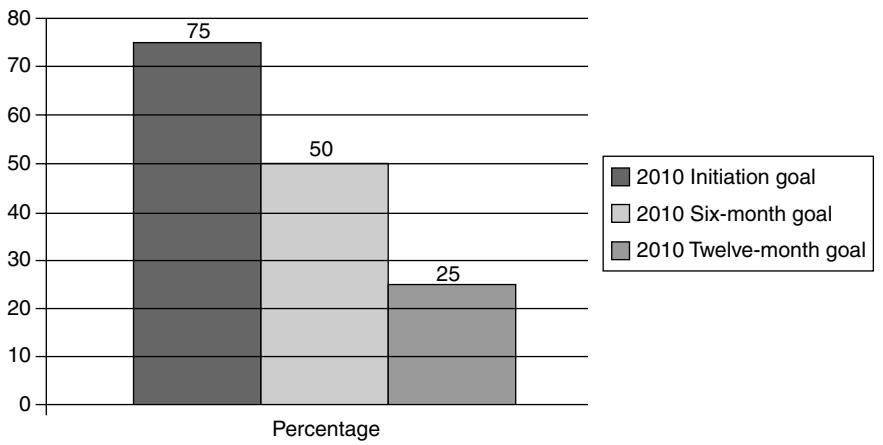

FIGURE 43-1 Healthy People Goals for Breastfeeding by 2010. *Source:* U.S. Department of Health and Human Services, Office on Women's Health, *HHS Blueprint for Action on Breastfeeding*, 2000.

Source: Ross Products Division, Abbott Laboratories, Ross Mothers' Survey.

12 months the disparity is pronounced, with only 9 percent of Black women, 19 percent of Hispanic women, and 17 percent of White women continuing to breastfeed (compared to the national goal of 25 percent of women continuing to breastfeed to one year). According to a report from USDA [8], meeting the Healthy People breastfeeding goals would save a minimum of $3.6 billion on only three diagnoses (otitis media, gastroenteritis, and necrotizing enterocolitis).

Maternal health advantages of having breastfed include the decreased risk of breast cancer [9] and increased bone density after weaning [10]. Breast cancer studies continue to indicate that accumulated duration of breastfeeding is a significant factor in reducing risk [11].

It is unclear whether the positive health outcomes attributed to individuals who have been breastfed are a result of the unique species-specific properties of human milk, the absence of exposure to potentially harmful formula components, or a combination of these factors. It is clear, however, that *not being* breastfed accrues recognized health risks to the baby. Exclusivity of breastfeeding and duration of breastfeeding also play a part in optimizing health outcomes. Babies should be fed breast milk exclusively (without formula or other foods) for about the first six months, adding appropriate complementary foods in the second half of the first year. Breastfeeding should continue to one year and then beyond as desired by the mother and baby [1, 12, 13].

The Baby-Friendly Hospital Initiative

The Baby-Friendly Hospital Initiative is an international effort developed by the World Health Organization (WHO) and UNICEF in 1991 to promote, protect, and support breastfeeding in hospitals and birth centers worldwide by encouraging the implementation of evidence-based best practices. Baby-Friendly USA was founded in 1997 as the responsible agency for the Baby-Friendly Hospital Initiative in the United States. In the United States, "Baby-Friendly" is a trademark of the U.S. Fund for UNICEF. The program has been built both nationally and internationally, around a list of ten research-supported practices, the Ten Steps to Successful Breastfeeding, that were developed for maternity facilities (Table 43-3) [14]. The change in three child health outcomes as a consequence of the

TABLE 43-3 Ten Steps to Successful Breastfeeding

Every facility providing maternity services and care for newborn infants should

1. Have a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help all mothers initiate breastfeeding within one hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless *medically* indicated.
7. Practice rooming-in in order to allow mothers and infants to remain together 24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Source: World Health Organization/UNICEF, 1989.

implementation of these ten steps has been studied in the large-scale PROBIT trial in Belarus [15]. Sixteen hospitals and polyclinics were randomly chosen to change policy and practice regarding breastfeeding using the Ten Steps to Successful Breastfeeding of the WHO/UNICEF BFHI, and 15 hospitals and polyclinics (the control group) did not. There was a significant difference in the duration and exclusivity of breastfeeding among infants born in the intervention sites. These changes were found to be significantly correlated to decreased risk of gastrointestinal tract infection and atopic eczema in the first year of life.

The International Code of Marketing of Breast-milk Substitutes

The World Health Assembly (WHA) adopted the International Code of Marketing of Breast-milk Substitutes in May 1981. All governments were enjoined to regulate marketing practices that promote artificial feeding (formula and other breast-milk substitutes) as well as the use of artificial feeding devices such as bottles and "rubber" nipples in an effort to protect breastfeeding.

One of the four operational targets of the Innocenti Declaration [16] to which the United States is a signatory is that by 1995 all governments would have "taken action to give effect to the principles and aim of all of the *Articles of the International Code of Marketing of Breast-milk Substitutes* and subsequent relevant World Health Assembly resolutions in their entirety" [17]. By 2002, no substantive action had been taken to implement the International Code of Marketing of Breast-milk Substitutes in the United States although evidence continues to accumulate that supports the Code. For example, the consequence of health care providers distributing formula company "gifts" (in the form of discharge bags as well as those designed to be given to antepartum mothers) has been studied and found to have a significant negative impact on breastfeeding outcomes, yet the practice continues. Howard and colleagues tested the effect of prenatal "gifts" from a formula company distributed to mothers via an obstetrical practice as compared with a noncommercial educational pack [18]. The study found that exposure to formula materials significantly increased the risk of weaning within the first two weeks. Among women with uncertain feeding intentions or short-duration goals, receipt of formula promotion materials significantly reduced rates of exclusive breastfeeding as well as duration. The authors conclude: "Educational materials about infant feeding should support unequivocally breastfeeding as optimal nutrition for infants; formula promotion products should be eliminated from prenatal settings" [18].

Distribution of formula company "gift" bags from the maternity unit at discharge has also been found to negatively impact breastfeeding outcomes [19] and the ethics of health care providers who participate in the marketing of formula has been questioned as well [20].

Anatomy and Physiology of Lactation

The breasts, or human mammary glands, begin their development in the fifth week of embryonic life from the milk lines, a line of glandular tissue. Occasionally, residual tissue from the milk line remains and accessory mammary tissue can develop anywhere along this line (Figure 43-4). The mammary gland is the only organ that is not fully developed in fetal life with continuing development through puberty to the duct end-bud stage and further growth in pregnancy and lactation.

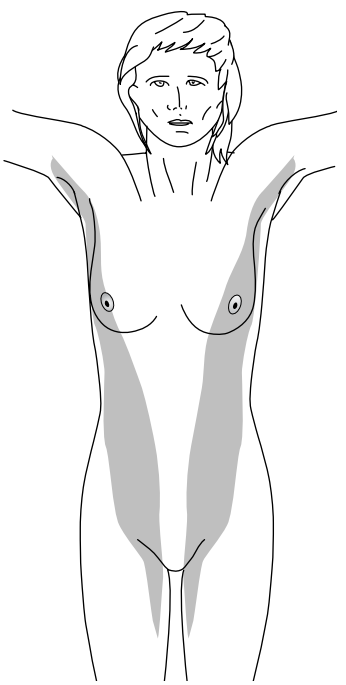

FIGURE 43-4 Possible locations of accessory breast and/or nipple tissue.

Source: Cadwell, K., Turner-Maffei, C., O'Connor, B., and Blair, A. *Maternal and Infant Assessment for Breastfeeding and Human Lactation: A Guide for the Practitioner*. Sudbury, MA: Jones and Bartlett Publishers, Inc., 2002.

The breast tissue includes two major divisions: the parenchyma and the stroma. The parenchyma includes the orderly, treelike lactiferous ducts that open onto the surface of the nipple and the lobular-alveolar structure. The stroma includes the connective tissue, fat (adipose) tissue, blood vessels, and lymphatics (Figure 43-5).

The functional unit of milk making is the alveolar cell, which produces milk and excretes it into the lumen of the alveolar sack. Ductules and ducts carry milk from the alveolus to the nipple pore.

The skin of the breast includes the nipple, located slightly below the midpoint of the breast, and the areola, which surrounds the nipple. The nipple end has 15 to 25 small openings that are the endings of ducts that connect back to the lobular-alveoli system. The elastic nipple contains smooth muscle fibers and is enervated with both sensory and autonomic nerve endings; it is a system that causes the nipple to become smaller and firmer in response to cold, touch, and sexual stimulation. Surrounding the nipple, the areola is a circular area, also elastic and usually more darkly pigmented than the general skin of the breast. The size of the areola varies from woman to woman and enlarges and darkens during pregnancy and lactation. It has been suggested that the darker color of the areola may serve as a visual signal to the newborn and aid in orienting the infant to the breast for feeding.

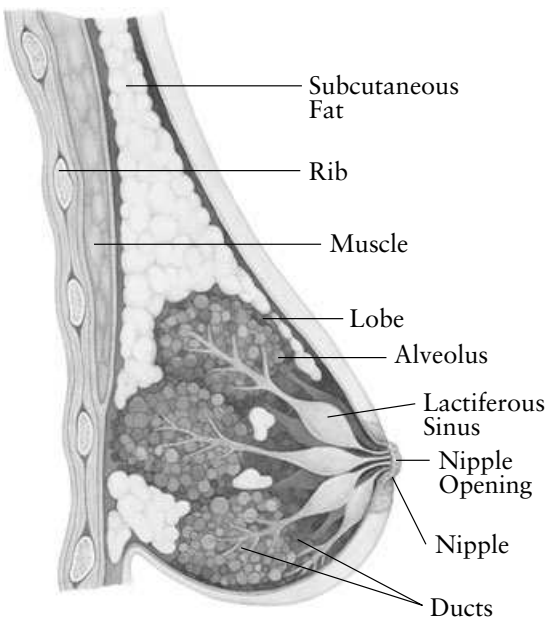

FIGURE 43-5 Side view of lactating breast.

Source: Walker, M. L. *Core Curriculum for Lactation Consultant Practice*. Sudbury, MA: Jones and Bartlett Publishers, Inc., 2002.

Montgomery's tubercles look like small pimples on the areola during pregnancy and lactation. They secrete a substance that is both lubricating and antimicrobial, protecting the nipples and areolae during pregnancy and lactation.

The breast is enervated by the fourth, fifth and sixth intercostal nerves.

During pregnancy, the size of the breast increases and the weight also increases from approximately 200 g to 400–600 g. In the first trimester of pregnancy, the woman's breasts respond to the changing levels of circulating hormones with rapid ductular-lobular-alveolar growth. During the third month of pregnancy, a secretory material known as colostrum begins to appear under the influence of prolactin, and in the last trimester the alveoli are filled with colostrum. By the sixteenth week of pregnancy, the breast is fully prepared for lactation, the physiologic completion of the reproductive cycle.

In lactation, the functioning mammary gland responds to complex nervous system and endocrine system signals in order to produce and deliver milk. The lactating breast weighs from 600 to 800 g. The mammary gland involutes, or regresses, during and after weaning but does not return to its prepregnancy state. During involution, the alveoli gradually collapse, any remaining secretion is absorbed, and adipose tissue increases within the breast.

Luteal and placental hormones influence the breast development of the pregnant woman, resulting in increased duct sprouting, branching, and lobular formation. Placental lactogen, prolactin, and chorionic gonadotropin are responsible for the continued and accelerated growth, with estrogen and progesterone also playing a role. Prolactin is the essential hormone for lobular-alveolar completion in pregnancy and initiates milk secretion via receptors on the alveolar cell walls. The prolactin-inhibiting factor (PIF) from the hypothalamus negatively controls prolactin, which is secreted by the pituitary. Although prolactin levels increase as much as tenfold to twentyfold during pregnancy, milk is not produced because of the elevated levels of progesterone. With the delivery of the placenta, estrogen and progesterone drop; high prolactin levels are maintained through the effect of suckling, and copious milk secretion begins and is noted clinically two to three days postpartum. Without nipple stimulation, prolactin levels drop to those of nonpregnant, nonlactating women within two weeks. Suckling via nipple stimulation provides the stimulus for prolactin release.

Within the breast, there are also local mechanisms of control of milk production. For example, milk removal stimulates milk synthesis and when milk is not removed secretion ceases over a period of days. The rate of milk synthesis and the amount of milk produced may vary from one breast to the other according to the frequency of suckling and the amount of milk removed.

During pregnancy the breast becomes increasingly sensitive to tactile stimulation as it prepares for the stimulation of breastfeeding and the task of ejecting milk. During suckling, oxytocin is released as the nipple is stimulated and stretched and also through sensory pathways when the mother sees, feels, touches, or hears stimuli that remind her of the baby and breastfeeding. Oxytocin causes the myoepithelium to contract, ejecting the milk from the alveoli and lobules. At 15, 30, and 45 minutes after the baby is born, significant elevations of oxytocin occur if the baby is placed skin-to-skin. If the baby does not suckle, the levels of oxytocin return to baseline [21]. Oxytocin is the hormone that promotes mother-infant bonding as well as other maternal behaviors.

Lactogenesis begins approximately 12 weeks before parturition as lactogenesis I and is initiated in the postpartum by the rapid fall in progesterone after the delivery of the placenta (lactogenesis II). Stage II is marked by copious secretion of milk two to three days postpartum. Galactopoiesis (stage III lactogenesis) is the ongoing production of mature milk. Weaning results in breast involution, which is characterized by two distinct physiological processes: the secretory cells undergo apoptosis (programmed cell death) and the mammary gland's basement membrane undergoes proteolytic degradation [22]. During breast involution, most mammary epithelium is reabsorbed.

Antepartum Preparation for Breastfeeding

Midwifery assessment of the pregnant woman for breastfeeding should include a physical assessment and evaluation of the breasts as well as the taking of a careful history.

History

In taking a history, the midwife should ask for the woman's age at onset of menses, whether there has been any chest or breast surgery, injury or trauma, any family history of breast cancer, or any history of discharge from the nipple(s). The midwife should also ask the woman if her breasts have been sore at any time during her menstrual cycle and if she has noticed breast changes during this pregnancy, such as tenderness or increase in breast size. Who among her family and friends has breastfed? Who will support her in breastfeeding? The midwife should ask a multipara if she has breastfed before, and if so how was that experience? What medications or herbs does she take on a regular or an intermittent basis? In addition, a discussion of infant feeding plans with an opportunity for the parents to ask questions should be part of the care plan.

Physical Assessment

The breast is divided into four quadrants for reference purposes: (1) the upper outer quadrant, (2) the lower outer quadrant, (3) the lower inner quadrant, and (4) the upper inner quadrant. The size of the breast varies from woman to woman and is not related to the ability to produce sufficient milk for the infant. The size and shape of the two breasts should be similar to each other. Markedly discrepant breasts may indicate diminished functional tissue, so close follow-up—including frequent weight checks of the breastfed baby—is imperative if the mother presents with this condition [23].

Increase in the size of the breast and the Montgomery glands along with the appearance of visible veins with an overall pattern on the breast indicate that the breasts are preparing for milk secretion. By the end of pregnancy, most women have noted breast changes. An occasional woman may experience most of the breast changes associated with pregnancy in the early days postpartum. Further evaluation of the breasts, the mother's hormones, and breastfeeding is indicated if breast changes are absent. Gigantomastia (extreme breast overgrowth) of pregnancy has been reported and is considered incompatible with breastfeeding. Underdeveloped breasts (micromastia) may indicate lack of glandular tissue or hormonal imbalance. Additional breast tissue and nipples (polymastia) may occur along the "milk line" that extends from the axilla to the groin (see Figure 43-4). This tissue is rarely fully functional although filling and involution may be experienced. The mother may need help with comfort techniques (warm or cold compresses, whatever feels best) during involution; breastfeeding proceeds normally in the two functioning breasts.

Because trauma to the chest could seriously impact the potential of the breast to produce and de-

liver milk, examination of the breasts and axilla should include questions related to any history of injury or surgery (including biopsy, reduction, and augmentation), and the midwife should consider the impact of the trauma on the ducts and nerves in the assessment. Signs of current inflammation, infection, or abscess should also be noted and treated.

An enervated nipple with patent ducts is necessary to continued production of milk. Lack of everted or enervated nipple tissue will not affect lactogenesis II (the copious production of milk "coming in") but will compromise the continuing production of milk (lactogenesis III). Congenital inverted nipples (nipples that retract toward the chest wall rather than protruding from the breast) have been studied in randomized controlled trials to determine the best method of correction. Neither the wearing of hard plastic shells designed for this purpose nor the performance of nipple exercises are more effective than natural softening effects of the hormones of pregnancy in everting previously inverted nipples [24]. Inverted nipples have been classified into three grades [25]:

1. Grade 1 inverted nipples are easily pulled out (by using a breast pump or by the infant nursing well, for example).
2. Grade 2 inverted nipples can be pulled out but do not maintain their projection (most inverted nipples fall into this category).
3. Grade 3 inverted nipples are difficult or impossible to pull out.

Experimental studies of postpartum nipple eversion techniques have not been published. If the nipple does not evert inside of the infant's mouth during nursing, the nipple may not be stimulated adequately and the milk supply will diminish over time. Inverted nipples in the mother are closely correlated with malnutrition and dehydration in studies of readmission of breastfed infants.

Engorgement or fullness of the breast may also temporarily invert nipples. This may make it difficult for the infant to latch on and for the nipple to stretch well back into the baby's mouth. Fullness may be relieved by hand expressing, soaking the breasts in a basin of lukewarm water, or gentle pumping.

Unusually shaped or sized nipples are usually congenital, although trauma may also be the cause. The functionality of the nipple must be assessed. The midwife should consider the patency of the nipple pores as well as the ability of the baby to stretch and suckle the nipple. Close follow-up may be needed to ensure adequate milk transfer.

Cancer of the breast may cause distortion of the nipple and the breast. Prompt referral is required if this or any other signs of breast cancer are detected.

Discussion of Infant Feeding Plans

The midwife can begin the discussion of infant feeding plans with an open-ended question such as "What have people told you about breastfeeding?" rather than asking, "Do you plan to breastfeed?" Pregnancy is the optimal time to deal with misconceptions and to explore information gaps. "What do you think breastfeeding will be like for you?" is another question that opens discussions. The midwife should listen for indications of self-doubt and/or misinformation—for example, comments such as "no one in my family makes good enough milk," "my breasts are too big (or too small)," or "I tried before and the baby never latched on"—and provide support to the pregnant woman by clarifying and teaching. Document the mother's understanding of breastfeeding in order to reinforce your teaching at a later time and continue to aid the mother in the development of her feeding plans.

Previous breastfeeding experiences (if any) should be discussed as well. Ask about how breastfeeding worked out before? What would the mother change for this time? How can the midwife help? This discussion is especially important if the woman stopped breastfeeding before she had intended. What problems did she have and how does she explain their etiology? What did she do to seek help?

A referral for a prenatal consultation with a lactation specialist may be appropriate for the pregnant woman who has had a prior lactation failure. An in-depth evaluation of the physical and psychosocial factors that played a part in her previous breastfeeding experience and discussion with a specialist may provide the education and reassurance needed to enable successful breastfeeding.

Ask the pregnant women what she is doing to prepare for breastfeeding. Discourage prenatal nipple preparation, vigorous nipple scrubbing with loofah sponges or rough washcloths, and any other potentially harmful activities. Nipple stimulation is known to cause uterine contractions [26] and is to be avoided during pregnancy in order to not risk initiating preterm labor. The use of hard plastic shells worn inside the bra during the last trimester of pregnancy with the intention of everting a flat or inverted nipple has not been shown to be effective in a randomized control trial [27]. Instead, the control group, which received no treatment, had the

greatest sustained improvement. In addition, the women who received the shells to correct their nipple inversion initiated breastfeeding at the lowest rate and stopped breastfeeding before six weeks at a significantly higher rate than the women who had been randomly assigned to groups that did not receive the shells.

Later prenatal discussions should also include the advantages of breastfeeding the baby soon after birth, rooming-in, and nursing on cue.

The Effect of Birth Practices on Breastfeeding

During pregnancy, the majority of women interviewed will indicate that they plan to "try" breastfeeding. However, in many areas, breastfeeding *intention* rates are much higher than *initiation* rates. A Canadian report found that while approximately 80 percent of mothers intended prenatally to breastfeed, only 30 percent breastfed for at least six months [28].

Similar discrepancies between breastfeeding intention and practice are found in the United States. The WIC Infant Feeding Practices study examined the experience of a sample of participants of this federal nutrition program for women, infants, and children from low-income to moderate-income families [29]. While 56 percent of mothers in this study initiated breastfeeding, only 46 percent were still breastfeeding (30 percent exclusively and 15 percent mixed feeding) at discharge. Participants had a number of experiences during the peripartum period that were detrimental to breastfeeding, including late initiation of breastfeeding after birth, extended separation from infant, supplementation with formula, limited or no help with breastfeeding problems, and receipt of gift packages including formula. Maternal race and ethnicity were found to be significantly associated with experience of detrimental practices. African American infants were among those most likely to receive formula supplements and to spend a night in the hospital nursery.

Other potentially detrimental experiences in childbirth and the postpartum period include receipt of anesthesia and analgesia during labor, delayed maternal-infant contact, delayed initiation of breastfeeding, maternal/infant separation, unnecessary supplementation of breastfed infants, and limited or no breastfeeding teaching and support.

A correlation between use of anesthesia and analgesia and disturbances in infant neurobehavioral functioning and suckling has been noted by several sources [30, 31, 32, 33]. Others have suggested that these effects are confounded by multiple factors including the variety of pain relief medications and protocols used as well as the impact of different childbirth and postpartum practices [34, 35].

Continuous support during labor and birth has also been linked with enhanced breastfeeding initiation and exclusivity [36]. A large trial in Mexico found that the frequency of exclusive breastfeeding was significantly higher among women who received psychosocial support during labor. These findings support the hypothesis that women who are nurtured throughout the childbearing process may be better able to nurture and nourish their babies. The midwife is in a unique position to offer support during labor and birth to women she has come to know in pregnancy and whom she will also care for in the postpartum period. This enhanced and long-term relationship makes the midwife's support and nurturing of these women even more powerful.

Successful Breastfeeding

The Ten Steps to Successful Breastfeeding and the Baby-Friendly Hospital Initiative

Research demonstrates that the management of the mother and baby in pregnancy, delivery, and the postpartum period influences the outcome of breastfeeding. In recognition of the importance of childbirth practices, UNICEF and the World Health Organization (WHO) created the Baby-Friendly Hospital Initiative (BFHI) to recognize maternity facilities that have worked to create a facility-wide environment that promotes, protects, and supports breastfeeding. This international initiative is constructed around *Ten Steps to Successful Breastfeeding* (see Table 43-3), a list of practices that are well supported by scientific evidence [37].

Step 1 calls for establishment of a facility-wide breastfeeding policy to guide practice. Step 2 indicates that all staff need to be oriented to the facility's breastfeeding policy and be knowledgeable of its content. Staff who interact with breastfeeding mothers and babies need sufficient training to implement the policy. A minimum of 18 hours of breastfeeding training is required of the maternity staff of a Baby-Friendly birth facility. Step 3 identi-

fies the importance of integration of parental education about breastfeeding during prenatal care and childbirth education.

Early mother-infant contact and early initiation of breastfeeding are the focus of Step 4. Righard and Alade have demonstrated that unrestricted skin-to-skin contact in the first hour postpartum is beneficial to breastfeeding [33]. After an hour of uninterrupted skin contact with their mothers, infants of nonmedicated births demonstrated an ability to crawl to the breast, root, attach, and begin to suckle. Swedish midwife-researchers discovered that infants who touched or licked the nipple or areola during the first 30 minutes after birth appear to elicit more interaction with their mother: their mothers were less likely to send the infant to the nursery and were more likely to talk to their infant during feedings [38]. Here again the midwife is in a unique position that allows her to support and facilitate early and prolonged contact between mother and baby and to assist in initiating an early first feeding. She can assist and observe this first feeding and another feeding later on when she does her postpartum rounds.

Step 5 indicates the importance of positive and frequent breastfeeding teaching interactions between staff members and mothers. Breastfeeding is a learned behavior, not an instinctive one. Mothers want and need the support of their caregivers during the critical early period. Gill has identified a gap between mother's expectations and the care they receive, finding that mothers want much more contact with their caregivers, more encouragement, more practical information and more consistency in the information they received from their health care team [39]. Mothers particularly wanted a midwife or nurse to stay with them throughout an entire feeding.

Step 6 discourages unnecessary supplementation of breastfed infants. The Baby-Friendly Hospital Initiative has identified a list of medical indications for supplementation (Table 43-4). Supplementation that is not medically necessary puts the exclusivity and duration of breastfeeding at risk. Research has indicated that receiving formula may delay the onset of lactation [40]. This step also links with the International Code of Marketing of Breast-milk Substitutes, which indicates that maternity facilities should not give breastfeeding women any literature, gift items, or samples from infant food manufacturers.

Step 7 calls on hospitals to practice rooming-in, keeping mothers and babies together throughout their stay, except when separation is medically necessary (see Chapter 42). Close contact assists the parents in learning their baby's feeding cues and increases the available feeding opportunities. Klaus has suggested that the effect of the hormone oxytocin, which is increased through physical contact and nipple stretching, may enhance the maternal-infant bond and decrease the risk of abandonment [41].

TABLE 43-4 Acceptable Medical Reasons for Supplementation

- Infants with very low birth weight (less than 1500 g) or those born before 32 weeks gestational age
- Infants with severe dysmaturity with potentially severe hypoglycemia, or who require therapy for hypoglycemia, and who do not improve through increased breastfeeding or by being given breast milk
- Infants whose mothers have severe maternal illness (e.g., psychosis, eclampsia, or shock)
- Infants with inborn errors of metabolism (e.g., galactosemia, phenylketonuria, maple syrup urine disease)
- Infants with acute water loss—for example, during phototherapy for jaundice, whenever increased breastfeeding or use of expressed breast milk cannot provide adequate hydration
- Infants whose mothers require medication that is contraindicated when breastfeeding (e.g., cytotoxic drugs and radioactive drugs)

Step 8 clarifies the importance of offering the breast according to infant feeding cues, rather than clock timing. A Cochrane review of the data regarding unrestricted versus restricted breastfeeding concluded that restricted breastfeeding was associated with an increase in the incidence of sore nipples, engorgement, and the need to give supplemental formula. In contrast, demand feeding was associated with fewer breastfeeding problems and a longer overall duration of breastfeeding [42].

Step 9 indicates that the use of pacifiers and bottle nipples should be avoided unless medically indicated. Time spent sucking on pacifiers or bottle nipples is sensation lost to the breast and endocrine system. Early use of pacifiers and nipples is associated with decreased duration and exclusivity of breastfeeding [43]. Howard and colleagues suggest that these decreases in breastfeeding may be due to less frequent feeding, and thus less stimulus to the milk-making cells [43]. Pacifier use has also been linked with recurrent ear infection [44].

Step 10 clarifies the responsibility of the maternity facility to assist mothers in finding postpartum

support. Breastfeeding women need proactive community services and resources. The maternity facility should take an active role in fostering the growth of culturally appropriate community resources, ranging from professional lactation services to peer counseling to mother-to-mother support. The facility should assist mothers in connecting with appropriate support services. Research indicates that community support can not only increase breastfeeding success, but also demonstrate measurable improvements in infant health: Pugh and colleagues found that support provided by a nurse/peer counselor team increased the duration of breastfeeding, and decreased the infant's number of sick visits and medications [45].

Evaluation of the implementation of these ten steps has identified a synergistic effect of the steps: the more beneficial practices women experienced, the less likely they were to stop breastfeeding early [46]. Late initiation of breastfeeding and supplementation of the breastfed infant were the strongest risk factors for early termination of breastfeeding in this study.

Newborn Behaviors

Healthy, full-term infants display a sequence of behaviors after birth that culminate in feeding at or around the end of the first hour of life [47]. Using the senses of touch, smell, sight, and hearing, and reflexes including stepping/crawling and rooting, newborn infants can locate and attach to the breast without assistance. The first hours of life are considered a sensitive period for breastfeeding. Optimal mother-infant contact during this period has been associated with better breastfeeding outcomes. When skin contact does not or cannot occur during the early sensitive period, and after use of pain relief during delivery, research suggests that prolonged skin-to-skin contact may revitalize the infant's quest to the breast [48, 49].

Infant behavior has been categorized into six states: (1) deep sleep, (2) light sleep (or active sleep), (3) drowsy, (4) quiet alert, (5) active alert, and (6) crying [50]. After the first hour, the infant signals its feeding readiness by eliciting cues, including making mewing sounds, yawning, stretching, movements of mouth (including smacking, salivating, searching with lips and tongue), moving hand to mouth or face, rooting, and head bobbing. These activities are characteristic of drowsy, quiet-alert, and active alert states. Crying is a late hunger cue. Crying infants are disorganized and are not able to move directly from crying into feeding. Nonetheless, crying is widely accepted as a feeding cue in American culture. Mothers should be supported in discerning and responding to their infant's early feeding cues. Feeding on demand would be better described as feeding on cue.

Positioning and Latch

Comfortable positioning for breastfeeding is imperative. Nipple and breast soreness are not normal sequelae of breastfeeding; rather, the most common cause of soreness is incorrect positioning and attachment at the breast.

Mothers should be adequately supported by their chair or bed. There is no one right position for breastfeeding. The Madonna, cross-cradle, and football positions are often helpful for new mothers. However, there is no need to adjust positioning if mother and infant are comfortable, and adequate milk transfer is occurring.

In the Madonna (or "cradle") position (Figure 43-6), the infant lies on its side, facing the mother. The infant's head, neck, and upper back rest on the forearm of the lateral breast. The mother uses her opposite hand to support the breast as needed.

In the cross-cradle position (Figure 43-7), the infant lies on its side, facing the mother. The infant's head, neck, and upper back rest in the mother's contralateral palm and along her forearm. The mother uses her other hand to support the breast as needed.

In the football (or "clutch") position (Figure 43-8), the infant lies on its side or back curled between the mother's arm and the side of her chest. The mother's forearm and hand support the infant, and she uses her other hand to support the breast as needed.

FIGURE 43-9 Sidelying position.

Source: Walker, M. L. *Core Curriculum for Lactation Consultant Practice*. Sudbury, MA: Jones and Bartlett Publishers, Inc., 2002.

In the sidelying position (Figure 43-9), mother and infant lie on their sides facing each other. This position is often the most comfortable for mothers recovering from surgical birth.

In order to feed well, infants must utilize a wide-open mouth latch, as shown in Figure 43-10 [51]. In order to achieve a wide gape, the infant's nose is aligned with mother's nipple. The mother provides gentle support to the infant's head and neck by resting her hand on the infant's occipital bones, and allows the infant's head to move back in a pose, as if sniffing a flower. As the infant's lower jaw gapes, the mother gently moves the infant in toward the breast, aiming the infant's bottom lip toward the outer edge of the areola. This results in an asymmetrical rather than centered latch. The infant's mouth should be completely full of breast tissue. The infant uses its lips, tongue, oral cavity, jaw, facial muscles, and buccal fat pads to generate both

negative and positive pressure, drawing forward the milk. The mother's hormonal response to nipple stretching and stimulation increase oxytocin circulation, which causes the myoepithelial cells to eject milk into the baby's mouth.

Breastfeeding has a visible and audible rhythm. The infant suckles in a burst of short, rapid, pistonlike motions of the jaw at the beginning of the feeding, followed by a slower, deeper rocking motion as the jaw indents the breast, drawing out milk. The ratio of sucks to swallows is high in the initial pistonlike phase, and reduces to 1:1 or 2:1 as the milk flows rapidly in the slower rocking phase.

Optimal Feeding Management

Optimal feeding frequency ranges between 8 and 12 feeds daily [1]. Although it is easy to divide a 24-hour day by 8 to 12 feedings, and come up with projected schedule, this is not how most infants feed. Most infants cluster several feedings within a stretch of a few hours, sleep for several hours, and awaken to cluster feed again. Mothers should be encouraged to feed in response to infant feeding cues, and stop feeding when the infant reaches satiety. (Satiety cues include full body relaxation, falling asleep at the breast, releasing the nipple, etc.) It is not necessary for the infant to feed from both breasts during each feeding. The mother should allow the infant to nurse on the first breast until satiety cues are seen. She may then offer the second breast, and allow the infant to determine how long to nurse on that side (if at all). If one breast is not nursed during a feeding, it should be offered first at the next feeding.

Timing the frequency and duration of feeds is unnecessary and may be detrimental to infant growth and maternal milk supply.

The best indicator of milk sufficiency is the infant's output and weight gain. It is expected that the newborn will (1) have a minimum of three to four bowel movements each 24 hours, that stools should be about 1 tablespoon or larger, and that after the third day, stools will be yellow in color; (2) wet a minimum of one to two diapers the first day, and six or so diapers daily after the third day; (3) gain more than 15 to 30 grams daily after the mature milk has come in; (4) be at or above birth weight by 10 days of age [52].

Breastfeeding should be comfortable for mother and infant. A mother should be encouraged to report any discomfort to her midwife or breastfeeding counselor as soon as possible. It is much easier to correct technique in the early days than to remedy problems later. Research suggests that clinical indicators of breastfeeding problems can usually be seen prior to discharge from the maternity unit [53]. Women report that a health care worker's observation and assistance throughout at least one complete feeding in the hospital or community is key to their breastfeeding success [54].

Finding Support

Midwives and other health care providers are important sources of breastfeeding support in the postpartum period, as well as friends, family, breastfeeding peer counselors, lactation care providers, and informal and formal support networks including the La Leche League and the Nursing Mothers Counsel. Mothers often require assistance in locating appropriate resources. Information about how to find breastfeeding support should be a routine part of discharge teaching. Proactive support services that reach out to mothers rather than waiting for the mother to call for help are among the most powerful strategies. Meeting the community support person before a new mother leaves the hospital usually makes her more likely to call for help as soon as a problem surfaces. Breastfeeding peer counseling has been shown to be effective in increasing the initiation, duration, and exclusivity of breastfeeding [55, 56, 57, 58, 59]. A message resounds throughout the body of knowledge about breastfeeding support. Ertem and colleagues state that "interventions aimed at prolonging the duration of breastfeeding . . . will need to shift focus from increasing knowledge and managing problems of lactation to enhancing mother's confidence regarding breastfeeding"[60]. This study found that the problems a woman experienced during lactation were not associated with early weaning. Rather it was the degree of a mother's confidence in her ability to overcome hurdles that was significantly associated with early weaning. Breastfeeding has been called a "confidence game." Midwives should focus breastfeeding support in a manner that nurtures the growth of women's confidence.

Problem Prevention and Management

As discussed above, breastfeeding problems are best prevented by optimizing antepartum care, childbirth routines, and breastfeeding management and

by providing proactive maternal support. Maternal and infant comfort level and infant's growth and output are important hallmarks of feeding. Common challenges to the breastfeeding dyad include nipple and breast discomfort, infant digestion and sleep, medical concerns, and lifestyle issues.

Nipple Discomfort

Nipple soreness is one of the most common reasons women give for early weaning. Researchers report that between 11 to 96 percent of mothers experience nipple soreness [61]. Rather than an expected sequela of breastfeeding, clinical impressions indicate that early onset nipple discomfort is caused by poor positioning and attachment of the newborn. Pain and soreness may be immediately relieved by improvements to the infant's positioning and attachment. In cases where fissuring and abrasion of the nipple and areola have occurred, pain should be greatly reduced with improvements to positioning and attachment. However, resolution of pain may not occur until damaged skin is completely healed. Nipple pain that is not resolved by improvements to positioning and attachment may be complicated by the following:

1. Inflammation due to reaction to topical creams, detergents, soaps, etc.
2. Infection with *Candida albicans* [62], *Staphlococcus aureus* [63], or rarely other infectious agents.
3. Damage from equipment or clothing (poor fitting bras, damp bra pads or bra cups, nipple shields, breast shells, and misused pumps and other gadgets).
4. Eczema or psoriasis of the nipple and areola.
5. Raynaud's phenomenon, vasospasm of the nipple that results in a color change of the nipple in response to exposure to cold air (as occurs at the end of a feeding) [64].
6. Rarely itching, burning, and eczema-like changes to the nipple and areola may be caused by Paget's disease of the breast, a cancerous condition [65].

Research regarding various suggested soothing topical treatments has demonstrated that there is no clear superiority of any treatment other than corrected positioning and, in one study, the application of warm compresses [66, 67].

Treatment protocols for *Candida* infection include treatment of the nipple with topical nystatin, miconazole, or clotrimazole [68].

Breast Discomfort

Discomfort in the lactating breast may be related to engorgement, plugged ducts, mastitis, abscess, and other processes.

Engorgement is the condition of excessive fullness in the breast. The engorged breast is likely to be hot and painful with tight, shiny skin. In the early postpartum period, the engorged breast is not necessarily only full of milk; it also contains extra blood and lymph drawn there by the hormonal changes precipitating the production of mature milk. Restricted feeding schedules are thought to be the main determinant of engorgement [69]. In order to prevent engorgement, and to relieve it when it has occurred, mothers should be encouraged to feed their infant based on cue, and with comfortable positioning. Research examining comfort modalities for the treatment of engorgement has found that the greatest relief for the engorged breast comes from breastfeeding [69, 70]. Milk must be drained in order for mother to experience relief. If the baby is unable to attach to the very swollen breast, warm soaks, cool packs, and/or gentle hand expression of milk (see Chapter 62) should be utilized until milk begins to flow and the breast softens a bit.

Plugged ducts—also referred to as clogged or caked breasts—are a fairly common occurrence in the early weeks of breastfeeding. Plugged ducts are thought to result from restriction of milk flow due to internal or external pressure (e.g., engorgement, tight bras, and clothing). Mothers should be encouraged to feed frequently, preferentially offering the affected breast first, when the infant is hungriest, to attempt to drain the plugged areas. Many clinicians suggest changing the orientation of the infant's position so that the infant's chin points to the plugged segment of the breast. This is thought to focus the massaging action of the tongue on the plugged area. Untreated plugged breasts may progress into mastitis; it is important to assist mothers in determining the factors that contribute to this problem, and in improving the milk flow during feedings.

In approaching this and other breastfeeding problems, it may be helpful to think like a detective. Look at the breast for signs of bra tracks, bruises, and other trauma; watch the mother and baby closely throughout a feeding. Is the mother compressing her breast? Is the baby too high or too low in her arms? Most problems are multifactoral, and require a bit of detective work to solve. Plugs that

do not respond to treatment may be unrelated to breastfeeding. When plugs do not resolve within 24 to 48 hours, mothers should be referred for further evaluation including ultrasound or stereotactic imaging. Breast cancer has been detected in the lactating breast. Milk retention cysts, or galactoceles, are thought to be rare products of plugged ducts and may be visualized by ultrasound or other imaging techniques. Upon aspiration, these cysts are found to contain milk. They will typically refill with milk after aspiration. Galactoceles are not a contraindication to breastfeeding [71].

Mastitis refers to an inflammation in which one or more segments of the breast will appear to be hot, red, and inflamed (see also Chapter 44). Mothers experience elevated temperatures and a feeling of malaise. Inflammation may be infective or noninfective. Noninfective mastitis may result from plugged ducts, resulting in reabsorption of milk from the duct into the interstitial spaces in the breast tissue and subsequent inflammatory response. Infective mastitis is associated with nipple fissure, or other trauma creating an entryway to the breast. The common infective agent is *Staphylococcus aureus*, although *Candida albicans*, *Escherichia coli*, *Enterobacteriaceae*, and rarely *Mycobacterium tuberculosis* have been cultured from infected breasts [71]. Simultaneous bilateral mastitis rarely occurs and is associated with *Streptococcus* infection. Because it is difficult to distinguish between infective and noninfective mastitis, typical treatment in the United States includes a 10 to 14 day course of the antibiotic dicloxacillin or cloxacillin in dosages of 500 mg four times daily. Hale and Berens note that clinicians should "review sensitivities of staph organisms for their individual regions" [68]. It is essential to encourage completion of the full course of antibiotic treatment, as mastitis has been noted to reoccur with incomplete treatment. Ensuring adequate drainage of the affected breast is crucial to the resolution of this condition and is accomplished through continued breastfeeding. Assist mothers to improve latch and attachment. Mothers may need to suspend other activities for a few days to focus on breastfeeding, rest, and care for themselves. Anti-inflammatory medications such as ibuprofen (Motrin, Advil, etc.) may also be beneficial [68]. Fetherston has identified several predictive factors for mastitis, including blocked ducts (caused by engorgement, hurried feedings, use of nipple shield, etc.), problems with positioning and attachment, tight bras, and nipple pain [72]. Clinicians have noted that mastitis tends to occur in anemic women, perhaps due to a reduced immune response. A sudden change in feeding frequency such as a delay or a skipped feeding with subsequent milk "back up" is enough to trigger mastitis in some women.

An abscess is a localized collection of pus in the breast, formed by disintegrated cells and surrounded by an inflamed area. Unresolved mastitis can result in the formation of one or several abscesses within the breast. Most abscesses require surgical lancing and may be drained to the exterior. Exudate from the abscess should be cultured to determine appropriate antibiotic treatment. Breastfeeding on the opposite breast is desirable throughout treatment, and feeding from the affected breast is possible in many cases. The safety of breastfeeding on the affected breast is likely to depend on the location of the drain(s). Milk expression via hand or pump should continue when feeding is suspended on the affected breast.

Infant Discomfort

Infants are often uncomfortable. The breastfeeding mother may decode all signs of discomfort as indicators of problems with herself and her milk. Midwives may need to help mothers assess infant discomfort and determine appropriate comfort strategies. Mothers often worry, for example, that the foods they ate may be the cause of infant's gas or gastric discomfort. Food eaten by mother rarely causes problems for her infant. Gassy foods eaten by the mother do not cause gas in her infant—gas is formed as a byproduct of the digestion of insoluble fiber in the intestinal tract [71]. Myths abound about colic caused by chocolate, broccoli, onions, and other tasty foods. However, it is unusual for infant discomfort to be relieved by changes in mother's diet. Colic is a poorly understood phenomenon that peaks between three weeks and three months of age, gradually subsiding after that time. It is characterized as crying and screaming that continues for three to four hours at a time [71]. Research indicates that about 35 percent of colicky infants improved after their mothers had removed cow's milk whey from their diets for more than a week [73]. An important role for the midwife is to distinguish between fussy behavior and true colic. All infants have fussy times. Fussy infants are typically soothed by being cuddled close, rocked, talked or sung to gently, and/or nursed. When the infant cries inconsolably for long periods of time, pediatric evaluation of the infant is indicated. No infant

should be left to cry for any period of time without being soothed—holding and cuddling does not "spoil" infants.

Occasionally infants will refuse to feed at the breast. When this happens in the newborn period, it can be a symptom of birth trauma, a reaction to being forced to the breast or fed in an awkward position, oral aversive behavior due to painful procedures (e.g., deep suctioning), anesthesia side effects, or a symptom of neurologic or craniofacial anomalies. Unexplained breast refusal requires physical assessment and follow-up.

In an older baby, sudden refusal to breastfeed is referred to as a "nursing strike"[71]. This can be related to ear infection, teething, superimposed pregnancy, or a reaction to parenting interactions (e.g., the baby who is scolded for biting at the breast may refuse the breast at the next feeding). Unexplained ongoing rejection of one breast requires follow-up: oncologists have reported that occasionally, breast cancer has been diagnosed in the rejected breast up to five years later [74].

Milk Supply

Milk production over the first four months of lactation has been estimated at 725 to 750 mls per day although volumes of over 1000 mls have been reported [75]. Early initiation of suckling and a pattern of frequent feedings are related to production of sufficient milk. When the infant's condition is such that he or she cannot participate in early initiation by feeding at the breast (prematurity is the most notable example), pumping should be started as soon as the mother's condition permits. The mother should be encouraged to mimic an infant feeding routine using the pump [76].

"Not enough milk" continues to be the number one reason for weaning in the early weeks of lactation, although about half of the mothers who are concerned about the milk supply have a baby who is gaining well [77]. This is called "perceived" (versus "actual") milk insufficiency. A feeding evaluation by a lactation specialist should be considered for both perceived and actual milk insufficiency.

There is no known limit to the ability to make milk. Mothers have exclusively breastfed twins, triplets, and quadruplets. The demand of multiple infants suckling appears to drive the milk supply. Early, frequent breastfeeding (or expressing if the infants are premature) will optimize the mother's long-term ability to produce milk. Midwives may refer mothers to La Leche League or a Lactation Consultant for assistance with positioning and caring for multiples.

Myths abound concerning milk supply and may lead mothers to unhelpful and potentially harmful behaviors. Following are some examples:

1. *Myth:* Drinking more will increase the milk volume (and the converse, drinking less will speed weaning). *Response:* mother's fluid intake and her milk composition and volumes have been studied in experimental trials. Neither the volume [78] nor the composition [79] is affected by the mother's fluid intake.
2. *Myth:* Eating better will make better milk (and the converse, eating poorly will cause the milk to be inferior). *Response:* as mammals, humans make human milk. Diet has almost no effect on the volume or composition of milk unless the mother is grossly undernourished, as in a prolonged famine. Studies of marginally nourished women have shown that the breastfed babies of those women whose diets were improved as part of the research design did not have babies who gained weight any better that those babies whose mothers' diets were not improved [80, 81]. Women who "diet" to regain their figure faster also have not been shown to negatively affect their babies growth pattern [82].
3. *Myth:* Hard work will decrease the milk supply and plenty of rest is needed to make enough milk. *Response:* there is no evidence that hard work has a negative impact on milk supply; indeed working hard has been the norm for generations of women. Separation from the baby, lack of nipple stimulation, and milk retention *do* negatively impact the milk supply.
4. *Myth:* Drinking (whatever is popular) herb tea or eating (an indubitably hard to find or expensive) food will increase the milk supply (or not drinking or eating them is the reason for the low supply). *Response:* many cultures have favorite galactogogues (substances that are thought to increase milk). There is no evidence that eating or drinking specific herbs or foods will increase the milk supply; indeed certain herbs can be harmful [71]. Herbs must be treated with the same respect as other medications and should be prescribed only by those with special training in their use and appropriate dosing. (See Chapter 10 for more information on medications and breastfeeding.)

Through discussions with pregnant women and new mothers, the midwife will uncover other local or emerging myths and theories about milk supply

and be able to counteract them, all the while giving culturally competent care.

Strategies for Increasing Milk Supply

The first step in increasing the milk supply is to assess the mother, infant, and breastfeeding in order to determine the reason (or reasons) that the supply is presently inadequate:

1. Infrequent or scheduled feedings, not on cue
2. Replacing or spacing breastfeedings with pacifier
3. Replacing breastfeedings with formula or baby foods
4. Compression of milk-making cells (too tight bra, engorgement)
5. Use of nipple shield
6. Stopping night feedings too soon
7. Poor letdown
8. Prematurity, dysmaturity
9. Retained placental fragments
10. Inadequate glandular tissue (often presents with breasts of markedly discrepant size)
11. Class 2 or 3 inverted nipples
12. Poor milk transfer by the infant
13. Breast surgery or injury
14. Cigarette smoking by the mother
15. Drugs or medications that could negatively impact milk supply, such as bromocriptine (Parlodel), L-dopa, or ergotamine [71]
16. Endocrine (especially thyroid) problem

The breastfeeding related behaviors (such as infrequent or scheduled feeds, use of a pacifier), the mother's physical condition, and the baby's behavior at the breast (with before and after weights using a digital scale with breast milk intake function) should all be part of the assessment. A skilled observer, such as a lactation specialist, may determine that there are problems with the mechanics of the feeding process.

Any interventions directed toward improving the milk supply should ensure adequate nutrition for the infant. Underfed babies do not nurse well and may decrease the mother's milk supply further by becoming sleepy and lethargic. Careful monitoring of the increase in the mother's milk supply and the decrease in other nutrition for the infant should be combined with frequent weight checks.

Corrective interventions should be focused on removing the cause of the poor milk supply and also remediation of the milk supply. Merely finding the cause is insufficient, especially if the baby is unable to stimulate the breast adequately. Pumping with a soft flange compression pump has been shown to stimulate the mother's prolactin levels equal to that of the baby [76]. The mother may find it helpful to pump after the feeding, between feedings, or during feedings. During the first months after birth if the cause of the low supply has been correctly identified and nipple stimulation is optimal, an increase in milk volume should be seen 24 to 48 hours after pumping is initiated. If an improvement in milk volume is not forthcoming, further evaluation is needed.

Supplementing the Breastfed Infant

The limited number of medical reasons for supplementation of the breastfed infant recognized by the UNICEF guidelines for Step 6 of the Baby-Friendly Hospital Initiative are shown in Table 43-4. Occasionally families will request supplementation for nonmedical reasons—for example, for relief feedings. While offering respect for the family's choices, midwives should offer informed consent about the rationale for exclusive breastfeeding, and the possible hazards of introducing formula. It is clear that the health benefits of breastfeeding accrue to those babies who are exclusively breastfed.

When supplementation is required or chosen, it is best done in a way that interferes least with feeding at the breast. Infants may be supplemented at the breast with the assistance of an at-breast supplementer [83], a tube and storage container device that delivers supplement to the baby while the baby suckles at the breast. When possible, expressed mother's milk can be used in the supplementer.

Many clinicians have noted that supplemental feeding appears less detrimental to the breastfeeding pattern when offered as a separate feeding (or feedings, as needed). This allows the mother to manually express or pump her breasts just before or after the infant receives formula, thus preserving the frequency of breast stimulation and milk removal. This is preferred over strategies for "topping up" the infant by offering a supplement after each feeding. Topping up strategies appear to increase the spacing between feedings (due to the slower digestion of formula), effectively delaying the timing of the next feeding, and thereby decreasing the stimulation and removal of milk.

Various feeding modalities, including cup and bottle, have been examined. Cup feeding and bottle-feeding take approximately the same amount of time.

Breastfeeding During the First Year of Life and Beyond

The experience of infant feeding changes for both mother and baby over time. At first, during the newborn period, the baby's need to feed may have no discernible pattern, averaging 10 to 12 cue-initiated feedings in 24 hours in order to gain at least one-half to one ounce per day. The baby may also have "frequency days"; feeding more often is recommended during these times. Night feedings are important for good weight gains in the early months.

By four months many babies begin to have a regular pattern of waking, nursing, and sleeping. Night feedings are common. "Distractible" is the best word to describe nursing babies from around four months through six months. "Playful" is another descriptive. The length of the feeding shortens as the baby becomes a pro at getting the milk to flow and transferring the desired amount. That leaves plenty of time for playing with mom's earrings, turning around to watch interesting motions, and practicing all kinds of gymnastic maneuvers at the breast. Solid foods are introduced around six months, although many breastfed babies prefer modified table food to packaged "baby" food.

Feeding during the second half of the first year is characterized as breaks in the infant's busy life of crawling and walking, falling, teething, and playing. Although mother's milk continues to be important nutritionally and immunologically, breastfeeding is important to the baby as a connection to mom—reassuring, winding down, and soothing. Juice, if given in the second half of the first year, should be offered via cup in moderate amounts (not more than about 4 oz daily). Overfeeding of juice has been associated with malnutrition, diarrhea, gas, abdominal discomfort, and tooth decay [84].

Fruits, vegetables, cereals, and other simple foods may be introduced to the diet of infants at about six months. Small amounts of new foods should be offered by spoon, rather than in a bottle. As the infant becomes more adept at dealing with solids, the texture and variety of foods can be increased. However, mother's milk, or formula, provides the backbone of the diet throughout most of the first year.

After the first year, the nursing bond is defined by the individual mother and child. For one family, nursing is the early morning and nighttime way to snuggle. For another, it is much like it was at seven or eight months.

Some women are concerned about teeth and teething if the baby is breastfeeding. Closeness to mom can be a real comfort to the baby who is experiencing the discomfort of teething. The bottom teeth are covered by the tongue during nursing, thus protecting the breast from biting during feeding. Biting happens rarely but is usually at the end of a feeding or during a hurried feed. The mother should firmly end the feeding and watch carefully for signs that the baby may bite at future feeds.

Breastfeeding the Special Needs Infant

Babies are born with congenital problems that affect their ability to breastfeed [85]. Most cleft defects do affect an infant's ability to latch on well and effectively transfer milk from the breast. Because of the variety of cleft defects and breast shapes and sizes it is difficult to predict the "success" of any particular mother baby dyad with a cleft defect. The midwife should support a mother's desire to breastfeed and assist her with interventions such as careful positioning, and expression of any residual milk, which also gives more breast stimulation to increase or maintain a milk supply. The infant's weight needs to be assessed frequently to ensure adequate milk intake. Whether or not a mother breastfeeds exclusively or combines feeding at the breast with giving expressed breast milk needs to be determined on an individual basis. Alternate breast massage and creative positioning are two techniques that mothers have found helpful in optimizing the infant's ability. The midwife can read breastfeeding literature or contact a lactation consultant for additional assistance. Early surgical repair of the cleft can be very beneficial. Generally speaking, the infant with a unilateral defect of the lip alone, lip and palate, or palate alone benefits from positioning that allows the breast to enter the mouth on the same side as the defect. Whether the baby's body is level with the breast, below the breast, or under the breast needs to be evaluated on an individual basis. Whatever position results in a rhythmic suck, followed by a swallow is a good position. The worst things that can be said to a mother are that she will not be able to breastfeed or that she should not have to express any milk but that she should try to feed at the breast only. Assist the mother and baby to reach their optimum level of proficiency and comfort. The midwife should be sensitive to each unique dyad.

Infants born with Down syndrome may also present a unique challenge [85]. As with infants with a cleft defect, early and prolonged contact

with the mother is very desirable. These infants may be more lethargic, do not give clear cues for feeding consistently, and do not sustain a rhythmic pattern of suck and swallow for any length of time. With good support and interventions for positioning and breast expression to remove residual milk and give additional breast stimulation, babies with a cleft defect usually go on to breastfeed well after repair. Again, the midwife can turn to resources such as literature, colleagues, and lactation consultants.

Premature infants have a special need for their mother's milk. Advantages of mother's milk for premature babies include enhanced brainstem maturation [86], decreased necrotizing enterocolitis [87], and improved wellness. Mothers should be assisted in collecting their milk as soon as possible after the birth. Expressed milk may be stored until the infant's condition allows oral feedings. The neonatal intensive care unit will have protocols for storage and containers that must be followed carefully, or the milk may be discarded as unsuitable. Nonnutritive suckling at the breast and kangaroo care have been shown to improve breastfeeding outcomes and should be implemented as soon as the infant is stabilized [88, 89]. Many mothers find that the high technology atmosphere of the NICU makes them feel insignificant and unneeded. Receiving support from their midwife to provide skin-to-skin contact and breast milk for their baby reinforces the irreplaceable connection of the mother-baby dyad.

Breastfeeding can often be reestablished. In the early months postpartum, a woman who has stopped breastfeeding her infant, or not chosen breastfeeding, can usually resume Lactogenesis III, which is called relactation. Women who have never been pregnant have been able to establish lactation; this is called induced lactation [90].

Relactation may be indicated when the infant is weaned prematurely or when a pump-dependent mother has a diminished supply. Nipple stimulation is often accomplished through the use of a breast pump. The baby may be enticed to suckle using formula in an at-breast feeding device [83]. A lactation specialist with experience helping mothers relactate or inducing lactation should be part of the support team. Close follow-up of the infant's weight gain is an important part of the plan, as underfed babies become sleepy and this can be misread as satiety.

Milk Expression

Mother's milk can be expressed manually or via pump. Hand expression is an important skill for all midwives to know and for breastfeeding mothers to practice. Hand expression is a method that is always available to women (see Chapter 62). Hand expression should be used prior to pumping to assist in the triggering of the milk flow.

A wide range of pumps is currently available on the market. Pumps range from the old "bicycle horn" pump that operates via compression of a rubber bulb, to high-tech hospital grade pumps that pump both breasts simultaneously with variable pressure. Not all breastfeeding mothers need a breast pump. Expression methods should be chosen and used in a way that is appropriate for the situation. For example, the mother who is pumping for a hospitalized premature infant will benefit from a hospital grade pump suitable for pump-dependent mothers. The mother who is expressing for a weekly relief bottle may use manual expression or an occasional-use pump. Occasional-use pumps are inexpensive and generally ineffective at building a milk supply.

Casual use pumps are used by a mother when she is away from a nursing infant, at work or school for example. These pumps are capable of removing substantial quantities of milk but not of building a milk supply.

Midwives should provide instruction about appropriate use of the pump and encourage women to use the manufacturer's directions for the cleaning and care of the pump.

Unless her milk is needed for medical reasons, mothers should be encouraged to wait until breastfeeding is well established before she begins to collect her milk. Many a mother has lost confidence in her ability to nurse after a dismal first pumping session where she has collected only a few droplets of milk. Mothers need to be told that babies are much more adept at expressing milk than either the mother's hand or her pump.

Milk Storage

Expressed milk should be treated carefully, like any other fresh food. Milk is best stored in food grade containers in feeding sized portions (2 oz for the newborn). Milk should be chilled, either in the refrigerator or in a cooler with ice packs, immediately after expression. Milk can be safely stored at room temperature (at a maximum of 25°C [77°F]) for 4 hours, in the refrigerator at 4°C (39°F) for 72 hours, and in the freezer at –20°C (–4°F) for 3 to 6 months or longer [91]. Chilled milk will separate into cream and liquid layers. Mothers are often concerned that this means the milk has soured and should be reas-

sured that milk can be gently swirled to remix the cream. (Specific storage requirements should be requested and followed for infants in special care.)

Expressed milk should be heated gently under running water. It need not be heated to body temperature. In fact, gentle warming will help to preserve living immune cells in the milk. Milk should never be boiled or microwaved. Frozen portions of milk can be thawed slowly in the refrigerator, or quickly in a pan of heated water that has been removed from the stove.

Combining Breastfeeding, Working, and/or School

Working outside the home, or attending school, is a reality for the majority of mothers with young children. While breastfeeding intentions do not appear to be different among women who plan to be employed postpartum, breastfeeding duration and exclusivity may be impacted by employment or schooling. Research indicates that full-time work decreases breastfeeding duration by 8.6 weeks on average relative to not working outside the home; however, part-time work (4 hours or less daily) does not appear to impact breastfeeding duration [92].

Helpful tips to share with mothers planning to return to work or school postpartum include the following:

1. Negotiate as generous a leave as possible during pregnancy.
2. Explore availability of job-sharing and at-home work possibilities.
3. Focus efforts in the immediate postpartum on building an adequate milk supply and making breastfeeding comfortable (rather than on expressing milk).
4. Determine feeding plans for return to work. Will breastfeeding continue after the return to work? Will mother collect milk during her work hours? How will she do so? How will the milk be stored? What are her child care plans? Can the baby be brought to the mother to be fed during breaks or lunches?
5. Begin to assume the schedule of the working day a week or so prior to return to work/school.
6. Consider returning to work or school part-time at first, gradually increasing to full-time (if necessary).
7. Consider starting back to work or school toward the end of the work week, rather than at the beginning.
8. Plan clothing for easy access to the breast if milk expression is planned.
9. Identify coworkers who understand the importance of breastfeeding and will support and encourage the effort.

Weaning

Weaning is a process of change that begins with the introduction of the first supplemental food. It is important for midwives to understand, and help mothers to understand, the difference between lactation failure and weaning. Breastfeeding mothers may grieve and mourn during the weaning process, whether at two weeks or two years, and fail to ask for help with their pain [93].

Weaning—whether from the breast or from the bottle—can be a stressful process for families. A gradual process of weaning is best for mothers and children, allowing time for both to adjust to the change physically and emotionally. Mothers may drop one feeding, and watch for the child's response. Possible negative reactions can include whiny, clingy behavior, anger, and withdrawal. Suitable replacements should be offered for the feeding, based on the child's age (formula for the child under a year, milk or other foods for the child over one). Weaning continues as the mother gradually replaces an increasing number of daily feedings with acceptable substitutes. Breastfeeding mothers should monitor their breasts for possible overfullness, plugged ducts, and inflamed areas during the weaning process.

Throughout the time of weaning, mothers and other family members should be encouraged to offer many opportunities for nurturing interaction with the child. Nursing, from the breast or the bottle, offers much more than food to children, it is very comforting as well. Alternate comforts in the form of hugging, holding, playing, and blankets and other "lovies" should be offered.

When Breast Is Not Best

Infant Conditions

Unless there are rare special health needs such as intestinal lactase deficiency, galactosemia, or phenylketonuria (PKU), there are no nutritional contraindications for an infant to breastfeed. Special diets are recommended for these babies. For example, infants with galactosemia require a specific lactose-free formula while infants with PKU may partially breastfeed in addition to receiving a phenylalanine-free formula. Blood levels of the in-

fant are drawn periodically and the diet adjusted to maintain an infant blood level of between 5 and 10 mg per deciliter. Even infants with PKU need some phenylalanine in the diet.

Maternal Conditions

Maternal medications may affect breastfeeding by decreasing the volume of milk, affecting the infant's behavior or passing to the infant in undesirable amounts. However, Lawrence offers this advice: "Before breastfeeding is summarily discontinued, adequate information should be sought and the clinician should consider the risk of the drug versus the benefit of breastfeeding for the infant" [94]. Other resources [71, 95] address the issue of drugs and breastfeeding more specifically (see also Chapters 10 and 12).

Acute infectious diseases in the mother that are readily controlled and treated are not in general contraindications to breastfeeding. Antibodies and other host resistance factors are present in the breast milk. Some conditions, such as beta-hemolytic streptococcus, group A, require both the mother and the infant to be treated. Breastfeeding may not be contraindicated. The American Academy of Pediatrics *Red Book* [96], Lawrence and Lawrence's *Breastfeeding: A Guide for the Medical Profession* [71], and the Centers for Disease Control and Prevention are excellent resources in the case of illness in the mother.

Breastfeeding should be withheld temporarily if the midwife suspects that a lesion on the breast or nipple is herpes simplex virus (HSV). A culture should be obtained. If the infant is under six months, and HSV is suspected, breastfeeding should be discontinued until all lesions are assessed, and if culture is positive, until lesions are completely cleared. The infant should be fed formula or banked milk (from a donor milk bank) during diagnosis and treatment. If the mother pumps for comfort, the pumped milk and the pump kit should be discarded once the infection has resolved. In older babies, the effects of HSV are not so devastating, but cautious practice is recommended.

Women who are HIV positive or who are at high risk for becoming HIV positive are advised not to breastfeed when the risk of infection of the infant exceeds the risk of mortality from other causes such as diarrhea. Recommendations vary from country to country and are based on perceived risks and benefits. In the United States, women who are HIV positive or who are at high risk are advised not to breastfeed. High-risk women include seronegative women:

1. who are injection drug users,
2. whose sexual partners are known to be HIV positive, or
3. whose sexual partners are injection drug users [96].

Some conditions may be presented erroneously as contraindications. For example, poor maternal diet is not a breastfeeding contraindication [71]. Breastfeeding should be encouraged, even if the mother's diet is not perfect. Improving the diet of women with restrictive eating habits (such as low caloric intake) does not make a better quality or quantity milk. Dietary advice should be focused on the mother's well-being (replenishing her stores) rather than the erroneous idea that improving her diet will improve her milk supply or composition. Specific advice for some restrictive eating patterns includes the following:

1. Women who take in fewer than 1800 kcals per day may not have a satisfactory intake of nutrients. These women should be advised to consume nutrient-rich foods and perhaps a balanced multivitamin-multimineral supplement.
2. Vegans, who eschew all animal foods, are at risk of a vitamin B_{12} deficiency and so is the nursing infant. A B_{12} supplement should be taken each day. Mothers who have had gastric bypass or other surgical procedures that affect the stomach also require B_{12} supplementation.
3. A dietitian should evaluate women who eliminate whole food groups for possible supplementation. For example, women who eliminate dairy products may require dietary adjustment or caloric supplements for vitamin D, calcium, and protein. Women who have inadequate exposure to ultraviolet light may also require vitamin D evaluation.

Breast Milk Substitutes

Breast milk alone, exclusive breastfeeding, is recommended for infants for about the first six months, continuing with the addition of complementary foods for the first year and beyond. In the event that breastfeeding is not possible or the mother chooses not to breastfeed, formula should be recommended for the first year with the addition of solid foods after about six months. Cup feeding should be initiated by the six-month point. Formula-fed infants should receive formula throughout the first year, then switch-

ing to whole cow's milk until two years (the fats in whole milk are required for nerve development).

Cow's milk–based formulas are considered standard and should be the choice for formula-fed infants except those with a known allergy to cow's milk or if there is a genetic tendency to diabetes. Soy-based formulas are reserved for infants with a proven allergy to cow's milk or if the family is adverse to the use of animal products [97]. However, many infants who are allergic to bovine proteins will also be allergic to soy. Special formulas should be recommended only when the infant's condition is such that a standard formula cannot be tolerated—for example, if the infant has been diagnosed with phenylketonuria (PKU). Hydrolysate formulas have had the cow's milk proteins modified, and lactose-free formulas do not contain lactose as the carbohydrate. In addition, some formulas have added ingredients that purport to be more like breast milk. However, research is clear that although they may be nutritionally adequate they are suboptimal compared to breast milk.

Donor milk banks provide screened and pasteurized human milk. A processing fee is charged and the distributing milk bank may prioritize recipients according to medical need. As Arnold explains, "One should remember, however, that banked donor milk is the only transplanted tissue that retains its functional properties and bioactivity after heat treatment"[98]. Informal sharing of milk (without a milk bank) should be discouraged.

Formula Feeding Methods

Formula should be prepared according to the manufacturers' instructions and the midwife should be assured that the caretakers are able to determine the difference between ready-to-feed, concentrated, and powdered formulations and dilute them appropriately. The water supply should be considered and if well water is used should be checked for the presence of organisms and heavy metals. Formula should also be stored according to the manufacturers' directions.

Cup feeding and bottle feeding have been found to take about the same amount of time [99]. Infants fed formula when there are inadequate resources available to clean the equipment are advised to cup feed with an open, easily cleaned cup. Research does not support the use of one type of bottle nipple over another or indicate that the shape of the bottle influences baby behavior. Feeding implements should be cleaned carefully, especially the tip of the nipple.

Parents and other caretakers should hold the baby closely while feeding, keeping eye-to-eye contact. It has also been suggested that the baby be switched from side to side as is the baby fed at the breast. Babies should never be fed "propped" bottles or given a bottle in the crib to hold. Stroking, talking, and interaction are important components of feeding that all babies should receive. When teeth have erupted, formula or juice should be carefully wiped away before the baby sleeps to prevent the development of "bottle mouth" caries.

Conclusion

Feeding is one of the most intensive interactions shared by parent and child during the first year. With the support and expert guidance of their midwife, families can learn to nurture and nourish their little one.

CHAPTER

44

Screening for and Midwifery Management of Puerperal Abnormality

The complications of the puerperium presented in this chapter are those that the midwife is most likely to confront. Those complications requiring physician consultation or referral in all cases are not included. Examples of the latter are Sheehan's syndrome, broken coccyx, muscle paralysis in the lower extremities, extended pelvic infections, and separation of pelvic joints. Students interested in these topics are encouraged to pursue their interests in medical and obstetric textbooks and journals.

The midwife needs to be thoroughly familiar with the normal physiological and anatomical changes of the puerperium in order to differentiate between the discomforts associated with healing after childbirth and abnormal conditions as early as possible. It is essential that the midwife be familiar with the signs and symptoms of complications in order to consult or collaborate with a physician as appropriate.

Puerperal infection, although fortunately rarely seen today after vaginal birth, is discussed in this chapter. The discussion serves as a reminder of what once was a most feared sequela of childbirth. The specter of puerperal morbidity and mortality can rise again if no thought is given to the routine use of third and fourth generation antibiotics so that more strains of bacteria develop resistance to antibiotics, and as professionals become careless about hand washing and aseptic technique. The history of puerperal infection is tragic and fascinating at the same time.

Puerperal Morbidity

Puerperal morbidity has long been defined by the Joint Committee on Maternal Welfare as a "temperature of 100.4°F (38.0°C), the temperature to occur on any two of the first ten days postpartum exclusive of the first 24 hours, and to be taken by mouth by a standard technique at least four times daily." Puerperal morbidity and puerperal infection are sometimes thought of as synonymous, although it is incorrect to do so. Puerperal morbidity may be caused by infections and conditions other than puerperal infection, such as dehydration, urinary tract infection, upper respiratory infection, and mastitis.

Nonobstetric Causes of Puerperal Morbidity

Making a differential diagnosis entails determining (1) whether evidence of puerperal morbidity reflects puerperal infection or one of the other causes; (2) if the morbidity is a result of puerperal infection, where the source is; and (3) if the morbidity is a result of another infection, what the offending organism is and to which antibiotics it will respond.

Temperature elevation caused by dehydration usually occurs during the first 24 hours postpartum. This time period is excluded from the definition of puerperal morbidity. Dehydration may be present in the first 24 hours as a carryover from decreased fluid intake during labor (especially if labor was prolonged) and may be compounded by a pe-

riod of rest and sleep during the early hours of the puerperium. If dehydration continues into the next day postpartum it may confuse the etiology and symptoms associated with temperature elevation. This confusion can be prevented by encouraging a woman to drink at least one glass of water per hour during her waking hours and anytime she awakens briefly from sleep. The woman should also be encouraged to urinate frequently. Frequent urination helps to prevent urine stasis and the increased potential for urinary tract infection.

During the immediate postpartum period, a urinary tract infection may be difficult to differentiate by signs and symptoms. Its symptoms are similar to those of some types of puerperal infection and may vary depending on whether it is a simple cystitis or pyelonephritis. Women catheterized during labor or with anterior vaginal trauma are more likely to be at risk. Urinary tract infections may cause urinary frequency, urgency, dysuria, and occasionally, lower abdominal pain; with the onset of pyelonephritis, low-grade fever with spikes, flank pain, and CVA tenderness appear. Definitive diagnosis of a urinary tract infection is made by culture of a clean-catch urine specimen demonstrating a significant number of a single type of bacteria (see Chapter 7).

Auscultation of the lungs should be part of the early postpartum examination of the woman with any respiratory symptoms. This examination would disclose the sounds of a lower respiratory infection, and point toward this as the cause of temperature elevation, as would the other usual signs and symptoms of bronchitis or pneumonia.

If a woman has an elevated temperature of more than 100.4°F (38°C) the midwife reviews her chart for possible predisposing causes of infection, collects an interval history and reviews current symptoms, performs an examination of her lungs, breasts, urinary tract, abdomen, lochia, and legs; obtains urine or lochial specimens, for culture and sensitivity if indicated; and discusses all findings to date with the consulting physician.

Puerperal Infection

Puerperal infection is a bacterial infection originating in the reproductive tract during labor or the puerperium. It is no longer responsible for a high incidence of puerperal mortality as it was historically, when it was known as childbed fever. However, puerperal infection is still responsible for a significant percentage of puerperal morbidity.

Predisposing Causes

The following circumstances predispose a woman to puerperal infection:

1. Prolonged labor, especially with ruptured membranes
2. Prolonged rupture of the membranes prior to labor
3. Numerous vaginal examinations during labor, especially with ruptured membranes
4. Breaks in aseptic technique
5. Carelessness regarding hand washing
6. Any intrauterine manipulation (e.g., uterine exploration, manual removal of the placenta)
7. Extensive tissue trauma or an open wound such as an unrepaired laceration
8. Hematoma
9. Hemorrhage, especially if more than 1000 mL of blood are lost
10. Operative delivery, particularly cesarean birth
11. Retention of placental fragments or membranes
12. Improper perineal care
13. Untreated vaginal/cervical infection or sexually transmitted disease (e.g., bacterial vaginosis, chlamydia, gonorrhea)

Infectious Organisms Organisms in puerperal infections come from three sources:

1. Those that normally exist in the lower genital tract or in the bowel
2. Infections of the lower genital tract
3. Bacteria that are in the nasopharynx or on the hands of attending personnel or in the air and dust of the environment

Bacteria from the first source are endogenous and become pathogenic only when there is tissue damage or when there is contamination of the genital tract from the bowel. Women should be routinely screened and treated prenatally for infections of the lower genital tract. The third source is best prevented with scrupulous attention to hand washing and asepsis.

Organisms common in puerperal infection include many *Streptococcus* species (including *S. viridans*, *S. pyogenes*, and *S. agalactiae*) *Staphylococcus aureus*, *Gardnerella vaginalis*, *E. coli*, *Klebsiella* species, *Proteus* species, the anaerobic *peptostreptococci*, *Bacteroides* species, *Ureaplasma*, and *Mycoplasma*. Some of these are common enough as

vaginal flora that their relationship to the infection is unclear. Both *Neisseria gonorrhoeae* and *Chlamydia trachomatis* may also cause postpartum genital infections, although prenatal screening will minimize the risk of their presence.

Signs and Symptoms

The signs and symptoms of infection generally include elevated temperature, general malaise, pain, and malodorous lochia. An increased pulse rate may occur, particularly with severe infection. Interpretation of laboratory cultures and sensitivities, further investigation, and treatment require discussion and collaboration with your consulting physician.

Sites of Puerperal Infection

While most postpartum infections are endometritis, which is far more common following cesarean birth than vaginal birth, any lacerated or traumatized tissue in the genital tract can become infected following birth. There are also extended infections, which originate from a localized infection and extend via the path of venous circulation or the lymphatics to produce bacterial infection in more distant sites. Extended sites of puerperal infection include pelvic cellulitis, salpingitis, oophoritis, peritonitis, pelvic and/or femoral thrombophlebitis, and bacteremia.

Infected Trauma of the Vulva, Perineum, Vagina, or Cervix Signs and symptoms of infected episiotomies, lacerations, or other trauma include the following:

1. Localized pain
2. Dysuria
3. Low-grade temperature—seldom above 101°F (38.3°C)
4. Edema
5. Red and inflamed repair edges
6. Oozing of pus or gray-green exudate
7. Wound separation or dehiscence

Visible episiotomy and laceration repairs should be checked routinely. The treatment of an infected repair includes first removing any sutures; opening, debriding, and cleaning the wound; and administering a broad-spectrum antimicrobial drug. In addition to episiotomy or lacerations, trauma may include bruising, abrasions (skid marks) too small to suture, and hematoma formation; it may also be caused by foreign objects such as a gauze sponge inadvertently left in the vagina.

Endometritis Signs and symptoms of endometritis include the following:

1. Persistently elevated fever to 104°F (40°C), depending on the severity of the infection
2. Tachycardia
3. Chills with severe infection
4. Uterine tenderness extending laterally
5. Pelvic pain with bimanual examination
6. Subinvolution
7. Scanty, odorless lochia, or malodorous, seropurulent lochia
8. Variable onset depending on the organism, with Group B streptococcus presenting earlier
9. White blood cell count may be elevated beyond the physiological leukocytosis of the puerperium

Treatment is with broad-spectrum antimicrobial drugs, including the cephalosporins (e.g., cefoxitin, cefotetan) and extended-spectrum penicillin, or a combination penicillin/betalactamase inhibitor (Augmentin, Unasyn). The combination of clindamycin and gentamicin may also be used, as may metronidazole if the mother is not breastfeeding. Mild endometritis can be treated with oral therapy, although more serious infections require hospitalization for intravenous therapy.

The spread of endometritis, if left untreated, can lead to salpingitis, septic thrombophlebitis, peritonitis, and necrotizing fasciitis. Any suspicion of worsening infection, unexplained symptoms, or acute pain mandates physician consultation and referral.

Other Puerperal Complications

Mastitis

Mastitis is an infection of the breast. Although it can occur in any woman, it is almost exclusively a complication of the lactating woman. It should be distinguished from the transient temperature elevation and breast pain associated with early engorgement as milk comes in. Mastitis develops as a result of invasion of breast tissue (e.g., glandular, connective, areolar, fat) by an infectious organism or in the presence of breast injury. Common organisms include *S. aureus*, *streptococci*, and *H. parainfluenzae*. Injury to the breast may be caused by bruising from rough manipulation, breast engorgement, milk stasis in a duct, or cracking or fissures of the

nipple. The bacteria may originate from a number of sources: (1) the mother's hands; (2) the hands of people caring for the mother or for the baby; (3) the baby; (4) the lactiferous ducts; or (5) the circulating blood. Stress and fatigue have been associated with mastitis [1]. This makes sense, as stress and fatigue can lead to carelessness in technique, especially hand washing, or a missed feeding or change in frequency of feedings, which could lead to engorgement and stasis.

The best treatment of mastitis is prevention. Prevention is accomplished through meticulous attention to hand washing with antibacterial soap; prevention of engorgement with early and frequent feedings; proper positioning of the baby on the breasts; good support of the breasts without constriction; cleansing with water only and no drying agents; daily observation of the baby for skin or cord infection; and avoiding close contact with people with a known staphylococcal infection or lesion.

Cracked or fissured nipples may provide a pathway for *S. aureus* infections to become established. The application of a few drops of breast milk to the nipple area at the end of the feeding seems to promote healing. Consideration should be given to culturing the milk if deep or persistent fissures occur, and to prophylaxis with a topical or systemic antibiotic when appropriate.

Other than severe engorgement, precursory signs and symptoms of mastitis usually are not evident before the end of the first postpartal week. After that time, the woman may have any of the following symptoms:

1. Mild pain in one lobe of the breast, which is exaggerated when the baby nurses
2. Flu-like symptoms: muscle aches, headache, fatigue

Mastitis is almost always confined to one breast. The actual signs and symptoms of mastitis include the following:

1. Rapid elevation in temperature to 103 to 104°F (39.5 to 40°C)
2. Increased pulse rate
3. Chills
4. General malaise, headache
5. Painful, swollen, inflamed, hard area of the breast

Untreated mastitis has approximately a 10 percent risk of developing an abscess. Signs and symptoms of abscesses include the following:

1. Purulent nipple discharge
2. Remittent fever with chills
3. Breast swollen and extremely painful; a large, hard mass with an area of fluctuation, reddening, and bluish tinge to the skin indicating the location of the pus-filled abscess

Early intervention when mastitis is suspected may prevent worsening. Intervention includes several hygiene and comfort measures:

1. Supportive but nonconstricting bra
2. Meticulous attention to hand washing and breast care
3. Warm compresses to the affected area
4. Massage of the area while breastfeeding to facilitate milk flow
5. Increased fluid intake
6. Rest
7. Helping the mother set priorities to reduce stress and fatigue in her life
8. Supportive, nurturing caretaking of the mother

The infant should continue to nurse, and if nursing is impossible due to breast pain or infant rejection of the infected breast, regular pumping should continue. Frequent emptying of the breast will prevent stasis.

Antibiotic therapy can include a penicillinase-resistant penicillin or a cephalosporin. Erythromycin may be used if the woman is allergic to penicillin. The most common initial therapy is dicloxacillin 500 mg by mouth qid for 10 days. This regimen can be prescribed based on signs of mastitis even if an office visit is impractical—for example, on a weekend or at night. In any case, follow-up in 72 hours to evaluate progress is essential. If the infection is not resolving, milk cultures should be performed.

If the mother is one of the approximately 10 percent of women who develop an abscess, the midwife needs to involve the consulting physician for either needle aspiration (small abscess) or incision of the abscess and drainage of the pus. The incision is left open, often with a drain, so as not to lock in the bacteria again. Healing is from the inside out and takes one to two weeks. Antibiotics should be continued even though the woman will experience a dramatic recovery within a couple of days.

Mother, midwife, and physician should agree on a plan for breastfeeding. Generally speaking, if the incision is not in the way, breastfeeding can continue on both breasts and is the best way to continue emptying the affected breast and avoid repeated problems. It helps to remember that any bacteria in the milk will be killed by the acids in the

baby's gastrointestinal tract and will not harm the baby [2]. If it is not physically possible for a woman to continue breastfeeding on the affected breast, then it should be emptied by pumping and massage, and she should continue to breastfeed on the other breast. Involvement of a lactation consultant who has experience with mastitis is most helpful.

Yeast infections of the breast can develop when the infant has thrush, or if the mother has persistent vaginal yeast infections. If the nipple has been injured, or when the mother has been on antibiotics that affect normal skin flora, breast yeast is more likely to occur [3, 4]. These infections are identified by the acute onset of sharp, stabbing pain at the nipple when the infant nurses. Few other objective signs are present. Treat both mother and infant, even if the child has no symptoms of thrush. Nystatin is the usual first-line therapy. Hand washing, treating the infant at the same time as the mother, and careful breast care that avoids touching both nipples without washing hands in between, and frequent changes of breast pads will reduce the risk of spreading infection from one nipple to the other.

Thrombophlebitis and Pulmonary Embolism

Postpartum thrombophlebitis is more common in women with varicosities or who perhaps are genetically susceptible to vein wall relaxation and venous stasis. Pregnancy fosters venous stasis by virtue of vein wall relaxation resulting from the effects of progesterone and pressure on the veins by the uterus. Pregnancy is also a hypercoagulable state. Compression of the veins during positioning for labor or birth may also contribute to the problem. Thrombophlebitis is described as superficial or deep, depending on which veins are involved.

Superficial thrombophlebitis is evidenced by leg pain, localized heat, tenderness, or inflammation at the site, and palpation of a knot or cord. Deep venous thrombophlebitis is evidenced by the following signs and symptoms:

1. Possible slight temperature elevation
2. Mild tachycardia
3. Abrupt onset with severe leg pain worsening with motion or when standing
4. Edema of the ankle, leg, and thigh
5. Positive Homans' sign
6. Pain with calf pressure
7. Tenderness along the entire course of the involved vessel(s) with palpable cord

Homans' sign is elicited by placing one hand on the mother's knee and applying gentle pressure in order to keep the leg straight. If there is calf pain with dorsiflexion of the foot, the sign is positive.

Treatment includes bed rest, elevation of the affected extremity, hot packs, elastic stockings, and analgesia as needed. A cradle for bedclothes may be needed if the leg is quite tender to touch (more likely with superficial thrombophlebitis). Referral to the consulting physician is necessary for decisions concerning anticoagulant therapy and antibiotics (more likely with deep venous thrombophlebitis). Under no circumstances should the leg be massaged.

The greatest risk associated with thrombophlebitis is pulmonary embolism. This is particularly true with deep venous thrombophlebitis and unlikely with superficial thrombophlebitis. Tachypnea, dyspnea, and sharp chest pain of sudden onset are the most common symptoms. Many other less specific symptoms may be present, and include altered lung or heart sounds and apprehension as the woman's blood oxygen level decreases. *Sudden onset of the first three symptoms mandates urgent physician evaluation of the woman.*

Hematomas

A hematoma is a tissue swelling that contains blood. The dangers of a hematoma are blood loss amounting to hemorrhage, anemia, and infection. Hematomas arise from spontaneous or traumatic rupture of a blood vessel. In the childbearing cycle, hematomas occur most often during delivery or shortly thereafter as vulvar, vaginal, or broad ligament hematomas. Possible causes include the following:

1. Operative delivery
2. Unrepaired laceration of a blood vessel torn during injection of local or pudendal anesthesia, or during repair of an episiotomy or laceration
3. Failure to effect complete hemostasis prior to repair of a laceration or episiotomy
4. Unligated vessels above the apex of an incision or laceration, or failure to start the suture line at that point
5. Rough handling of vaginal tissue at any time or of the uterus during massage

The common sign of a hematoma is extreme pain out of proportion to the expected amount of discomfort and pain. Other signs and symptoms of a vulvar or vaginal hematoma are as follows:

1. Perineal, vaginal, urethral, bladder, or rectal pressure and severe pain
2. A tense, fluctuant swelling
3. Bluish or blue-black discoloration of tissue

Vulvar hematomas are the most obvious, and vaginal hematomas are generally identifiable when careful inspection of the vagina and cervix are performed. Small and moderate-sized hematomas may be spontaneously absorbed. If a hematoma continues to enlarge, rather than stabilizing, the midwife should notify the consulting physician for further evaluation and care, which might include monitoring continued bleeding with hematocrits, an incision to evacuate blood and blood clots and closure of the cavity, and the need for any other surgical intervention, blood replacement, or antibiotics. The midwife continues to manage the other aspects of the mother's postpartum course and adjustments.

The signs and symptoms of a broad ligament hematoma include the following:

1. Lateral uterine pain sensitive to palpation
2. Extension of pain into the flank
3. A painful swelling identified on high rectal examination
4. Ridge of tissue just above the pelvic brim extending laterally (this is the edge of the swollen broad ligament)
5. Abdominal distention

If a broad ligament hematoma is suspected, physician consultation is essential.

Late Postpartum Hemorrhage

Late (delayed) postpartum hemorrhage is hemorrhage that occurs after the first 24 hours postpartum. Common causes include the following:

1. Subinvolution of the placental site
2. Retained placental fragments or membranes
3. Previously undiagnosed reproductive tract laceration
4. Hematoma

The signs and symptoms of late postpartum hemorrhage include obvious external bleeding and the signs and symptoms of shock and anemia. The midwife collaborates with the consulting physician for diagnosis of the cause and appropriate treatment.

Hemorrhage that occurs during the first 24 hours postpartum is managed as discussed for immediate postpartum hemorrhage (see Chapter 34). The first step is to diagnose the cause (e.g., uterine atony, reproductive tract laceration), and institute appropriate management while awaiting the arrival of the consulting physician or resolution of the problem. This might include use of pitocin or methergine to contract the uterus, or, if the cause is a laceration, a reconsideration of the need for repair. This repair should be done in consultation with a physician.

Subinvolution

Subinvolution occurs when the process of uterine contraction does not take place as it should and is either prolonged or stops. The process of involution may be hampered by retained placental fragments, myomata, or infection. Retained fragments of membranes or placenta are the most frequent cause.

Subinvolution may be diagnosed during the postpartum examination or when the woman calls to complain of increased or persistent bleeding. The usual history includes a longer than normal period of lochia, followed by leukorrhea and irregular, heavy bleeding. Pelvic examination will reveal a soft uterus that is larger than normal for the week postpartum during which the woman is being examined.

Subinvolution early in the puerperium presents as a soft, boggy uterus that does not decrease in size and whose fundal height remains stationary rather than descending. The lochia is profuse and bright red to reddish brown. A lochial culture should be taken to rule out endometritis. At the four- to six-week postpartum visit, an infection is not considered unless there is tenderness or pain of the adnexa or on movement of the uterus.

Subinvolution is treated with ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg by mouth every 4 hours for 3 days; the woman is reevaluated in two weeks. If the woman also has endometritis, the midwife additionally prescribes broad-spectrum antibiotic therapy.

Postpartum Depression

The identification of postpartum depression rests in the hands of midwives and other clinicians who see women throughout the first postpartum year. As with any other disease process about which a woman may be reticent to speak, active listening and acceptance of her description of her experiences are key to hearing her fears and concerns. Beck has cited the phrase "the thief that steals motherhood" to describe the effect of postpartum depression on the woman's life [5]. In fact, as many as half of all women with postpartum depression either do not seek help or are not diagnosed with this common disease [6, 7]. One estimate of the rate of

postpartum depression puts major depression at 12 percent, with an additional 19 percent of women experiencing symptoms of minor depression. Other estimates are similar [8, 9].

In contrast to the baby blues, which are mild and transient, true postpartum depression can develop at any point in the first months postpartum, and shares the diagnostic characteristics of major or minor depression. At the far end of the spectrum of postpartum mood disorders, the rare postpartum psychosis is characterized by suicidal or infanticidal behaviors, and delusional thinking, in addition to symptoms related to depression [10].

Postpartum depression also must be differentiated from postpartum thyroiditis, which has an incidence of 5 to 7 percent. A thyrotoxic phase is followed by hypothyroidism. Fatigue and depression are associated with both phases. Although thyroiditis has generally been considered to be transient, there is a relationship with the later development of permanent clinical hypothyroidism [11].

Screening for thyroid dysfunction in cases of depression may lead to better therapy for some women. Beck's extensive work with postpartum depression has led to the development of the Postpartum Depression Predictors Inventory (PDPI) [12]. The most recent version of this screening tool includes 13 predictors:

1. Prenatal depression
2. Child-care stress
3. Life stress
4. Social support
5. Prenatal anxiety
6. Marital satisfaction
7. History of previous depression
8. Infant temperament
9. Maternity blues
10. Self-esteem
11. Socioeconomic status
12. Marital status
13. Unwanted/unplanned pregnancy

Table 44-1 shows the tool used in collecting the data for the PDPI-Revised. The format is that of an interviewing rather than a self-assessment tool. The

Do you feel you receive adequate emotional support from your partner?	❑	❑
Do you feel you receive adequate instrumental support from your partner (e.g., help with household chores or babysitting)?	❑	❑
Do you feel you can rely on your partner when you need help?	❑	❑
Do you feel you can confide in your partner?	❑	❑
(Repeat social support questions for family and again for friends.)		
Marital Satisfaction		
Are you satisfied with your marriage or living arrangement?	❑	❑
Are you currently experiencing any marital problems?	❑	❑
Are things going well between you and your partner?	❑	❑
Life Stress		
Are you currently experiencing any of the following stressful events in your life:		
Financial problems	❑	❑
Marital problems	❑	❑
Death in the family	❑	❑
Serious illness in the family	❑	❑
Moving	❑	❑
Unemployment	❑	❑
Job change	❑	❑
After delivery, add the following items:		
Child-Care Stress		
Is your infant experiencing any health problems?	❑	❑
Are you having any problems with your baby feeding?	❑	❑
Are you having any problems with your baby sleeping?	❑	❑
Infant Temperament		
Would you consider your baby irritable or fussy?	❑	❑
Does your baby cry a lot?	❑	❑
Is your baby difficult to console or soothe?	❑	❑
Maternity Blues		
Did you experience a brief period of tearfulness and mood swings during the first week after delivery?	❑	❑

strongest associations were with prenatal depression, poor self-esteem, child-care stress, and prenatal anxiety. Those with the smallest effect were single (nonpartnered) status, poverty, and unplanned or unwanted pregnancy [7].

Prevention through the identification of risks during the prenatal period as well as early intervention, including telephone or office follow-up in the early postpartum phase based on indicators of risk, is key to shortening the cycle of postpartum depression [7]. A recent program of individualized and enhanced postpartum care in Britain supported this argument for extension of postpartum care beyond assessment of purely physical recovery from childbirth [13].

The midwife's role is one of identification, support for women with mild symptoms, and referral to a supportive therapist or psychiatrist for women with significant depressive symptoms.

Coaching women to plan for life changes that will increase positive stimulation, open lines of good communication with family and friends, and care for themselves are helpful tools, but they do not replace the need for professional mental health care with true depression. Midwives who wish to participate in this care need to develop counseling skills, be informed about medication and talk therapies, and be prepared to devote significant time to this component of practice. It is also essential that consultation with a mental health professional be available.

Attachment Failure and the Potential for Child Abuse or Neglect

In the calendar year 2000, in the United States alone, approximately 879,000 children were identified as neglected or abused. Child maltreatment is the global term that is used to describe neglect of the physical, educational, or emotional needs of the child as well as physical abuse, sexual abuse, and emotional abuse [14]. The causes are diverse and complex; it is impossible to point to a single event or condition in most cases and to allege that this is the "cause" of neglect or active abuse. Among the factors that have been identified as potential causes are the following:

1. *Parenting:* History of abuse of the parent during childhood, substance abuse, personality traits such as poor self-esteem, depression, isolation, or immaturity, poor parenting skills, and the specific social situation of the family.
2. *Infant or child:* Social isolation, "differentness" such as illness or developmental delay, child behaviors.
3. *Family:* Financial, relationship, or violence issues.
4. *Environment:* Poverty, cultural issues, lack of social support [15].

Another study of family characteristics during early infancy identified low levels of social support, maternal depression, poor education, complaints of physical aches and pains, alcohol use, financial dependence on public programs, multiple dependent children, and maternal separation from her own mother at an early age as predictive of child maltreatment [16]. There is an obvious overlap between the issues that may lead to postpartum depression discussed earlier in this chapter and those associated with neglect or abuse of the young child. Beck's meta-analyses of studies on the relationship between postpartum depression and maternal-infant interaction, on infant temperament, and on depression's effect on child development suggest that the mother's inability to interact effectively with her infant not only affects early infant behaviors but also has a long-term effect on both emotional and cognitive function [17–19]. The midwife observes for behaviors that suggest not only maternal illness but also a home in which the infant is at risk.

Morton and Browne reviewed the literature on attachment and child maltreatment in 1998 [20]. Attachment is the process by which infants, at around six months of age, begin to develop behaviors that help them maintain proximity to their caregivers—a change from earlier months, when infants rely on sounds and facial expressions to attract attention and care. On the adult side, the response of the caregiver (usually considered to be the mother) reinforces or alters infant behavior. Rejection, inconsistency, or withdrawal behaviors by parents thus affect the infant's repertoire of behaviors. A synthesis of this research supported a belief that impacting these early relationships can break a cycle of maltreatment.

Periodic home visits have been explored as one intervention to promote healthy parenting and observe for risks of neglect and abuse. Several studies have provided repeated nursing visits during pregnancy and infancy and found that there was a potential benefit, although it is not clear whether the benefit is in promoting more effective parenting,

providing information the mothers could use to respond more effectively to their infants and develop secure attachment behaviors, or identifying risks and intervening earlier in cases of maltreatment [21–23]. The presence of domestic violence has been reported to interfere with the effectiveness of a program of home visiting [24].

Active abuse is not the only factor that plays a role in subsequent development. The midwife needs to be alert for indications of neglect, which has been linked to defects in learning, social interactions, developing independence, and coping skills [25]. Because neglect—especially neglect based on emotional detachment—may be subtle, observation of parent-child interactions during visits is an important tool.

There is also increased interest in the relationship of early neglect and abuse to brain development in the young child. The world to which the child is exposed—beginning with prenatal exposure to substances of abuse, to adaptation to negative stimuli (such as failure to interact with the infant), to malnutrition, to the chronic stressors of physical or emotional abuse—affects the ability to learn and to respond effectively. When the attachment process of early infancy is disrupted, the infant may not develop appropriate awareness of the self in relationship to others, or of other people's emotions. In addition, neglect and decreased stimuli may lead to decreased growth of the brain, with long-term deficits in learning and behavioral problems [26].

All midwives must assume the professional responsibility to observe for signs of childhood abuse and neglect and access the appropriate resources to protect children. Beyond that basic requirement, each midwife serves the families in her care by monitoring for warning signs and predictive behaviors, offering support for behavioral change, and working toward prevention of child abuse.

PART

VIII

Skills

Part 8 is a compilation of some of the necessary skills and procedures used in managing the primary care of nonpregnant women, normal childbearing women, and neonates in a variety of different settings both within and outside the United States. Some of these skills are used in obtaining a database for evaluation; others for implementing a plan of care. Skills that were discussed in the management sections in other parts of the book are not repeated here (e.g., timing contractions, Nitrazine test for ruptured membranes, evaluation of dilatation). Conversely, the skills and procedures discussed here are referred to but not described in other parts of the book.

As long as a skill or procedure is performed safely, effectively, accurately, and with the minimum possible trauma, variations in *how* it is done do not matter. The step-by-step procedures and rationale detailed in this book are based on experience that has shown the described method to be safe, effective, and accurate and to inflict the least possible trauma. However, other approaches may be equally valid. Alternative methods are described for some skills and procedures, and the advantages and disadvantages of each method are stated. Because of the multitudinous variations among hospitals and medical supply companies in packaging materials for procedures, a listing of necessary supplies is not given. The essential supplies for a given procedure are obvious from the discussion.

The importance of being able to perform essential skills efficiently need not be belabored. Suffice it to say that you should *never* base management of care decisions on whether you are capable of performing the necessary skill or procedure. Since experience and efficiency reduce trauma, it is essential to practice, practice, practice.

This portion of the book discusses only how to perform a skill or procedure once you have made the decision to do it. When and why to use a skill or do a procedure and the factors involved in making these decisions are part of the management process and are discussed in other parts of the book.

In accord with the educational principle that theoretical content is best learned when it is applicable, relevant anatomy is presented when pertinent. When this content is not presented, references are given for the learner to use for study purposes. The discussion of physical and pelvic examination skills also differs from the discussion of other skills and procedures in Part 8 in that observations and findings elicited by the examination and their significance are included. This is in keeping with the same principle of learning.

In addition to performing a skill or procedure in a manner that is safe and effective, yields accurate results or findings, and causes the minimum possible trauma, you should follow certain general principles and approaches with all procedures:

1. Obtain the woman's consent and cooperation.
2. Inform the woman of what you are doing or will be doing throughout the procedure.

3. Use a gentle, smooth, and firm touch (not jerky, rough, or inconsiderate, with additional nervous or repetitious movements).
4. Demonstrate respect for the woman's body and for her as a person.
5. Do the procedure safely as quickly as possible.
6. Forewarn the woman immediately prior to any step in a procedure that will be uncomfortable or painful.
7. Be honest; if a procedure is going to hurt, say so.
8. Reassure the woman and praise her for how well she is coping with the procedure.
9. Time the procedure so it is not done at a time when another procedure is being done or when the woman is experiencing temporary pain or other distraction. For example, unless the situation is an emergency, drawing blood from a woman in labor can wait until she is between contractions.

CHAPTER

45

Universal Precautions

Modern-day hospitals have always followed isolation precautions for the protection of both patients and care providers. In addition, obstetric personnel for years took extra precautions to protect themselves and others if they knew they were working with a woman with infectious hepatitis, syphilis, tuberculosis, or other communicable disease. For years, the use of sterile technique for normal birth was predicated on not bringing infection to the mother and her baby. Nurse-midwives prided themselves on changing labor and delivery room policy and eliminating the barriers between mother and provider and mother and baby created by sterile technique "overkill" for normal childbearing. Caps, masks, gowns, foot gear, wrist straps (to keep the mother from contaminating the sterile field), and extensive sterile draping gave way in the hospital as birth became more humanized.

Then came HIV/AIDS. In 1987, the Centers for Disease Control and Prevention (CDC) first published a document entitled *Recommendations for Prevention of HIV Transmission in Health-Care Settings* [1] in which it recommended that blood and body fluid precautions be used with *all* patients, regardless of their bloodborne infection status. The policies outlined in this document became known as *universal precautions*—an approach that considers all patients potentially infectious for HIV, hepatitis B virus, and other bloodborne pathogens. The CDC subsequently updated, clarified, and elaborated its universal precautions and guidelines for prevention [2, 3]. These have not changed since 1989. The most recent CDC publication on this subject, issued in 2001, addresses management of health care personnel with occupational exposure to human immunodeficiency virus (HIV), hepatitis B virus (HBV), or hepatitis C virus (HCV) [4].

Midwives went through a period of difficult transition getting back into masks, gowns, and footgear and adding eye protection and double gloving for delivery [5]. In 1988 a survey of Certified Nurse-Midwives revealed that only 55.1 percent were using universal precautions. Concern that precautions might interfere with the relationship between the midwife and the woman was identified as the most frequent reason for not using universal precautions [6]. Denial of the problem (with resulting carelessness) was another factor [7]. It may well be that the midwives most at risk for transmission of a bloodborne pathogen are those working with a population that is at low risk for HIV/AIDS and who foolishly think they thus do not need to be as conscientious in using universal precautions. However, as Zeidenstein writes, "responsibility to ourselves, our families and loved ones, and future generations of midwives must take precedence" [8].

Copies of universal precautions can be obtained from the CDC's National AIDS Clearinghouse ((800) 458-5231). The basic components of universal precautions specific to midwifery are as follows:

1. Appropriate barrier precautions should be used to prevent exposure of skin and mucous membranes (eyes, nose, mouth) to blood, amniotic fluid, vaginal secretions, semen, repeated contact with breast milk, and body fluids or secretions containing visible blood. Barrier precautions include gloves, cover gowns or aprons, masks, protective eyewear, footgear cover, and mouthpieces or other barriers for use during resuscitation.
2. Gloves should be worn for vaginal examinations; collection of cultures from lesions; birth;

phlebotomy, finger and heel sticks; handling the newborn before the baby is washed and dried; and handling of any sanitary or bed pads, clothing, linens, or other items soiled with body fluids.

When double-gloving, the first glove you put on should be one-half size larger than your usual size glove. Use your usual size glove for the outer glove. This will increase maneuverability [8].

3. Hands and skin surfaces that have been contaminated should be washed immediately and thoroughly.
4. Needles should not be recapped, removed from disposable syringes, bent, broken, or otherwise manipulated by hand after use.
5. All sharp instruments and needles should be placed in puncture-resistant disposal containers located in the immediate area.

CHAPTER

46

Finger Puncture

Procedure	Rationale
1. Check and organize materials and equipment, making sure all are present, appropriate, and placed conveniently.	**1.** Failure to do so may result in the need to stick the woman again, since hemostasis will occur while you gather missing equipment.
2. Ask the woman if she is left- or right-handed and if she has any preference as to which finger is used.	**2.** Use a finger on the hand least used because the puncture site will be sore for several hours upon direct pressure.
3. Ask the woman to hold her hand down while you get the materials ready. Do *not* milk the finger as preparation for the puncture. If needed, warm the puncture site area with a warm, moist gauze or cloth.	**3.** Utilize gravity to aid blood flow to the area. Milking the finger has potential for diluting the specimen with interstitial fluid, thereby possibly yielding inaccurate results. Warmth increases blood flow and results in arterial-enriched blood, which is more uniform in composition.
4. Put on gloves.	**4.** Universal precaution, to protect yourself from any bloodborne pathogen the woman may have.
5. Clean the ball of the selected finger with an alcohol sponge. Allow to air dry or wipe dry with a dry cotton ball or gauze square.	**5.** Wet alcohol will sting in an open wound such as will be created with the puncture.
6. Grasp the finger firmly in one hand, still holding it down, and tell the woman there will be a short, sharp stick pain and not to jerk her hand away (see Figure 46-1).	**6.** Elicit the woman's cooperation. If she jerks her hand, it may spoil your puncture and require you to stick her again. Your firm grasp of the finger helps to control any tendency to jerk.
7. Make a deep puncture slightly lateral to the center of the ball of the finger. Use a quick down-and-up (in-and-out) movement with deliberate pressure behind the movement to make the lancet go deeper. Some clinicians also twist the lancet a bit at the bottom of their thrust.	**7.** You want to create a puncture from which blood will flow freely; this requires a puncture that cuts enough tissue to obtain this result. Otherwise, excessive pressure and milking the finger to get blood will dilute the specimen with interstitial tissue fluid and render test results inaccurate. A deep puncture is therefore preferable to a shallow one. One deep puncture is no more painful than two shallow punctures. Don't worry about going too deep, as the length of the lancet prohibits this. You should take advantage of the full length of the lancet.
8. Apply slight pressure just above the puncture site with the thumb of the hand holding the finger.	**8.** This causes the blood to flow freely. More than slight pressure will contaminate the specimen with tissue fluid.

FIGURE 46-1 Proper positioning for finger puncture.

Procedure	Rationale
9. Wipe off the first drop of blood with a dry gauze square or cotton ball.	**9.** The first drop of blood usually contains tissue fluid and may be otherwise contaminated. Dry gauze is preferable to a dry cotton ball because the fibers of the cotton ball may stick to the wound or on the finger.
10. Again apply slight pressure above the puncture site and, when a drop of blood has formed, do either of the following:	**10.**
a. Place the blood drop on a special slide used in a hemoglobin machine; or	**a.** Be sure to read the instructions for the particular machine being used so you know where to put the blood drop without getting blood everywhere.
b. Fill capillary tubes for a hematocrit by holding one end of a red-tipped (heparinized) capillary tube against the blood in as close to a horizontal position as possible.	**b.** Holding the capillary tube horizontal facilitates the flow of blood into the tube, which operates by capillary action. Holding the capillary tube below the blood drop will cause blood to flow into the tube even faster because of the additional effect of gravity. Holding the tube above the blood drop will inhibit the blood flow.
Do *not* milk the finger.	
11. Control blood flow into the tube with your index finger, which is held at the end of the capillary tube opposite the end touching the blood. Blood will not flow in any direction if your finger covers that end. Otherwise, blood will ascend or descend in the tube depending on whether the tube is touching blood and the angle of the tube.	**11.** If air gets into the capillary tube it must be expelled. Cover the end of the tube with your index finger, hold the opposite end over a dry gauze square, and release your finger. Allow the blood to drop on the gauze square or cotton ball without touching it with the tube. (If blood at the end of the tube touches the gauze, more plasma than red cells will be attracted by the gauze and escape from the tube. The blood remaining in the tube will then be a false sample of the proportion of the component parts in the woman's blood. If this happens, a new specimen must be collected.) When the air is expelled, cover the end of the tube again with your finger to preserve the remaining blood in the tube and refill the tube with blood from the puncture site.

Procedure	Rationale
12. Fill two capillary tubes two-thirds full of blood with no more than one-sixth of the two-thirds that contains blood being air.	**12.** A small amount of air will not affect a hematocrit reading so long as the air is not of sufficient quantity to prevent blood from occupying over half of the tube. Filling the tube two-thirds full leaves room for the sealing clay.
13. When each tube is filled, cover the end, move the tube to a horizontal position, uncover the end, and gently tilt the tube back and forth without letting the blood get too close to either end of the tube.	**13.** Tilting the tube back and forth mixes the blood with the heparin in the tube. If not mixed immediately with the dried heparin in the tube, the blood will clot and readings will be inaccurately high. If blood gets in the end of the tube it may prevent a good seal with the sealing clay.
14. With sealing clay, close the end of the tube that did not touch the blood, by pressing with a rotary motion. Fill one end of the tube with approximately 5 mm of clay. If the hematocrit is not going to be run immediately, seal both ends of the tube.	**14.** Some of the plasma will evaporate if the tube is left sitting. This can raise the hematocrit reading considerably and erroneously. Evaporation can be prevented for a longer period of time by sealing both ends of the tube. Sealing both ends has no effect on the accuracy or running of the hematocrit.
15. Note where the blood is in the tube when you seal it and be sure it is not too close to either end.	**15.** If the blood is too close to the end being sealed, an ineffective seal may result and the pad of sealing clay will be smeared. If the blood is too close to the other end, it may be pushed out while the first end is sealed and you may be left with too little blood for the test.
16. Seal the tubes either by holding the sealing clay vertically and the tube horizontally or by placing the sealing clay on a flat surface and holding the blood tube vertically and inserting it into the clay. If you use the latter method, be sure to cover the upper end of the blood tube with the tip of your index finger. This will keep the blood suspended no matter at what angle you hold the tube, thereby preventing the blood from moving or escaping from the tube.	
17. When you are sure that you have two unbroken, appropriately filled, sealed tubes, clean off the woman's finger and, using an alcohol sponge for antisepsis, apply pressure (or ask the woman to apply pressure) to the puncture site until hemostasis has occurred and there is no further bleeding.	**17.** Do not apply pressure and effect hemostasis until you are sure you have all the blood you need. Otherwise, you may have to restick the woman.
18. Dispose of the lancet, gauze, hemoglobin slide (after reading the results), and gloves in a biological hazardous waste disposal receptacle.	**18.** Protect yourself and others from bloodborne pathogens.

Some medical supply companies make microcollection systems. If using such a system, read the directions carefully, wear gloves, and dispose of materials appropriately.

The purpose of the colored ends of the microcapillary tubes is color coding. A red-tipped tube is heparinized with dried heparin in it; a blue-tipped tube is plain with nothing in it. Red-tipped tubes, then, are the capillary tubes to use in doing a finger puncture to obtain blood for a hematocrit.

The colored tips can serve an additional function. Since only one end is colored, you can use them for remembering which end has touched the blood drop; fill the other end with sealing clay, thereby ensuring an effective seal. Form a habit of always using the same end (plain or colored) for the same substance, blood or clay.

CHAPTER

47

Venipuncture

Procedure	Rationale
1. Check and organize materials and equipment, making sure all are present, appropriate, and placed conveniently.	**1.** Failure to do this may have a number of results, all leading to having to restick the woman. The blood may clot in the syringe prior to transfer to the appropriate test tube; body movements made in trying to reach ill-placed equipment may cause the needle to slip out of or go through the vein wall; you may discover that the syringe is not large enough to collect all the blood needed or that not enough blood tubes are on hand.
2. Poke a hole through each rubber stopper in each test tube with a needle. Discard the needle. This step is not necessary if you use a Vacutainer.	**2.** This releases the pressure vacuum in the tubes. See Step 19.d. The needle is no longer sterile.
3. Apply the tourniquet.	**3.**
a. The tourniquet should be 1 inch wide.	**a.** A wide tourniquet causes less discomfort than a narrow one.
b. Place the tourniquet approximately 3 inches proximal to the intended insertion site.	**b.** Position it far enough so that it does not interfere with blood drawing but close enough to provide the needed occlusion and distention of the vein.
c. Slip the tourniquet around the arm with the ends up; hold one end steady while stretching the other end. Hold both ends away from the arm. Then (1) cross the stretched end in front of the steadied end, (2) cross over the steadied end, and (3) create a half loop in the stretched end under the steadied end with your finger.	**c.** Stretching one end of the tourniquet provides the necessary tension on the arm for occlusion of the vein; holding the ends away from the arm prevents you from pinching the woman's skin while you form and anchor the loop that creates the slipknot.
d. Lower both ends of the tourniquet onto the arm with the loop of the stretched end anchored underneath the steadied end of the tourniquet and release your grasp on the tourniquet (see Figure 47-1).	**d.** Anchors the slipknot.

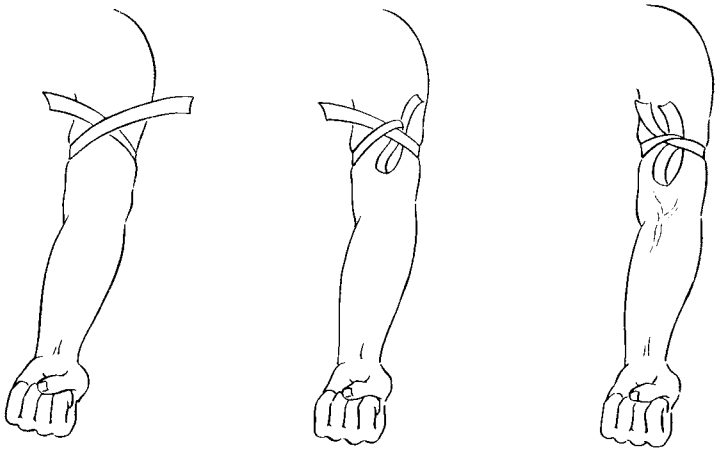

FIGURE 47-1 Applying a tourniquet for venipuncture.

Procedure	Rationale
e. Check if the tourniquet is too tight or too loose, and reapply it in either case.	**e.** The tourniquet should be tight enough to occlude the vein but not tight enough to occlude arteries. If the tourniquet is too tight, the woman usually complains. If the tourniquet is too loose, the vein will not become distended.
f. Do not leave the tourniquet on longer than one minute. An unduly long length of time for the tourniquet to be in place is evidenced by the extremity below the tourniquet becoming cyanotic or distended and the woman complaining of pain.	**f.** Prolonged application of the tourniquet causes hemoconcentration as well as discomfort to the woman resulting from lack of venous circulation below the tourniquet.
4. Put on gloves.	**4.** Universal precaution to protect yourself from any bloodborne pathogen the woman may have. It is easier to put on the tourniquet without gloves, as gloves tend to stick to the tourniquet. Once the tourniquet is applied, however, you need to put on your gloves without delay (see 3f).
5. Distend the vein by one or more of the following methods with the extremity angled downward:	**5.** Enlarges the vein, which makes it easier to find the vein and insert the needle.
a. Ask the woman to open and close her hand several times.	
b. Rub vigorously with the alcohol sponge while cleaning the area.	
c. Tap or gently slap the vein.	
d. Apply warmth (a warm towel) to the vein.	
6. a. The vein you select should be well supported by subcutaneous tissue and should appear full without being prominent.	**6. a.** A well-supported vein will not roll and tissue will not dimple as the needle is inserted; either may happen with a prominent, easily movable vein.
b. The vein should be in the forearm—look first at or near the bend of the elbow, in the antecubital fossa (see Figure 47-2).	**b.** Veins in the forearm are larger than those around the wrist or on the back of the hand. These other veins may also be used but not as the primary choice, since they are smaller and the procedure in this area is more painful.

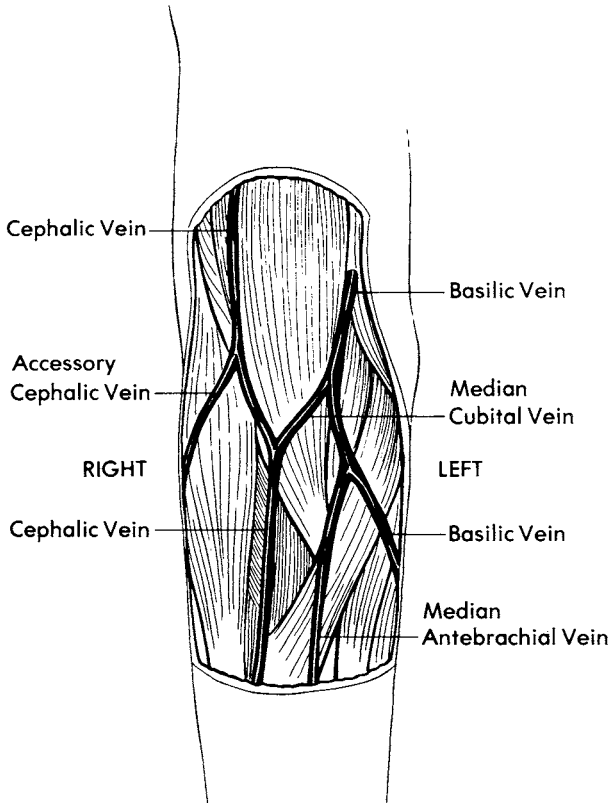

FIGURE 47-2 Veins in the antecubital fossa (right arm).

Procedure	Rationale
c. You should be able to feel and ideally also see the vein.	**c.** Touch is essential to inserting the needle into the vein. Being able to see it also promotes accuracy in hitting the vein, especially for the inexperienced, but it is not absolutely essential. Touch also aids in identifying whether the vein will roll when touched by the needle. There should be a feeling of give when you touch the vein, but it should not roll.
d. Do *not* use a vein in the same arm as one receiving an intravenous transfusion. If it is absolutely mandatory to use the same arm, select a vein that is distal to the IV insertion site (not the same vein), turn off the IV, and apply the tourniquet below the IV site.	**d.** The fluid entering the vein from the intravenous transfusion has chemicals and a diluting effect, which cause erroneous results on most laboratory tests.
e. The vein should *not* be anatomically adjacent to a nerve or artery.	**e.** There is less chance for the inexperienced to puncture a nerve or artery accidentally—the former causing excruciating pain and the latter yielding the wrong blood for lab tests, unless arterial blood is specified.
7. Clean the insertion site with a circular motion, starting at the insertion site, moving outward, and ending peripherally to the insertion site. Use firm pressure and a rather vigorous motion. An alcohol sponge is usually used as the antiseptic.	**7.** Make the area as clean as possible in order to reduce the possibility that the skin will contaminate the needle, leading to subsequent infection.

Procedure	Rationale
8. Let the area dry.	**8.** This lessens discomfort. Wet alcohol stings when it touches tissue such as at the insertion site.
9. If you feel the vein again, clean the area again with another alcohol sponge.	**9.** You have contaminated the insertion site with your palpating finger.
10. Double-check the needle and syringe to make sure the needle is well attached to the syringe, the barrel of the syringe moves easily, and the syringe is large enough for the amount of blood needed. If you are using a Vacutainer holder and needle, be sure the holder is securely screwed onto the needle and the first tube is placed in the holder and started onto the inner needle. If you push the tube no further than the guideline on the holder, then you will have pushed it just far enough for the needle to pierce but not go through the rubber stopper, which would release the vacuum in the tube.	**10.** If you notice a problem after the needle is in the vein, the subsequent manipulations to resolve them may dislodge the needle. The system will not work without this vacuum, as you have no syringe or other means with which to withdraw the blood.
11. Make sure there is no air in the syringe and that the barrel of the syringe fully occupies the syringe.	**11.** Avoid the danger of inserting air into the vein or of finding that there is no room for blood in the syringe because it is full of air. In the latter situation you have no way of getting rid of the air except to disconnect the syringe from the needle and expel the air; this manipulation may dislodge the needle.
12. Place the thumb of the hand not holding the syringe directly over the vein, approximately 1 to 2 inches below the probable point of entry into the vein, and the rest of your hand on the other side of the arm. Fix the vein by pressing down firmly with your thumb and pulling the skin away from the entry site, thereby making the skin over that area taut. Some clinicians anchor the vein by placing their thumb below and either their index or middle finger above the insertion site, firmly pressing down over the vein, and pulling away from each other (see Figure 47-3).	**12.** Fixing the vein helps keep the vein from rolling or the skin from dimpling when the needle enters.
13. Align the direction of the needle with the direction of the vein and hold the syringe at approximately a 15-degree angle from the woman's arm. See Figure 47-3.	**13.** A 15-degree angle reduces the chance of going through or missing the vein. A smaller angle may cause the needle to skim along the top of the vein. A wider angle may cause the needle to go through the vein.
14. Enter the vein directly or penetrate the skin and tissue directly adjacent to the side of the vein and then angle the needle into the vein. Either way, use a quick, steady motion and control the movement of the needle by holding your index finger against its hub.	**14.** The users of both methods of entry claim their method decreases the possibility of missing the vein because the vein does not roll. Those who enter the vein directly say they are in and the vein is stabilized before it has a chance to roll. Those who advocate penetration to the side of the vein first and then entry into the vein say that the tissue helps hold the vein in place, keeping it from rolling while the needle pushes against it.

FIGURE 47-3 Preparing to perform a venipuncture: gloves on; skin held taut; vein fixed; needle aligned with vein and at a 15° angle.

Procedure	Rationale

Note: The unending discussion of whether the needle should enter the vein with the bevel up or down is based on the notion that one position or the other prevents the escape of any blood into the surrounding tissues, which may result from incomplete entry into the vein. However, the debate seems pointless, since extravasation of blood is possible with the bevel of the needle in either position. Use the method with which you are most comfortable as dictated by your own experience and experimentation.

15. Hold the barrel steady and withdraw the blood by pulling back on the plunger. Use slow, even tension. Fill the syringe to the amount needed. Some clinicians use their free hand (the hand that set the vein) to do this. Others use that hand to stabilize the needle in the vein by holding the hub or juncture of the needle and syringe steady while using the hand that had previously held the needle hub and syringe to pull back on the plunger.

If you are using a Vacutainer holder and needle, you can prevent the needle from becoming dislodged from the vein by holding the needle firmly in place and stabilizing it at the point of junction with the holder against the body part with one hand while the other hand manipulates the tube and holder.

15. The syringe is filled by the mechanism of negative pressure. Pulling back on the plunger too quickly may collapse the vein or cause hemolysis.

The manipulation involved in placing the tube on the inner needle and removing it again, which must be repeated for several tubes, may cause you to dislodge the needle from the vein. Unless the needle is stabilized, when you place a tube on the needle you may go through the vein; when you take a tube off the needle you may pull out of the vein.

Procedure	Rationale
An alternative is to use a 21-gauge butterfly needle attached to the Vacutainer.	A butterfly needle used when filling multiple tubes eliminates the risk of dislodging the needle from the vein while manipulating the tubes on and off the inner Vacutainer needle.
16. Release the tourniquet by pulling on one end of the tourniquet (Figure 47-4). It is important to release the tourniquet *before* withdrawing the needle. Some clinicians release the tourniquet when the blood begins to flow.	**16.** There will be extravasation of blood into the surrounding tissue from the distended vein when the needle is withdrawn if the tourniquet is not released first. This leaves the woman with a painful blood clot in her tissues, which will take some time to dissolve and be absorbed.
17. Slowly withdraw the needle as you gently but firmly apply an alcohol or dry sponge on the puncture site.	**17.** Slow withdrawal of the needle decreases the risk of injuring any tissue with the point of the needle. The alcohol or dry sponge allows you to apply pressure instantaneously with withdrawal of the needle. A dry sponge hurts less.
18. Apply pressure (or have the woman apply pressure) on the puncture site with the alcohol or dry sponge for 1 to 2 min. Contrary to popular practice, do not have the woman bend her elbow if an antecubital site was used.	**18.** Pressure facilitates hemostasis. Bending the elbow increases the chance of bruising.
19. The Vacutainer test tubes are filled with blood when the blood is drawn. If you drew the blood into a syringe, then fill the appropriate test tubes with the appropriate amount of blood: **a.** Remove the rubber stoppers from the tubes. **b.** Remove the needle from the syringe.	**19.** **a.** and **b.** If the needle is pushed through the rubber stopper, the blood will be drawn into the tube at a rapid rate. The rapidity and force of transfer and the narrow opening of the needle may hemolyze the red blood cells.

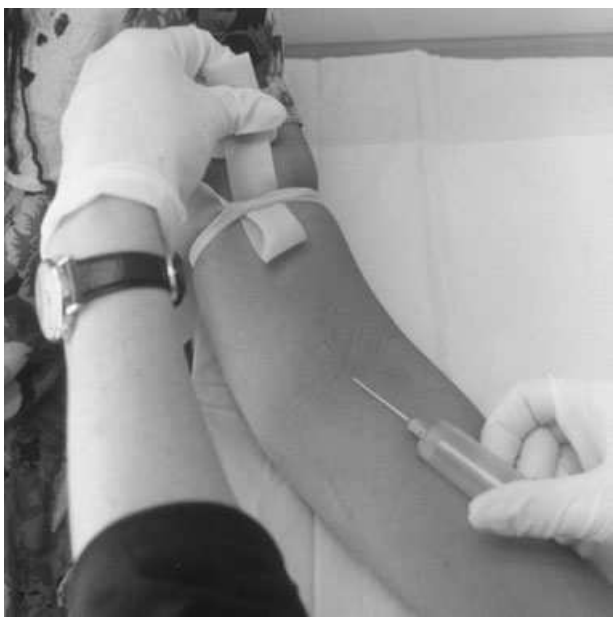

FIGURE 47-4 Releasing the tourniquet before removing the needle.

Procedure	Rationale
c. Fill the tubes with blood by slowly pushing the plunger and holding the syringe and test tube at such an angle that the blood runs down the side of the tube.	**c.** Forceful transfer of blood to the bottom of the tube may cause the blood to hemolyze. The appearance of froth on the surface of the blood is indicative of hemolysis.
d. Replace the rubber stoppers in the test tubes.	**d.** Keep the rubber stoppers from popping back off the tubes when replaced by releasing the pressure in the tube; see Step 2. Blood is not lost then if the tube subsequently is laid on its side. It doesn't matter if the holes are poked through the rubber stopper before they are replaced in the test tube as long as the holes are made before any blood is lost.
20. If you are using a heparinized test tube, then invert the stoppered test tube completely at medium speed approximately ten times without shaking.	**20.** The blood needs to be mixed with the heparin so that it will not clot; however, shaking the contents can cause hemolysis.
21. Label the test tubes with the woman's name and any other appropriate identifying information and the date and time of collection.	**21.** Test results may be mixed up if the woman's blood tubes are not properly identified.
22. Check the woman's puncture site and apply an adhesive bandage or tape and gauze dressing over the site if indicated.	**22.** Make sure the bleeding has stopped.
23. Dispose of the used needle, syringe, gauze, alcohol sponges, and gloves in a biological hazardous waste disposal receptacle.	**23.** Protect yourself and others from bloodborne pathogens.

If there is no blood return or if blood enters the syringe and then stops:

1. Rotate the needle in case it is simply flush against the vein wall. Blood may now enter the needle. If there still is no blood, proceed to the next step.
2. Recognize that the needle is not in the vein.
3. Palpate, with the index finger of the hand that was fixing the vein for the location of both the vein and the tip of the needle.
4. To identify the location of the tip of the needle, it helps if the hand controlling the needle angles the needle upward toward the surface or skin of the body part so you can feel the needle more readily with your palpating finger.
5. If the needle simply isn't far enough into the vein, insert it further and withdraw the needed blood.
6. If the needle is not in the vein but rather to the right, left, underneath, or on top of it, then withdraw your needle the necessary amount to reangle and redirect it for insertion into the vein. Do not withdraw any part of the bevel through the puncture site in order to avoid contaminating the needle. Insert the needle into the vein and withdraw the needed blood.
7. If the needle was in the vein but then went on through it (as evidenced by obtaining several drops of blood and then no more blood), *slowly* withdraw the needle while simultaneously pulling back on the plunger of the syringe until the blood flows again into the syringe. Stop withdrawal of the needle at that point until the needed amount of blood is obtained.
8. If at any time during this procedure or through manipulations to get the needle into the vein you touch the needle or scrape it against the woman's skin, the needle is contaminated and must be withdrawn and discarded and the woman must be restuck with a new sterile needle. Be alert for contamination of the needle; concentration on getting it into the vein may cause you not to notice breaks in sterile technique.
9. If you cannot get the needle into the vein successfully, try again, paying particular attention to selecting a likely vein. If you fail twice, ask someone who has a high success rate to do the venipuncture. Do not ask someone inexperienced or try again yourself. Venipuncture is painful and the woman should not have to endure multiple attempts. This is an unwarranted assault on the woman's body.

CHAPTER

48

Inserting an Intravenous Catheter

Procedure	Rationale
1. Hang the intravenous infusion bag with tubing attached. Clear the tubing of air in preparation for connection to the intravenous catheter.	**1.** Once the intravenous catheter is in place there is an open route into the woman's vein. If you are not ready to connect the infusion, blood will be lost if the catheter is left open or may clot in the catheter if the system is closed without being connected to the intravenous fluid. An open system also increases the chance of infection.
2. Apply a tourniquet and distend the veins in accord with Steps 3 and 5 in the procedure on venipuncture (Chapter 47).	**2.** Aids in identification and selection of a vein into which to insert the intravenous catheter.
3. Select a vein in accord with Steps 6(a), (c), and (e) in the procedure on venipuncture (Chapter 47). It is preferable to select a vein site such that the catheter will not cross a joint. Veins in the forearm are first choice, with the vein just beside and above the wrist bone a frequent selection. Veins in the back of the hand frequently are used but are not as ideal as well-defined veins in the forearm (see Figure 48-1).	**3.** An intravenous catheter is more painful when inserted in the hand than in the forearm. Although one of the ideas behind the flexible catheter was that it would not injure the patient when in place as was possible with a straight needle, it does bend with flexion of a joint and may occlude the intravenous infusion. This then necessitates placing an arm, wrist, or hand board on the woman to immobilize the joint, which is uncomfortable. A board is unnecessary if the catheter does not cross a joint.
4. Place a disposable absorbent pad, such as a Chux, under the limb into which you will be inserting the intravenous catheter.	**4.** This catches any blood or fluid lost during the procedure, thereby avoiding the necessity of changing the bed linen and the possibility of contamination with a bloodborne pathogen.
5. If blood specimens are going to be collected at the same time, decide which of the following methods you are going to use to collect these specimens:	**5.** All actions must be preplanned so you do not lose blood, risk blood clotting in the catheter, or have to do manipulations to the point that the catheter comes out of the vein. The procedure should proceed smoothly, quickly, and with minimal trauma to the woman.
a. Have the blood flow directly from the catheter into the blood tubes.	**a.** Care must be taken not to contaminate the catheter when using this method.
b. Attach a syringe (a size large enough for the number of milliliters of blood needed) to the intravenous catheter hub.	**b.** This method may be cleaner than the one described in 5(a).

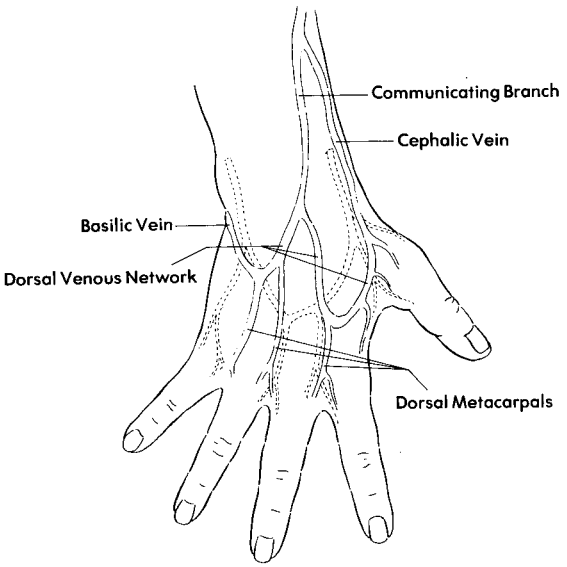

FIGURE 48-1 Veins of the hand and forearm.

Procedure	Rationale
If the latter method is to be used, attach the syringe and make sure there is no air in the syringe.	This eliminates the danger of injecting air into the vein.
If the former method is to be used, have available a paper cup into which you can place the tubes of blood.	Once they are filled the blood tubes need to stand upright since the tops may pop off if they are replaced. If the tubes are on their sides, you will lose the blood. After you are through with the procedure, you can ensure that the tops will stay on the blood tubes if you do one of the following: (1) pierce the rubber top with a needle to release the vaccum; (2) make sure that the rubber top and the part of the blood tube where the top inserts are both dry before replacing the top.
6. Put on gloves.	**6.** Follow universal precautions to protect yourself from any bloodborne pathogen the woman may have.
7. Clean the insertion site in accord with Steps 7, 8, and 9 in Chapter 47, Venipuncture.	
8. Perform a venipuncture in accord with Steps 11 through 14 in the procedure on venipuncture (Chapter 47).	**8.** Emphasis should be placed on fixing the vein and holding the woman's skin taut. This facilitates insertion because the vein does not roll and the skin is prevented from puckering at the site of puncture. In doing this be careful not to contaminate the catheter against the woman's skin or against your finger.
9. Make sure the tips of the needle and the catheter are in the vein by advancing both approximately $^1/_4$ inch once you are getting blood back into the unit.	**9.** The tip of the needle extends approximately $^1/_8$ inch beyond the tip of the catheter in intravenous catheter units. It is possible to get a blood return with just the tip of the needle in the vein. However, the vein will be lost during Step 11 if the catheter is not in the vein also.

Procedure	Rationale
10. If using a syringe to draw blood for blood specimens, fill the syringe with the number of milliliters of blood needed.	
11. Again, hold the woman's skin taut with one hand and do one of the following with the other hand: **a.** Withdraw the needle a short distance, advance the catheter into the vein, and then remove the needle altogether. **b.** Withdraw the needle altogether and advance the catheter into the vein. **c.** Leave the needle where it is, advance the catheter into the vein, and then withdraw the needle altogether. Whichever method is used, never advance the needle inside the catheter once it has been even slightly withdrawn and never move it back and forth within the catheter. If the vein is lost during this step, *do not* reinsert the needle through the catheter. Instead, remove the entire unit, discard, and start again with a new sterile intravenous catheter unit. Be careful during this step not to contaminate the catheter by sliding it over the woman's skin while inserting it.	**11.** Taut skin will not pucker. Puckered skin causes difficulty in advancing the catheter and creates the need for forceful action, which may ram the catheter through the vein. **a.**, **b.**, and **c.** No matter which method is used, the principle is to cover the needle point, thereby both protecting the vein from the possibility that the needle might go on through it, and allowing the flexible catheter to be threaded into the vein. If the needle is not totally removed before advancing the catheter, the needle needs to be immobilized while the catheter is advanced. If the needle is totally removed, blood will drip through the catheter during the threading process. It is imperative that the needle never be advanced again once its tip has been withdrawn inside the catheter. If the needle is advanced again, its sharp tip may shear off a fragment of the catheter, which would then remain in the bloodstream as a foreign object embolus.
12. If you are collecting blood by having it drip directly from the catheter into the blood tubes, press down over the area of the tip of the catheter inside the vein between tubes, between manipulation of materials, and before starting the intravenous infusion.	**12.** Applying pressure stops the blood from flowing since the vein is occluded at the point where blood enters the catheter. This is done briefly so that blood will not clot inside the catheter.
13. Connect the intravenous infusion tubing to the catheter, release the tourniquet, and start the infusion flow at the desired rate.	**13.** It is essential to release the tourniquet before starting the flow of the infusion. Otherwise the vein fills with fluid and ruptures from overdistention. These three steps are listed as one, as they must be accomplished quickly and in sequence, in order to have a patent intravenous system.

14. Tape the catheter and IV tubing securely to the limb involved. The following method is one way of taping (see Figure 48-2):

- **a.** First use a narrow ($^1/_8$ to $^1/_4$ inch) strip of tape underneath the hub of the intravenous catheter with its edge against the place where the catheter enters the skin and with its sticky side up. Crisscross the tape over the insertion site with the ends going at an angle away from the site. Attach the tape to the woman's skin so that the catheter is straight and not bent, which would interfere with the flow of the infusion.
- **b.** Now use a wide (1 to $1\,^1/_2$ inch) strip of tape over the crisscross at the insertion site.
- **c.** Make a loop of the intravenous tubing and tape it down just beside the edge of the catheter hub.
- **d.** You may need to tape down one or both sides of the loop of the intravenous tubing so it does not catch on anything and pull apart from the hub of the catheter.
- **e.** Run the intravenous tubing a few more inches away from the insertion site and tape it to the woman's skin so the strain of the tubing isn't at the site of insertion. Avoid taping over where the catheter hub and IV tubing join, covering up any connectors, or taping over the rubber medication appendage, since you may need access to these sites.
- **f.** Be considerate of people with hairy arms by using a minimal amount of tape.

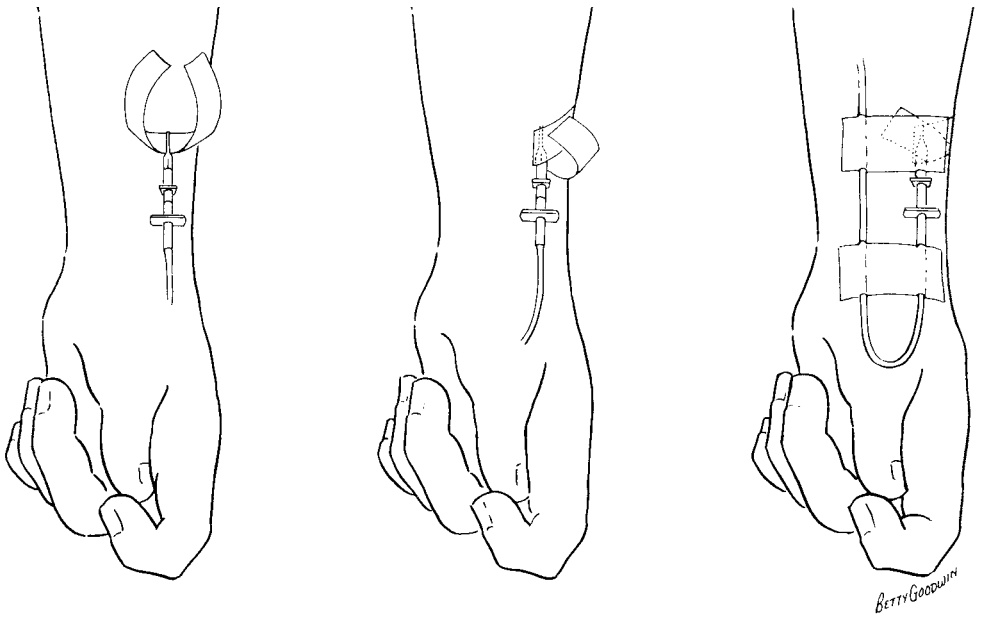

FIGURE 48-2 Taping an intravenous catheter and tubing.

Procedure	Rationale
15. Wipe any blood off the woman with water or soap and water, and dry the skin.	**15.** This is done for the woman's comfort since blood is sticky. Alcohol sponges will not remove blood.

16. After the procedure is completed, ask the woman to wriggle her fingers, do range of motion at the wrist and elbow, and wave at you. This helps her realize that it will not hurt her to move her fingers, hand, or arm with the IV in place and she therefore will not hold herself rigid in fear hour after hour.

17. Label the blood tubes in accord with Step 21 in Chapter 47, Venipuncture.

18. Dispose of the used needle, syringe, alcohol sponges, gauzes, disposable pad (Chux), and gloves in a biological hazardous waste disposal receptacle.

Note: If you anticipate that the IV will be in place more than 24 hr, the following additional steps should be added to this procedure to decrease the incidence of phlebitis:

1. Use povidone-iodine (Betadine) instead of alcohol for cleaning the insertion site prior to puncture if the woman is not allergic to Betadine.

2. Apply an antibiotic ointment to, and a sterile dry dressing over, the puncture site.

CHAPTER

49

Giving Intravenous Medications

Procedure	Rationale
By Venipuncture	
1. Perform venipuncture. (See Chapter 47, Venipuncture.)	
2. Remove the tourniquet when the needle is in the vein but before giving the medication.	**2.** The tourniquet occludes the vein, which facilitates the venipuncture. However, the vein must not be occluded for receipt of the medication.
3. Aspirate to be sure that the needle is still in the vein.	**3.** Movement during removal of the tourniquet may have dislodged the needle from the vein.
4. Inject at a rate in accord with the medication—for example, 50 mg of meperidine hydrochloride (Demerol) would be injected slowly over a 2-minute period.	4. Slow injection is for safety and comfort of the mother and safety of the baby. For example, Demerol given rapidly can cause the mother to have nausea, vomiting, flushing, dizziness, and a sense of being too warm—all of which can be avoided by slow injection of the medication.
By Intravenous Infusion Tubing	
1. Ascertain status of the IV.	**1.** You must be sure that the IV is patent and that the medication will be going into a vein and not into infiltrated tissue.
2. Wipe off the rubber medication appendage on the IV tubing with an alcohol sponge.	**2.** Cleanse the site of entry into the sterile system.
3. Insert the needle of the syringe containing the medication through the rubber medication appendage on the IV tubing.	**3.** Rubber seals itself, and the appendage is on the IV tubing for the purpose of giving medications. To stick a needle into the IV tubing itself would cause the IV to leak through the resulting hole since the tubing does not self-seal.
4. Pinch off the IV tubing above the rubber medication appendage.	**4.** This prevents the medication from going up the tubing rather than down the tubing into the body during injection. Occluding the tubing stops the flow of intravenous fluid, which allows you to control the amount of medication the mother is receiving and the rate at which it infuses.

Procedure	Rationale
5. Inject at a rate in accord with the medication—for example, inject a few milligrams of Demerol, remembering that the entire injection should take 2 min for 50 mg and 1 min for 25 mg of this drug.	**5.** to **9.** Inject the drug slowly for the safety and com-fort of the mother and safety of the baby (see Step 4 under "By Venipuncture," above). If you follow this procedure you are better able to control how much medication the mother is getting at a given time. A full amount of medication entering the maternal-fetal circulatory system at once can produce fetal depression. Remember that the drug injected prior to letting the IV fluid run probably does not even reach the vein as there is insufficient volume to traverse the distance of the tubing from the rubber medication appendage to the vein. Running the IV fluid forces the medication on through the tubing in small, controlled amounts.
6. Release the IV tubing, open the IV flow, and let the IV solution run for approximately 15 to 30 sec.	
7. Pinch off the IV tubing above the rubber medication appendage.	
8. Inject more of the medication—in the present example, a few more milligrams of Demerol. If the amount of Demerol is 50 mg/mL, inject one-quarter of the medication over a period of 15 sec and then let the IV run for 15 to 30 sec; within the combined 30- to 45-sec period, 12.5 mg of Demerol would be administered.	
9. Repeat steps 6, 7, and 8 until you have given all of the medication.	

CHAPTER

50

Spin-Down Hematocrit

Procedure	Rationale
1. Obtain the blood specimen. If the blood specimen is taken directly from a finger puncture site, fill two red-tipped (heparinized) capillary tubes (see Chapter 46, Steps 10b–16). If the blood specimen is in a blood tube with an anticoagulant, fill two blue-tipped (plain) capillary tubes as follows:	**1.** Two tubes are always obtained in order to balance the hematocrit machine and to still have one tube to use in case one gets broken. This prevents having to stick the woman again.
a. Put on gloves	**a.** Follow universal precautions to protect yourself from any bloodborne pathogen the woman may have.
b. If the sample has been sitting, mix the blood sample thoroughly by inverting the tube back and forth gently, without shaking, 10 to 15 times.	**b.** Shaking can cause hemolysis of the red blood cells.
c. Cover the stopper with gauze. Twist, do not pull, the stopper out.	**c.** Gauze prevents the blood from getting on your fingers. Twisting the stopper out prevents the blood from splattering, which might happen if the stopper were pulled out.
d. *Slowly* tilt the blood tube until the blood approaches the edge of the tube.	**d.** Tilt slowly because blood moves more rapidly after it begins to flow and might spill if the tube is tilted too fast or too far.
e. Place the end of the capillary tube in the blood and hold it at an angle as close to the same longitudinal plane of the blood tube as possible.	**e.** The capillary tubes are filled by capillary action.
f. Fill and seal the tubes as described in Steps 11, 12, 14, 15, and 16 in Chapter 46 on finger puncture.	
g. *Do not* fill the capillary tubes with blood that has collected in the stopper of the blood tube.	**g.** Such a sample may contain dried red cells and plasma that would yield erroneous results and invalidate the test.
2. Open the microhematocrit centrifuge and remove the cover on the head.	
3. Check the rubber lining inside the rim of the head. If there are holes in this lining where you intend to place your capillary tubes, rotate the lining so the capillary tubes will rest against an unbroken surface. The liner should be replaced if it is cracked and brittle.	**3.** The rubber lining serves two functions: **a.** It cushions the sealed end of the capillary tube from the metal rim. **b.** It prevents loss of the specimen that can occur if clay is forced out during centrifuging.

Procedure	Rationale
4. Place the capillary tubes in grooves opposite each other.	**4.** Balance the centrifuge.
5. Make note of the numbers of the grooves you place your specimens in and the woman's name for each set of numbers.	**5.** Specimens will not get mixed up when several capillary tubes are centrifuged at the same time.
6. Be sure the sealed end of the capillary tube is resting against the rubber lining.	**6.** The sealed end is to the outside so blood will not fly out when the centrifuge is spinning. Resting the sealed end against the rubber lining reduces the chance of breakage, which can happen if the capillary tube is not properly in the groove or is only partly protruding from the end of the groove.
7. Place the cover on the head and tighten it with your hand until there is no give. Do not use a wrench to tighten the cover and do not overtighten it.	**7.** Hand tightening is sufficient. Repeated overtightening ruins the thread on the screw.
8. Close the microhematocrit centrifuge and lock the lid by closing the latch.	
9. Check to see that the centrifuge is firmly attached to the surface on which it rests. If it is attached with suction cups but is loose, put a few drops of oil or water in each cup and force the centrifuge down to create a suction that will hold.	**9.** "Walking" of the centrifuge disturbs its balance. Oil is better than water in creating a suction that will hold, but water may be all that is available.
10. Turn on the centrifuge and set the time by turning the timer dial past 5 min and then returning the indicator to 3 min.	**10.** Red blood cells are completely packed down within 3 min of very high speed rotation.
11. The centrifuge will stop by itself. Do not open the lid and try to stop the spinning head with your hand.	**11.** Trying to stop the spinning head can be dangerous. Also, the red cells can become loosened or dislodged if the spinning head is stopped suddenly. This may yield erroneously high readings.
12. Unlock the lid by unlatching it. Open the centrifuge after it has stopped.	
13. Loosen the cover and lift it off the head. The centrifuge comes with a wrench to loosen the cover if needed. Place the cover inside the open lid of the centrifuge.	**13.** The force of the high speed rotation may tighten the cover so that you cannot open it by hand. Routinely placing the cover inside the centrifuge lid ensures that the cover will not become separated from the centrifuge and get lost.
14. Examine each capillary tube. **a.** If the tube is not in the groove (missing), it has probably shattered. Most likely the tube was not properly placed in the groove and became dislodged. **b.** If the tube is empty or only partially full, the blood has leaked out. The seal was not good or the tube did not rest against the rubber rim of the head. **c.** Look for red cell hemolysis. This is indicated by the red color of the plasma layer.	**14. a.**, **b.**, and **c.** If both tubes are missing, have leaked out, or have hemolyzed, another blood specimen will have to be obtained and the procedure repeated. If this specimen was a finger puncture, the woman will have to be stuck again. If the blood was taken from a blood tube, fill two more capillary tubes from the specimen already drawn after checking for hemolysis (if this was the problem with the capillary tubes). If the blood specimen is no longer good for tests, perform another venipuncture and obtain a fresh specimen. If one capillary tube is not usable but the other one is, read the results on the satisfactory tube.

Procedure	Rationale
15. Remove the capillary tubes from the head of the microhematocrit centrifuge.	
16. Read the results by using a microhematocrit reader. There are a variety of microhematocrit reader devices. Each has its own way of doing it, but they all follow the same basic procedure.	**16.**
a. Align the junction of the bottom of the red cell layer and the sealing clay with the zero percent reading. Move the tube up and down in whatever slot is provided for it until it is aligned.	**a.** and **b.** Precision in aligning the junctions with the zero percent and 100 percent lines is essential to obtaining an accurate reading.
b. Align the top of the plasma layer with the 100 percent reading. Do not move the tube to make this alignment because the tube's position was set in the preceding step; move the reader instead.	
c. Read the hematocrit at the junction of the top of the red cell layer and either the bottom of the plasma layer or the bottom of the buffy layer if it is present.	**c.** The buffy layer of white blood cells and platelets often is visible as a narrow white band between the packed red blood cells and the plasma layer. The buffy layer is not to be included in the reading, since you only wish to measure the volume of the packed red blood cells. An unusually large buffy layer generally indicates leukocytosis (increased number of white blood cells).
17. The hematocrit value can also be obtained with the following measurements and formula:	**17.** This is handy to know in the event your microhematocrit reader gets broken or lost.
a. Using a ruler calibrated in millimeters, measure (1) the length of the red cell layer; (2) the length of the entire contents in the tube (red cell, buffy, and plasma layers)	
b. Calculate as follows: $\frac{\text{length of red cell layer (in mm)}}{\text{length of total contents (in mm)}} \times 100 = \text{hematocrit value}$	
18. If two tubes are used, the findings should be within a 1 percent reading value of each other.	
19. Record the results.	
20. Dispose of the capillary tubes and gloves in a biological hazardous waste disposal receptacle.	**20.** Protect yourself and others from bloodborne pathogens.

CHAPTER

51

Removal of Norplant

The key to an easy removal of Norplant is proper insertion. There are at least five removal procedures: standard [1, 2, 3], pop-out [3, 4], Emory [3], needle-lift [5], hook-traction [6], and the "U" or "modified U" technique [3, 7]. All removal procedures involve local anesthetic, an incision, some measure of "nicking" or dissection of the fibrous tissue sheath that forms around each implant and surrounds their ends, and some means of guiding the implant capsule into the incision and grasping it for removal. Complications that affect removal of Norplant include breaking the implant during the removal procedure, imbedding of the implant, incorrect spacing or displacement/migration of the implant, and considerable weight gain after the implants are inserted [3, 6]. These complications make removal difficult and time-consuming for the approximately 5 percent of women in which they occur [3].

Two of the more commonly used removal procedures are presented here: standard and pop-out. The pop-out method requires less time, creates less pain, involves a shorter incision, and reduces trauma, but is not as effective a method with deeply placed or immobile capsules or for difficult removals.

Procedure	Rationale
1. Check and organize materials and equipment, making sure all are appropriate and placed conveniently: sterile surgical drapes, talc-free sterile gloves, antiseptic solution, sterile water, marking pen, 5 mL syringe, 22 gauge $1^1/_2$ in. needle, 1% lidocaine, #11 scalpel, one straight and one curved mosquito forceps, steri-strips or other skin closures, sterile 4×4s, gauze or cling wrap, and adhesive tape. The trocar is not necessary, but one 5 in. straight forceps and one 5 in. curved forceps is required. Removal usually takes about 20–30 minutes.	**1.** Having all equipment together and conveniently placed facilitates an organized, smoothly executed procedure.
2. Have the woman lie down on an examination table; raise the head of the bed. Flex the elbow of the woman's nondominant arm and have her rotate her arm externally. Her hand should be lying by her head.	**2.** Removal will proceed more quickly if the woman is relaxed and her arm is positioned to make the site more accessible.

3. Palpate the capsules and mark both the proximal and the distal end of each implant with a marking pen. Choose a point for the removal incision that is equidistant from the proximal ends of the capsules and mark this spot. Avoid, if possible, the old incision site.	**3.** Marking the capsules helps you plan the removal. Avoiding the old incision site prevents the problem of removing the capsules through any scar tissue that may have formed.
4. Put on talc-free sterile gloves.	**4.** Using talc-free gloves helps prevent an allergic reaction in the incision.
5. Prep the arm with antiseptic using forceps and 4×4s.	**5.** Cleanse the surgical area to decrease risk of infection from bacteria on the skin.
6. Place sterile drapes under and over the arm, exposing a large enough opening to remove the capsules.	**6.** Create a sterile field.
7. Draw up 5 mL of 1% lidocaine. Inject a small amount of anesthetic at the incision site and *under* the proximal end of each capsule.	**7.** Injection of the anesthetic *over* the capsules will obscure the ends of the capsules. Injection under the ends of the capsules not only provides anesthesia but also raises the tips of the capsules.
8. Make a small transverse 4 mm incision at the chosen site.	**8.** Keep the incision small to minimize bleeding, swelling, and scarring.
9. Insert the straight forceps in the incision and gently spread and move horizontally in two planes, one above and one below the ends of the implants.	**9.** Opens a plane of dissection above and below the capsules.
10. Start with the capsule closest to the incision and nearest to the skin. Pressing on the distal end, push this capsule gently toward the incision.	
Standard Method	*Pop-Out Method*
a. When the end of the capsule becomes visible at the incision, grasp the capsule with the curved mosquito forceps.	**a.** Use the fingers of both hands to maneuver the end of the implant into the incision.
b. As an alternative, introduce a closed curved forceps into the incision. Work the forceps under the capsule by gently dissecting the tissue while maintaining finger pressure on the distal end of the capsule. Grasp the end of the capsule with the forceps and bring it to the incision. Be careful to grasp as little tissue as possible.	**b.** Use a scalpel to incise the fibrous tissue sheath.
c. Incise the end of the fibrous tissue sheath with a scalpel to open it.	**c.** The implant will pop out through the incision, after which you can grasp it with your fingers and pull it out.
d. Grasp the capsule with the straight forceps, remove the curved forceps, and pull out the capsule through the incision.	
11. Now choose the next capsule that appears easiest to remove. Add more anesthetic under the capsule if needed.	
12. Repeat steps 10 and 11 until all capsules are removed.	
13. Show all six capsules to the woman and document that all six capsules were removed.	**13.** To assure her and yourself that all the capsules have been removed and to have in her medical record the complete removal of all Norplant capsules.

14. Achieve hemostasis with direct pressure to the site for 2 to 3 min.	**14.** Applying pressure will minimize bruising and hematoma formation.
15. After cleansing the area with sterile water or Zephiran and patting it dry, press the skin edges together and apply a butterfly bandage or steri-strip skin closure. Cover the site with a folded 4 × 4 to make a dry compress and wrap gauze or cling wrap snugly around the woman's arm to hold the compress in place.	**15.** The bandage and compress continue pressure and hemostasis.

Postremoval instructions to the woman include:

1. Keep the pressure dressing in place 24 hours.
2. Leave the butterfly bandage or steri-strips on until they are ready to fall off in 3 to 4 days.
3. Keep the incision area dry for 24 to 48 hours.
4. Expect tenderness, bruising, or swelling in the area for the first few days. This is normal.
5. Call the midwife if you have
   a. arm pain
   b. excessive swelling
   c. pus or bleeding at the insertion site
6. Begin using an alternative form of contraception *immediately* if you do not wish to become pregnant.

Occasionally, you may be unable to remove all the capsules at the first visit. If you encounter difficulties, the resulting trauma and edema make the procedure even more difficult and you may be unable to remove all of the capsules in 30 minutes. If so, STOP. Apply a compression dressing and ask the woman to return in 4 to 6 weeks when the area has fully healed, so that you can remove the remaining capsule(s). You may want to consider using one of the other methods for removal described in the references.

CHAPTER

52

Breast Examination

Relevant History

1. *Age:* the incidence of breast cancer increases with age [1].
2. *Symptoms*
   a. *tumor, when found:* note any change since the tumor was first discovered if the woman has delayed seeking medical consultation; location; any change during menstrual cycle, especially during premenstrual and menstrual phases; and changes in nipples.

      This information contributes during examination to the differential diagnosis between normal breast tissue with cyclic physiological nodularity and breast disease.

   b. *nipple discharge:* note whether spontaneous or elicited; unilateral or bilateral; character (serous, bloody, thin and watery without color, thick and yellowish, thick and grayish, greenish, or milky); amount; when noticed; related to pregnancy or nonpregnancy; using combination hormonal contraception or not; breastfeeding or not; date of termination of last pregnancy; date of termination of breastfeeding of last baby; whether discharge occurs during menstruation; whether discharge occurs during the period of breast growth and development; if the woman jogs or runs for exercise; amount of sexual stimulation and manipulation to the breasts and nipples.

      Discharge is significant and requires physician consultation *if* the woman is *not* pregnant, postpartal, breastfeeding, within a year of termination of breastfeeding, within 6 months of termination of last pregnancy, using combination hormonal contraception, in the period of breast growth and development, experiencing friction between clothing and nipples during jogging or running, experiencing excessive sexual stimulation and manipulation of her breasts and nipples, or making frequent attempts to elicit a discharge.

      Generally an elicited nipple discharge is not of pathological significance. Nipple discharge is pathologically significant if it occurs spontaneously [2]. Nipple discharge is especially significant if the woman is amenorrheic and not pregnant or postpartal. Pathologic nipple discharge is usually unilateral [3] A drop of thick, grayish discharge expressed from the nipple of a middle-aged woman is usually normal and comes from terminal ectatic (stretched) ducts. A bloody discharge requires consultation with a physician for further investigation.

   c. *pain or tenderness in one or both breasts:* constant or cyclic with the menstrual cycle; character: dull, sharp, constant, or intermittent.

      Cyclic pain or tenderness indicates physiological rather than pathological origin.

3. *Past history of mammograms/breast ultrasound:* routine? if not, what was the indication for the examination? note results.
4. *Past history of breast disease:* operations, biopsies, aspirations (date, physician, hospital); location of the disease in the breast(s); diagnosis, treatment, outcome.
5. *Family history of breast disease:* include woman's female and male relatives; type, if known; age of relative at time of breast disease.

   One first-degree relative (mother, sister, daughter) with breast cancer approximately doubles the risk [1].
6. *Menstrual history:* age at onset, frequency, duration, amount, regularity, age of onset of menopause.

Early menarche or late menopause increases the risk of breast cancer because of the extended number of ovulatory cycles.

7. *Pregnancy history:* age at time of first full-term birth; date of each pregnancy termination; length of each pregnancy.

   A first full-term birth before age 18 reduces the risk of breast cancer; a first full-term birth after age 35 increases the risk of breast cancer. Nulliparity also increases the risk of breast cancer.
8. *Lactation history:* whether each child was breastfed; length of time each one was breastfed; date of termination of last breastfeeding.
9. *Hormonal history:* for contraception, menstrual irregularity, menopausal symptom relief, cosmetic, or medical problems; length of time hormones were taken; name and dosage or date of termination of last use of hormones.
10. *Other specific significant history:*
    a. Oophorectomy decreases the risk of breast cancer, especially if before age 35.
    b. The risk of breast cancer increases with increased amounts of alcohol consumption [1].
    c. Exposure to radiation increases the risk of breast cancer.

Physical Examination

Inspection of Breasts and Palpation of Lymph Node Areas

Procedure	Rationale
1. The woman should be seated either at the end or the side of the examining table with her legs over the edge so she is facing you.	1. The breasts need to hang freely at a level that enables good visualization.
2. The woman should be draped up to her waist with her entire chest area exposed.	2. Exposure of only the area necessary protects the woman's sense of modesty.
3. The room must be well lighted.	3. Good lighting is necessary if you are going to be able to see slight changes in breast contour, color, retraction signs, and the nipple epithelium.
4. Inspect the breasts when the woman is in each of the following positions:	4.
a. with her arms by her side.	a. and b. These positions allow you to see different aspects of the breasts.
b. with her arms raised high over her head.	b. This position elevates the pectoral fascia. If there is a carcinoma, the fibrosis around it may have attached it to the underlying fascia and to the overlying skin. Arm elevation will reveal this through the signs of asymmetry (indentation in the contour) or skin retraction.
c. with her hands either pressed against her hips or with the palmar surfaces pressed against each other at the level of her chin.	c. Either of these maneuvers contracts the pectoral muscles underlying the breasts. Slight elevation of the breast is normal; a carcinoma may be evidenced by an abnormal elevation of the breast resulting from the fibrosis of the carcinoma being fixed to the underlying pectoral fascia, and by retraction signs such as skin dimpling and nipple deviation (Figure 52-1).
d. standing and bent forward from her hips with her chin up and her arms and hands extended toward you. Support her with your hands under her outstretched hands as you sit in front of her.	d. The normal breast will fall freely away from the chest wall when the woman is in this position and be symmetrical. The accompanying fibrosis of a breast lesion will fix the breast to the chest wall, and asymmetry and retraction signs that are not otherwise evident become evident in this position.

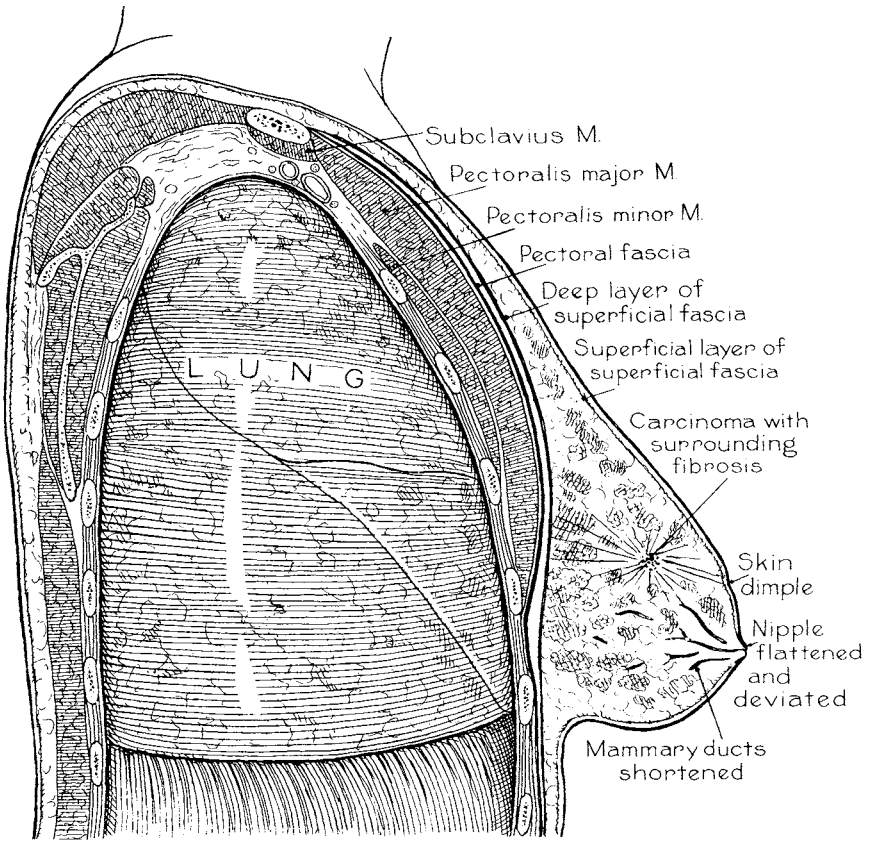

FIGURE 52-1 Diagram of the parasagittal section through the breast and thorax to illustrate the mechanism of retraction in carcinoma of the breasts.

Source: Reproduced by permission from Haagensen, C. D. *Diseases of the Breast*, 3rd ed. Philadephia, PA: W. B. Saunders, 1986, p. 528.

Observations	Significance
1. Breasts unequal in size (usually one breast is slightly larger than the other) but with the same contour.	**1.** Usually normal; developmental in origin.
2. Size of breasts small, large, or pendulous.	**2.** Individual variation is of no pathological significance.
3. Accessory breast tissue—alone or any combination of supernumerary nipples, areola, glandular parenchyma.	**3.** Developmental anomalies with no pathological significance; usually located along the embryological milk lines.
4. Asymmetry in breast contour, such as a bulge or indentation in the contour.	**4.** Abnormal; physician consultation/referral required.
5. Retraction signs, such as skin dimpling, puckering, or furrows (Figure 52-1).	**5.** Abnormal; physician consultation/referral required.
6. Nipple deviation (deviation in the direction the nipple is pointing) or nipple retraction with or without broadening and flattening of the nipple (Figure 52-1).	**6.** Abnormal; physician consultation/referral required.
7. Inverted nipples—not retracted or deviated.	**7.** No pathological significance.
8. Shrunken breast.	**8.** Abnormal; physician consultation/referral required.
9. Edema; orange-peel skin.	**9.** Abnormal; physician consultation/referral required.

Observations	Significance
10. Dilated subcutaneous veins—woman not pregnant.	**10.** Abnormal; physician consultation/referral required.
11. Elevation of skin temperature or redness—woman not postpartal.	**11.** Abnormal; physician consultation/referral required.
12. Ulcerations.	**12.** Abnormal; physician consultation/referral required.
13. Excessive breast elevation and asymmetry with contraction of pectoral muscles.	**13.** Abnormal; physician consultation/referral required.

Procedure	Rationale
5. With the woman again sitting on the side of the examining table with her arms by her sides, palpate the supraclavicular and infraclavicular regions on both sides for the subclavian nodes.	

Findings	Significance
1. Palpable nodes.	**1.** Abnormal, usually indicating advanced lymph node involvement; physician consultation/referral required.

Procedure	Rationale
6. Supporting the woman's arm with one of your own, gently palpate the axilla with the fingertips of your other hand. Move your palpating hand within the axilla area to press anteriorly for the pectoral nodes, posteriorly for the subscapular nodes, along the upper arm for the lateral brachial nodes, and deep in the middle for the central axillary nodes. Move the woman's arm through a full range of motion while palpating. Reverse the procedure for the opposite axilla. This procedure may also be done when the woman is lying down.	**6.** Supporting the woman's arm relaxes the pectoral muscles. This relaxation is essential to examination of the axilla. Taking the arm through range of motion may uncover lesions obscured by fat or muscles. Lymph nodes are more easily felt with gentle palpation.

Findings	Significance
1. Palpable nodes. In the absence of breast pathology, inspect the fingers and hand of the affected side for small abrasions and cuts, especially around the cuticles and fingernails.	**1.** Abnormal; physician consultation required. Infections distal to the nodes may cause inflammation of the lymph nodes and thus yield sizable, soft, palpable axillary nodes. The physician should be consulted for confirmation of this diagnosis.

Inspection of Nipple Epithelium and Palpation of Breasts

Procedure	Rationale
1. Have the woman assume a supine position on the examining table, again draping her so only her chest area is exposed.	**1.** Inspection of the nipple epithelium requires close observation in good light. This is more easily accomplished with the woman in a supine position.
2. Inspect the nipple epithelium.	

Observations	Significance
1. Erosion, ulceration, thickening, or unusual roughness.	**1.** Abnormal; physician consultation/referral required.
2. Redness—woman *not* breastfeeding or having nipples sexually manipulated.	**2.** Abnormal; physician consultation/referral required.
3. Crusting indicating dried discharge—woman *not* pregnant, postpartal, or breastfeeding.	**3.** Abnormal; physician consultation/referral required.
Procedure	**Rationale**
3. Have the woman raise her arm above her head on the same side of her body as the breast you are going to palpate. Place a small pillow under her shoulder on the same side if possible (that is, if a pillow is available and there is room for it on the examining table).	**3.** Raising the arm flattens and distributes the breast more evenly over the chest wall, thereby facilitating palpation of all breast tissue. Placing a small pillow under her shoulder distributes the breast tissue more medially toward the thorax, facilitating palpation of the outer lateral breast. The breast tends to fall to the side, especially if it is large, even if the woman raises her arm.
4. Palpate with the flat portion of the fingers of your examining hand (Figure 52-2), using a gentle to-and-fro or rotary motion that compresses the breast tissue against the chest wall.	**4.** Gentleness is the key to an informative, accurate examination. Soft breast lesions can be felt only with extremely gentle palpation. There is no excuse for an examination that traumatizes the woman with pain or causes bruising. It is also possible to cause metastasis of a breast carcinoma by a rough, heavy-handed, or kneading type of examination.
5. If the woman has pointed out an area in her breast where she has found a lump or point of tenderness, start your examination by palpating the opposite breast first.	**5.** Beginning with the opposite breast lessens the possibility of missing other findings because of concentrating on obvious disease, if present. It also facilitates your differentiating normal from abnormal breast tissue if you have first felt her normal breast tissue.
6. Palpate the breast, using any one of the following methods **a.** *Radial:* start on the upper outer margin of the breast and proceed in a circular, clockwise fashion in ever-smaller concentric circles, ending with palpation beneath the nipple (Figure 52-3).	**6.** This is an example of different but perfectly acceptable ways of doing the same thing. Certain principles are to be followed regardless of which method is used: **(1)** Every square inch of breast tissue is palpated. This includes beneath the nipple and into the axilla. It does not matter which

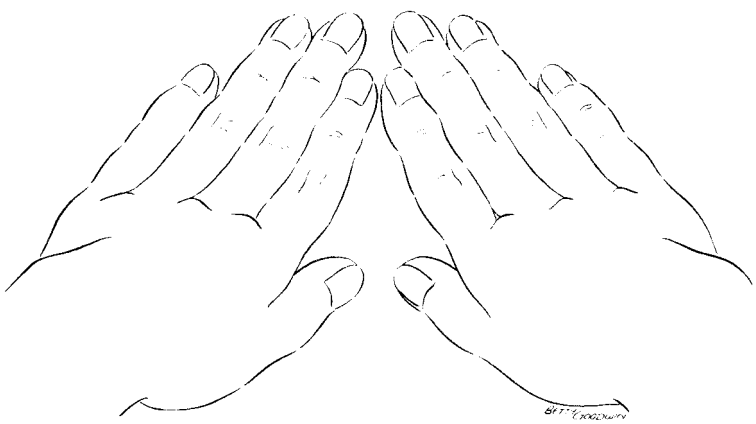

FIGURE 52-2 Position of hands for palpation.

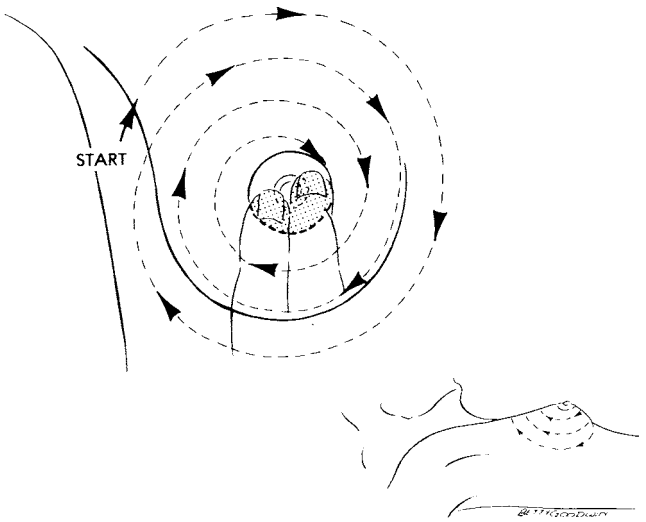

FIGURE 52-3 Radial method of palpating the breasts.

Procedure

A variation of this method is to start at the margin of the areola and proceed in a circular, clockwise fashion in ever-larger concentric circles to the outer margin of the breast, returning at the end to palpate beneath the nipple.

b. *Wheel-spoke:* start at the upper outer margin and palpate in to the areola as though following the spoke of a wheel. Move in a clockwise fashion around the breast, repeating the direction of palpation from outer margin to the areola for each spoke of the wheel. End with palpation beneath the nipple (Figure 52-4).

Rationale

method you use to cover the breast as long as you palpate every square inch. The inch you miss may have a lesion.

(2) Your palpation is gentle and nontraumatic.

(3) Your palpation compresses the breast tissue against the chest wall. Palpation that compresses breast tissue between your fingers or hands may give the erroneous impression of a mass.

Method a. has the advantage of ensuring coverage of every square inch of the breast and is particularly useful for beginning practitioners.

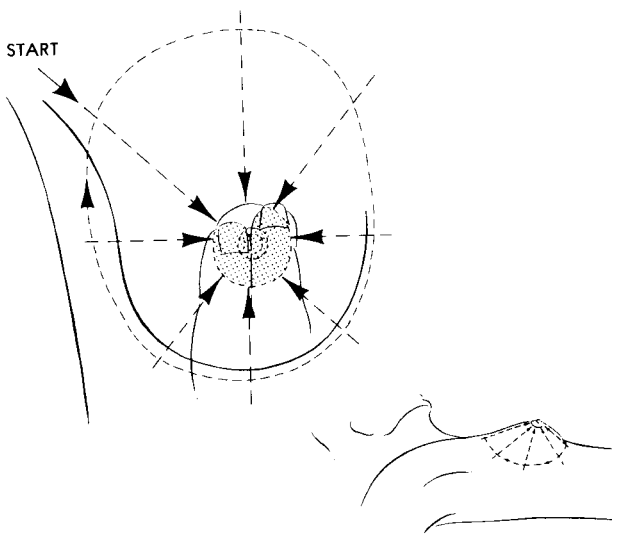

FIGURE 52-4 Wheel-spoke method of palpating the breasts.

Procedure	Rationale
A variation of this method is to start at the areola and palpate out to the breast margin, again as though following the spoke of a wheel. Repeat around the breast, ending with palpation beneath the nipple.	Method b. has two major drawbacks:
c. *Traversing:* divide the breast into its medial and lateral halves, using an imaginary vertical line through the nipple as the dividing line. Start with the medial half at the level of the clavicle and palpate in a series of parallel transverse lines from the nipple line to the sternum down to the caudal edge of the breast. Then move to the lateral half of the breast and again palpate in a series of parallel transverse lines, this time from the nipple line to the posterior axillary line back up to the level of the clavicle (Figure 52-5).	**(1)** Examiners frequently palpate the nipple and areola at the inner end of each "spoke." This means that this area is palpated a number of times in the course of the examination. This is unnecessary; repeated palpation can be traumatic. **(2)** While the inward ends of the spokes are being repeatedly palpated, areas between the outer ends of the spokes frequently are missed, especially by learners who are concentrating more on the method than on palpating every square inch of the breast. This problem can be alleviated by adding the maneuver of circularly palpating the outer margin of the breast either at the beginning or at the end of the method. Method c. is the most comprehensive coverage of tissue because its borders (clavicle, sternum, caudal breast edge, and posterior axillary line) encompass not only the observable protuberant breast tissue but also the thin layer of breast tissue that extends over a larger area at the outer limits of the visible breast.
7. In all three methods of palpation be sure to palpate the extension of the breast into the axilla. You will need to lower the woman's arm to the level of her shoulder while palpating the axilla.	**7.** Lower the arm in order to relax the muscles, which may otherwise interfere with your palpation of the axillary area.

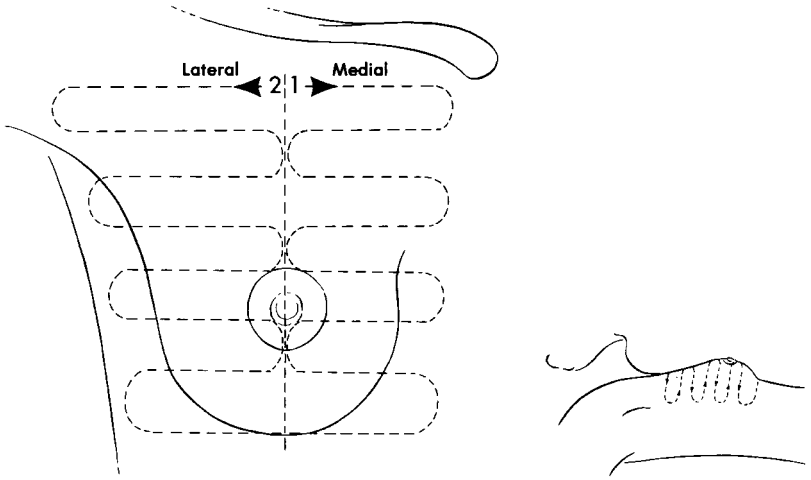

FIGURE 52-5 Transversing method of palpating the breasts.

Observations	Significance
Contrary to popular practice, it is *not* necessary to attempt to express discharge from the nipples as part of a routine breast examination. Unless it is most gently performed it is a traumatic procedure that may of itself cause a discharge from tissue damage. Discharge that is elicited by expression from the breast usually has no pathological significance. Discharge that escapes from the nipple spontaneously during palpation is significant and requires physician consultation or referral. If there is a cancerous lesion, traumatic examination and expression run the risk of causing metastasis.	

Observations	Significance
1. A transverse ridge, perhaps slightly tender, at the caudal edge of the breast.	**1.** Inframammary fold; normal.
2. Fine nodularity throughout the breast.	**2.** Normal breast tissue consisting of lobules of glandular tissue.
3. Coarse nodularity generalized throughout the breast, occurring during the premenstrual or menstrual phases of the menstrual cycle.	**3.** Normal physiological engorgement. If you are unsure of normality, consult with the physician.
4. Coarse, granular nodularity in a localized area.	**4.** Abnormal; physician consultation/referral required.
5. Loss of elasticity of nipples or breast tissue with increased firmness or thickening of the skin texture.	**5.** Abnormal; physician consultation/referral required.
6. Any mass. Note and chart the following: **a.** location—expressed in terms of location on a clock face with the woman in a supine position. Note the distance of the mass from the nipple. **b.** size—length and width in centimeters **c.** shape or contour—for example, round, nodular, smooth, elongated, irregular **d.** consistency—for example, elastic, tense, firm, soft, hard. **e.** delimitation (demarcation, discreteness, circumscription)—the degree of discreteness or sharpness of the edges or margins of the mass; usually charted as well defined or delimited, or poorly delimited, or difficult to determine boundaries **f.** mobility or movability—for example, freely movable, fixed, moderately fixed, movable only in certain directions.	**6.** Abnormal; physician consultation/referral required. All the information to be charted provides baseline data from the first time the mass is noted; the information is especially useful if you have to refer a woman to a physician from an outlying clinic. The specific observations about the mass aid the physician in making a differential diagnosis and deciding on a course of action. Generally, a cancerous lesion will be found in the upper outer quadrant, have an irregular shape, a wooden or hard consistency, poor delimitation, and be nonmovable, or fixed. Some breast cancers, however, do not fit this description. Even if you are quite sure that what you are feeling is a cyst, you must refer the woman to a physician. Final diagnosis is by biopsy.

Charting of Findings

If findings are normal, the following will be charted:

> Breasts symmetrical, soft, and without masses. Nipples symmetrical, clean, and not retracted. No palpable supraclavicular, infraclavicular, or axillary nodes. History noncontributory.

If findings are abnormal:

1. Describe any findings. If you note a mass, draw a sketch locating the mass. The sketch may be simple, simulating a clock face with the nipple in the center. Note whether the sketch is of the left or the right breast. Describe the size, shape, consistency, delimitation, and mobility or movability of the mass.
2. Note whether there were any palpable supraclavicular, infraclavicular, or axillary nodes and, if so, the number of them and the size and consistency of each.
3. Describe any asymmetry or retraction signs, note where these were located, what position the woman was in, and what maneuver allowed you to observe them.
4. Note and describe any nipple changes or discharge.
5. Note any relevant history.
6. End your note with the name of the physician with whom you will consult or to whom you are referring the woman.

Variations in Breast Examination and Findings for the Pregnant Woman

The basic breast examination is performed during the woman's initial prenatal physical examination. Because of physiological changes occurring during pregnancy, it is more difficult to diagnose breast

masses. The following breast findings are considered normal in the pregnant woman:

1. Bilateral increase in size, often accompanied by tingling, tenseness, and tenderness. Occurs in the first trimester.
2. Increased generalized coarse nodular and lobular feel of the breast as a result of hypertrophy of the mammary alveoli. Occurs in the first trimester.
3. Discharge of colostrum from the nipples. May appear as early as the sixth week of gestation as a clear viscous fluid. May become yellow and less viscous later in the pregnancy. Spontaneous discharge of colostrum may dry and form a crust on the nipples if they are not carefully cleaned daily with warm water.
4. Montgomery's follicles: hypertrophied sebaceous glands in the areola. Occurs in the first trimester.
5. Enlargement and increased erectility of the nipples. Occurs in the first trimester.
6. Broadening and increased pigmentation of the areola. Starts in the first trimester. Heavier pigmentation of the areola in the first trimester is called primary areola. A darkening and mottling of the skin around and beyond the primary areola during the second trimester is called secondary areola.
7. Dilated subcutaneous veins usually seen beneath the skin as a tracing of bluish veins. Occurs in the first trimester.
8. Vascular spiders on the upper chest (also upper arms, neck, and face). Occurs in the second trimester.
9. Striae of the breasts. May occur with excessive increase in the size of the breasts.

Although not part of every antepartal revisit, the woman's breasts are subsequently examined for the following:

1. Adequate support with a properly fitting brassiere.
2. Condition of the nipples (e.g., dried or crusted colostrum; duct openings clogged with powder; progress in bringing out flat or inverted nipples in women who plan to breastfeed).

There are certain situations in which it is of value to attempt to express colostrum from the nipples during pregnancy.

1. Presence of colostrum is a presumptive sign of pregnancy in primigravidas and in multigravidas who have not had a baby or breastfed in the past few years. Expression of colostrum is useful in clinically evaluating the possible diagnosis of pregnancy early in the first trimester, as colostrum appears by the sixth week of gestation.
2. An anxious woman who is close to term or immediately postpartum who wants to breastfeed may decide against it because she erroneously thinks she has nothing in her breasts to give her baby. Such anxiety is immediately allayed rather dramatically by expressing a few drops of colostrum.

Variations in Breast Examination for the Postpartal Woman

The woman has had the basic breast examination during her initial prenatal physical examination and again early postpartum. It is important to examine her breasts additionally during each postpartal examination:

1. Check for adequate support with a properly fitting brassiere or a breast binder.
2. Palpate the breasts to ascertain their condition:
   a. soft
   b. filling—tense, increasing firmness, slightly enlarged
   c. engorged—enlarged, hard, reddened, shiny, skin temperature elevated, painful, dilated veins
3. If the mother is breastfeeding, inspect the nipple epithelium:
   a. signs of irritation—reddened, tender
   b. precursory signs of cracking—tiny pinpoint blisters or subepithelial petechiae (best seen with a small magnifying glass)
   c. cracking—sore, possibly bleeding

There are also situations during the postpartal period in which it is of value to express colostrum or milk from the mother's nipples.

1. Expression of a drop or two of colostrum or milk helps the baby to learn where to suckle through immediate gratification.
2. When the breasts, and especially the areola, are engorged it will be easier for the baby to latch on properly if milk is first expressed, which diminishes the rigid hardness of the area so that it is soft enough that the baby can compress the lactiferous sinuses (see Chapter 62).

Teaching Breast Self-Examination

Teaching the woman how to do breast self-examination (BSE) is an inherent part of performing a breast examination on any woman. The importance of both annual breast examination by a clinician and monthly self-examination of the breasts should be emphasized to women throughout their life spans. Experienced clinicians often incorporate this teaching into their own examination of the woman rather than having a separate time for teaching the woman. (This approach saves time but still gets the teaching done, which is especially important in a busy clinic or office situation.) A number of pamphlets illustrate the technique for doing breast self-examination. These are available at no cost from the American Cancer Society.

You should begin by asking the woman if she knows how to do breast self-examination and if she is doing it. If the answer is affirmative, have her demonstrate her method. Also ascertain the frequency of her examinations. If she says she knows how to do self-examination but admits to not doing it, ascertain why she is not doing it. If she does not know how to do self-examination, ascertain if she wants to learn how and, if not, why not.

The following information should be included in any education about breast self-examination:

1. Why breast self-examination is important.
2. Assurance that a cancer identified early enough most often can be cured.
3. A reminder that not all lumps mean cancer but they must be diagnosed quickly.
4. When to do breast self-examination during the menstrual cycle and why. Instruct the woman to perform breast self-examination every month, a day or so after the end of her menstrual period. The end of the menstrual period serves as a reminder. It also keeps her from doing examinations during the premenstrual or menstrual phases of her menstrual cycle, when she may feel normal physiological changes that may unduly frighten her.
5. The positions to assume for inspection while situated in front of a mirror.
6. What she is looking for during inspection.
7. The position to assume for palpation (supine), the raising and lowering of her arm on the same side of her body as the breast she is palpating, and the placement of a small pillow under her shoulder on the same side.
8. Proper palpation technique and the importance of covering every square inch of the breasts and axillae. Women frequently squeeze or mash their breasts rather than palpating gently and compressing the breast tissue against the chest wall.
9. What she is looking for during palpation.
10. Anatomical structures that she might encounter during examination, such as ribs, the inframammary fold, and her normal breast tissue. (Have her feel them so she will not be unnecessarily frightened by them.)

In order for breast self-examination to be an effective screening tool for breast lesions, it is necessary for you to evaluate the effectiveness of your teaching. If your teaching has been effective, the woman should be performing monthly breast self-examination and should be able to do the following:

1. State the importance of doing breast self-examination.
2. State the proper time of the month for doing breast self-examination.
3. Demonstrate the proper positions for inspection in front of a mirror.
4. State accurately what she is looking for during inspection.
5. Demonstrate the proper position for palpation of her breasts.
6. Demonstrate a method of palpation that covers every square inch of each breast, includes palpation of her axillae, and gently compresses the breast tissue against her chest wall.
7. State accurately what she is looking for during palpation.
8. State what she is going to do if she finds something abnormal during inspection and palpation.

CHAPTER

53

Obstetric Abdominal Examination

The term *obstetric abdominal examination* is used to indicate that this examination covers only the manifestations or results of pregnancy as elicited abdominally. This chapter is not intended to cover all that would be encompassed in an abdominal examination done during a routine screening physical examination as outlined in Chapter 2.

Antepartal/Intrapartal Abdominal Examination

General

As outlined in Chapter 22, abdominal examination of the pregnant woman includes the following:

1. noting any scars and obtaining explanation of them
2. checking for diastasis recti
3. checking for hernia
4. observation for linea nigra
5. observation for striae gravidarum
6. observation or palpation of fetal movement
7. measurement of fundal height
8. determination of lie, presentation, position, and variety
9. checking for fetal heart tones
10. estimation of fetal weight

The significance of these findings is also discussed in Chapter 22. The underlying physiology for findings that are presumptive, probable, or positive signs of pregnancy is discussed in Chapter 21.

This section on the antepartal and intrapartal abdominal examination is limited to the methods used in measuring fundal height; indications and procedure for measuring abdominal girth; the procedure for doing abdominal palpation and Leopold's maneuvers for determining abdominal muscle tone and fetal lie, presentation, position, variety, and engagement; and the probable location of the fetal heart tones based on the findings elicited using Leopold's maneuvers. The skill of estimating fetal weight is discussed in Chapter 22.

Measuring Fundal Height

Fundal height can be measured in a number of different ways. Engstrom and Sittler write the history of fundal height measurement from 1752 to present in fascinating detail [1].

Four ways of measuring fundal height are presented in this book. All have an inherent degree of inaccuracy because each depends on the examiner's identifying the top of the fundus correctly. Unfortunately, often some unidentifiable point on the anterior slope of the fundus is mistaken for the top of the fundus. This error can be avoided by doing the following:

1. Facing the woman's head as she lies supine, place your hands on each lateral side of the uterus approximately midway between the symphysis and the fundus.
2. Ballotte the uterus between your hands with gentle pressure and, being sure to keep your hands on the transverse (lateral) portion of the uterus, palpate up to the fundus.
3. As you near the top, make sure that your hands will begin to come together and they will meet at the top of the fundus.

Keeping your hands on the transverse (lateral) portion of the uterus assures reaching the actual top of the fundus and keeping off its anterior slope.

Even when the top of the fundus is identified correctly, sequential recording of fundal height from antepartal visit to antepartal visit will most likely be rendered useless if different examiners see the woman and use different ways of measuring fundal heights. If more than one person will be examining a woman during her pregnancy, all the persons involved must agree to measure fundal height the same way in order for this evaluation tool to have any meaning. They should also agree on the position of the woman during the measurement, as the measurement may vary depending on whether the woman is supine or has her trunk elevated with or without her knees flexed [2]. The discrepancies between ways of measuring fundal height become apparent in comparing the following discussion of each.

Method 1 The time-honored but most inaccurate way of measuring fundal height combines a knowledge of where to expect the fundal height to be at various weeks of gestation in relation to the woman's symphysis pubis, umbilicus, and tip of the xyphoid process and the use of the examiner's fingerbreadths as the measuring tool.

The inherent inaccuracies of this method are obvious immediately. First, women vary considerably in the distance from their symphysis pubis to their xyphoid process and in the location of the umbilicus between these two points. Second, the width of examiners' fingers varies considerably. For example, two fingerbreadths of a thick-fingered person can be the same as three fingerbreadths of a thin-fingered person.

Nevertheless, this method is useful if you do not have calipers or a tape measure immediately available, as it does enable you to ascertain that growth is occurring. Also, it does provide you with a good guide for establishing general expectations that can be used as a baseline against which to compare actual findings. Although this baseline may indeed be of somewhat questionable accuracy, it is a rule of thumb accurate enough to identify gross discrepancies between estimated gestational age by dates and by findings and to indicate the need for further investigation to rule out the possible causes for this discrepancy.

Table 53-1 lists the approximate expected location of the fundal height at various weeks of gestation. These are also shown in Figure 53-1.

Method 2 The caliper method of measuring fundal height is used infrequently, probably because a tape measure is cheaper, more portable, easier to read, and less awkward to use. The caliper method is, however, probably the most accurate method of measuring fundal height after the twenty-second to twenty-fourth week of gestation. A study by Engstrom, McFarlin, and Sittler indicates the possible improved reliability of fundal height measurement obtained with calipers over those obtained with a tape measure but also notes several practical problems [3].

The calipers are used by placing one tip on the superior border of the symphysis pubis and the other tip at the top of the fundus. Both tips are placed in the abdominal midline. Do not confuse the superior edge of the pubic hair line with the superior border of the symphysis pubis. These two *different* landmarks often do *not* coincide. You

TABLE 53-1 Approximate Expected Fundal Height at Various Weeks of Gestation

Weeks of Gestation	Approximate Expected Fundal Height
12	Level of the symphysis pubis
16	Halfway between symphysis pubis and umbilicus
20	1–2 fingerbreadths below umbilicus
24	1–2 fingerbreadths above umbilicus
28–30	One-third of the way between umbilicus and xyphoid process (three fingerbreadths above umbilicus)
32	Two-thirds of the way between umbilicus and xyphoid process (three to four fingerbreadths below xyphoid process)
36–38	One fingerbreadth below xyphoid process
40	Two to three fingerbreadths below xyphoid process if lightening occurs

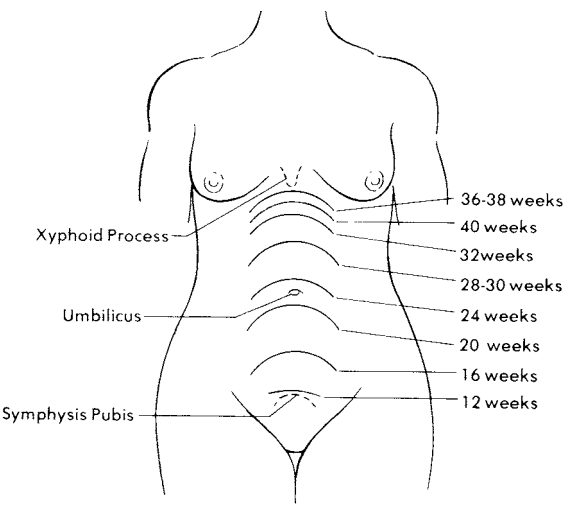

FIGURE 53-1 Approximate normal fundal heights during pregnancy.

must palpate for the symphysis pubis in order to locate its superior border. The measurement is then read on a centimeter scale located on an arc close to where the two ends of the calipers come together. The number of centimeters should be approximately equal to the weeks of gestation after about 22 to 24 weeks of gestation.

Method 3 Measuring fundal height with a tape measure is the most frequently used method for obtaining an exact measurement. It is also probably the second most accurate method of measuring fundal height after the twenty-second to twenty-fourth week of gestation. The zero line of the tape measure is placed on the superior border of the symphysis pubis and the tape measure is stretched across the contour of the abdomen to the top of the fundus. The abdominal midline is used as the line of measurement. Again, do not confuse the superior edge of the pubic hair line with the superior border of the symphysis pubis. The number of centimeters measured should be approximately equal to the weeks of gestation after about 22 to 24 weeks gestation.

Method 4 The fourth method of measuring fundal height also utilizes a tape measure, but the method of measuring differs. The zero line of the tape measure is again placed on the superior border of the symphysis pubis in the abdominal midline. The midwife's other hand is placed vertically—that is, with the thumb up, the palm toward the woman's abdomen, and the edge of the little finger touching the top of the fundus. The midwife then runs the tape measure through the index and middle finger of this hand and reads the measurement where the tape goes between the fingers over the top of the fundus. In effect, the tape measure follows the contour of the abdomen only as far as its apex and then is relatively straight to the point held by the midwife's fingers; the tape does not follow the anterior slope of the fundus. The centimeters not measured because the tape does not follow the anterior slope are accounted for mathematically, as follows:

Before the fundus reaches the level of the umbilicus, add 4 cm to the number of centimeters measured. The total number of centimeters should be approximately equal to the weeks of gestation.

After the fundus has reached the level of the umbilicus, add 6 cm to the number of centimeters measured. The total number of centimeters should be approximately equal to the weeks of gestation.

Although a number of clinicians use this method, there has not been any research done to show its equivalency to (or deviation from) the other methods of obtaining a centimeter measurement or to show whether the mathematical formula is indeed correct in relation to the weeks of gestation.

The problem is that if one examiner were to use this method and record the actual measurement (without the addition of the centimeters in the formula) and the next examiner were to measure the fundal height using the other tape measure method (method 3), there would be a discrepancy that would cause serious concern about the gestational growth of the fetus. Thus, the plea for communication and uniformity of method among clinicians practicing together is well founded.

Measuring Abdominal Girth

The measurement of abdominal girth is an adjunctive screening tool for determining any deviation from normal after the thirty-fourth week of gestation in women of no more than average size. Specifically, measuring abdominal girth is useful when you suspect the woman has an oversized uterus. Of the conditions that may cause an oversized uterus, two increase the breadth of the uterus as well as the length. These two conditions are multiple gestation and polyhydramnios.

To measure abdominal girth, encircle the woman's body with a tape measure at the level of the umbilicus. Generally, the normal girth measurement is approximately 2 inches less than the week of gestation. For example, you would expect a measurement of about 32 in. (81 cm) at 34 weeks gestation; 34 in. (86 cm) at 36 weeks gestation; 36 in. (91 cm) at 38 weeks gestation; and 38 in. (96.5 cm) at 40 weeks gestation.

A general rule of thumb is that any measurement more than 100 cm (or $39^1/_2$ in.) is larger than normal at any week of late gestation, and further investigation is necessary to ascertain the reason for this oversized uterus.

Gross obesity will skew the accuracy of abdominal girth findings, which is the reason for limiting the use of this tool to women of no more than average size. Possibly this inaccuracy could be circumvented by obtaining a baseline measurement on obese women prior to the thirty-fourth week of gestation.

Abdominal girth measurement, like fundal height measurement, may be inaccurate because of different body builds. It is, however, still accurate

enough to be useful as a gross screening tool, especially when in a situation of limited access to more sophisticated diagnostic tools such as ultrasound.

Abdominal Palpation and Leopold's Maneuvers

The term *abdominal palpation* is often used to mean doing Leopold's maneuvers for determining fetal lie, presentation, position, variety, and engagement. However, this is not precisely accurate. Other information is also obtained while doing Leopold's maneuvers, and further abdominal palpation may be involved than that strictly needed for doing Leopold's maneuvers. Abdominal palpation that includes the performance of Leopold's maneuvers is conducted for the following purposes:

Evaluation of uterine irritability, tone, tenderness, consistency, and any contractility
Evaluation of abdominal muscle tone
Detection of fetal movement
Estimation of fetal weight
Determination of fetal lie, presentation, position, and variety (see Chapter 26, pp. 747–749)
Determination of whether the head is engaged

Evaluation of abdominal muscle tone is important because poor muscle tone can influence the pregnancy in a number of ways, ranging from the discomfort of low back pain to the presenting part's overriding the symphysis pubis and having difficulty entering the true pelvis. Abdominal muscle tone becomes progressively more lax with increasing parity, especially if the woman has not done muscle tightening and toning exercises after each delivery. The method for evaluating abdominal muscle tone is described later in the chapter, in the discussion of the postpartal abdominal examination.

Before performing abdominal palpation and Leopold's maneuvers during the antepartal or intrapartal abdominal examination, make sure you carry out the following preparatory and general procedures:

Preparatory and General Procedures	Rationale
1. The woman's bladder should be empty.	**1.** A full bladder makes abdominal palpation very uncomfortable for the woman, as her bladder is subjected to pressure during the procedure. A full bladder also makes it difficult to feel fetal structures beneath the bladder, thereby obscuring findings pertaining to the presenting part.
2. The woman's abdomen should be completely exposed from just below the breasts to the symphysis pubis. (Have her lift her hips so she or you can pull down the back of her pants below the level of her hips.)	**2.** The abdomen should be completely exposed so you can observe its contours. Pulling down just the front of her pants causes her clothing to pull from her waist in the back, which interferes with your ability to locate the symphysis pubis and does not really expose the lower portion of her abdomen.
3. The woman's abdominal muscles should be relaxed. You can make sure they are by doing *all* of the following: **a.** Place a pillow under her head and upper shoulders. **b.** Ask her to place her arms by her sides or across her chest. **c.** Explain what you will be doing. **d.** Help her with relaxation breathing techniques, if needed. **e.** Have her bend her knees slightly. This is especially important for Leopold's third and fourth maneuvers.	**3.** Palpation is difficult for both the woman and the examiner if the woman's abdominal muscles are contracted. It is difficult for the examiner to feel the fetus and thus the examiner must take longer and use more forcible palpation. This causes the woman discomfort and she tenses her muscles. Thus, a vicious cycle is in operation. All of this can be avoided by starting with relaxed abdominal muscles. The examiner should have warm hands and use smooth and gentle but firm palpation, as described in Steps 4 and 6; these steps reduce stretching and, therefore, tension of the abdominal muscles.
4. Be sure your hands are warm. If not, hold them under warm water, rub them together, or hold them under a light until they are warm.	**4.** Cold hands are uncomfortable for the woman. They may also cause muscle contraction.

5. Before palpating, lightly rest your hand on the woman's abdomen (but not so lightly as to tickle). A good time for this is while you are explaining what you are going to do. (See Figure 53-2.)
6. The technique of palpation is as follows:
   a. Use the flat palmar surface of your fingers for palpating—*not* your fingertips.
   b. Keep the fingers of your hands together.
   c. Apply smooth deep pressure as firm as is necessary to obtain accurate findings.
   d. Avoid any sudden movement, jabbing, poking, or prodding—you are palpating a woman's abdomen, not kneading bread.

5. This action gives the woman an opportunity to adjust to your touching her. A light preliminary touch is not uncomfortable and allows her initial muscle-tightening reaction to being touched to dissipate.
6. This technique of palpation is designed to give the woman the least possible discomfort and to permit the examiner to gather the greatest amount of information and cover the greatest contiguous area in the shortest amount of time with the greatest degree of tactile sensitivity.
   d. There is no excuse for a rough abdominal examination. Not only do you lose the woman's cooperation and trust but such an examination may also cause abdominal muscle tension and uterine contraction, rendering it difficult if not impossible to obtain accurate findings.

Before starting palpation, inspect the abdomen to determine what its contours can tell you about the fetal lie, presentation, position, and variety. Palpation then gives you further information with which to confirm or rule out this initial impression.

Leopold's maneuvers (Figure 53-3) are four maneuvers that start at the fundus and end at the pelvic brim. The experienced midwife may start with any one of the four maneuvers. It is suggested that the learner, however, go through the steps sequentially, as the pattern they form contributes to a thought process and creates a mental image for determining fetal position that will most quickly aid you in developing skill and accuracy. Consistently following an orderly sequence will also help you remember to include all the maneuvers and gather all the necessary information. In doing Leopold's maneuvers, stand at the side of the bed most convenient and comfortable for you. Unless the room arrangement prevents it, right-handed people generally stand on the woman's right side and left-handed people generally stand on the woman's left side.

Observations	Significance
1. Uterine shape is a longitudinal ovoid; fundal height as expected for gestational age.	1. Indicates a longitudinal lie.
2. Uterine shape is a transverse ovoid; fundal height lower than expected for gestational age.	2. Indicates a transverse lie.
3. A long smooth curve is prominent on one side of the abdomen.	3. Indicates that the back of the fetus is on that side of the abdomen.

FIGURE 53-2 Midwife preparing to do an abdominal palpation.

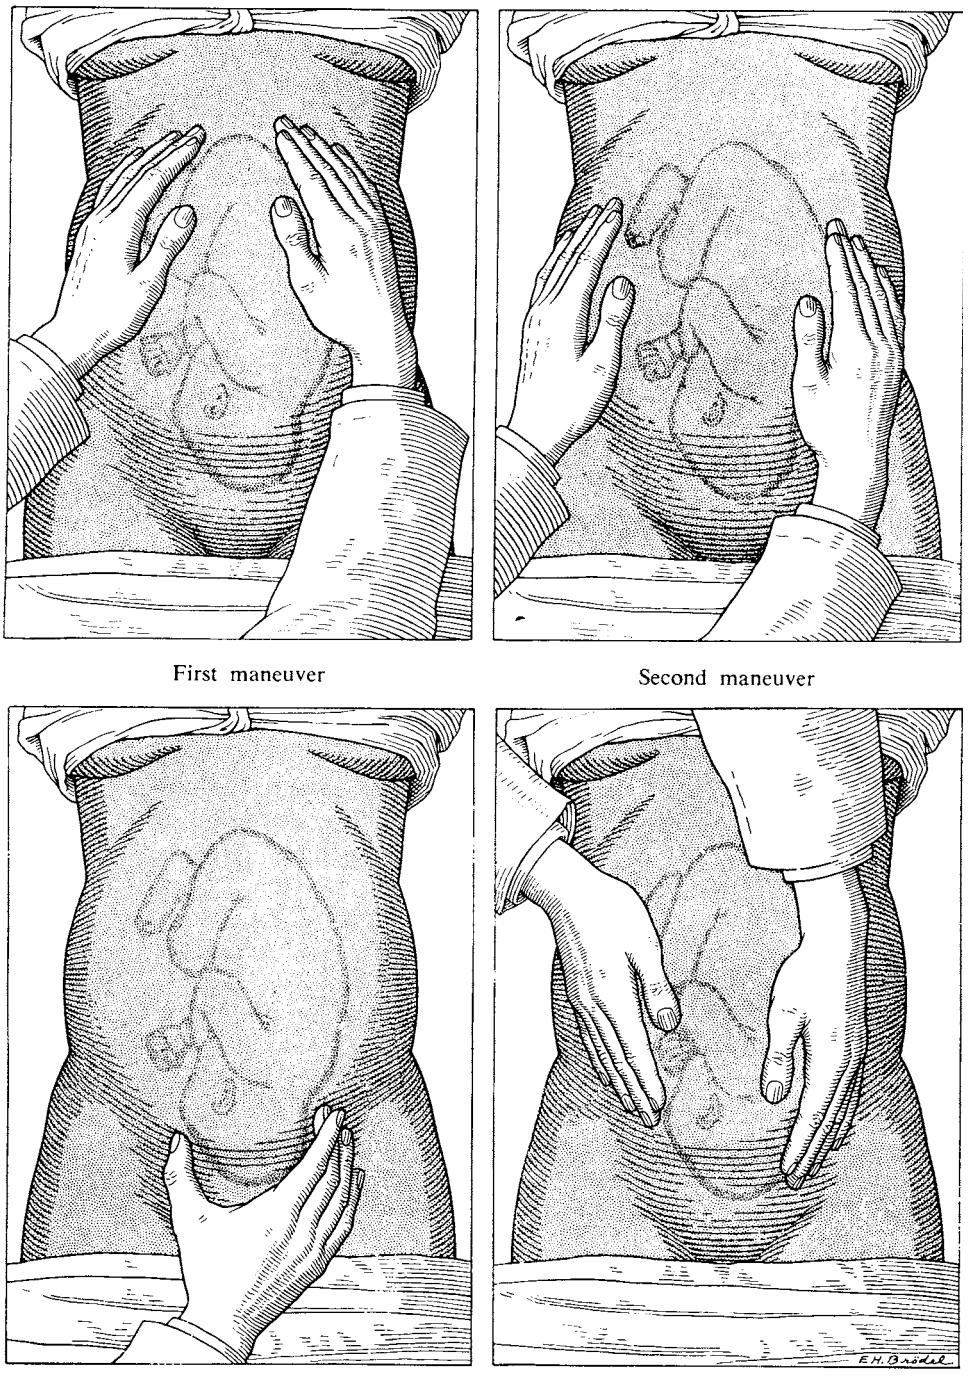

FIGURE 53-3 Leopold's maneuvers. Palpation of the fetus in left occiput anterior position.

Source: From Cunningham, F. Gary, Gant, Norman F., Leveno, Kenneth J., Gilstrap, Larry C. III, Hauth, John C., Wenstrom, Katherine D. *Williams Obstetrics*, 21st Edition. McGraw-Hill, New York, 2001. Reproduced with permission of the McGraw-Hill Companies.

Observations	Significance
4. A saucerlike depression appears just below the umbilicus and a bulge like a full bladder appears above the symphysis pubis.	**4.** Indicates a posterior position.
5. Movement of fetal small parts can be seen all over the abdomen.	**5.** Indicates a posterior position.

Procedure	Findings	Significance
1. First maneuver (see Figure 53-3):		
a. Face the woman's head.		
b. Place your hands on the sides of the fundus and curve your fingers around the top of the fundus.		
c. Palpate for shape, size, consistency, and mobility.		
d. Ask yourself the question: What is in the fundus?	**(1)** Fetal part feels round and hard; is readily movable; and can be ballotted between the fingers of your two hands or between the thumb and a finger of one hand.	**(1)** Indicates a fetal head. The mobility arises from the head's being able to move independently of the trunk. The lie is longitudinal.
	(2) Fetal part feels irregular, larger or bulkier, and less firm than a head. It cannot be well delineated or readily moved or ballotted.	**(2)** Indicates the fetal breech. The breech cannot move independently of the trunk. The lie is longitudinal.
	(3) Neither of the above is felt in the fundus.	**(3)** Indicates a transverse lie.
2. Second maneuver (see Figure 53-3):		
a. Continue to face the woman's head.		
b. Place your hands on both sides of the uterus about midway between the symphysis pubis and the fundus.		
c. Apply pressure with one hand against the side of the uterus, thereby pushing the fetus to the other side of the abdomen against your examining hand and stabilizing it there. Maintain this pressure while your examining hand palpates the other side of the uterus for the fetus.	**(1)** A firm, convex, continuously smooth, and resistant mass extending from the breech to the neck.	**(1)** Indicates the fetal back. The location of the back in the left or right side of the woman's abdomen determines the position in a longitudinal lie. The location of the back in the anterior, lateral, or posterior portion of the abdomen determines the variety (see Chapter 26, p. 748).
	(2) Small, knobby, irregular masses which move when pressed on or kick or hit your examining hand.	**(2)** Indicates the fetal small parts—hands, feet, knees, elbows. Should be in the side of the woman opposite from the side the fetal back is in.
	(3) Small parts all over the abdomen. The back is difficult to feel and seems to be just out of reach in the posterior portion of the abdomen.	**(3)** Indicates a posterior position.
d. Palpate the entire area with your examining hand, from the abdominal midline to the lateral side and from the symphysis pubis to the fundus. Use firm, smooth pressure and rotary movement.		
e. Reverse the procedure to examine the other side of the uterus.		

Some midwives either add or substitute another procedure for the second Leopold maneuver. Its name, "walking your fingers over the abdomen," describes the procedure, which is as follows:

1. Start on one side of the abdomen and apply deep and firm pressure with the fingers of both hands.
2. Then move (walk) your fingers across the abdomen from one lateral side to the other lateral side.

The pressure applied by your fingers will enable you to differentiate the firm back from the knobby small parts, which will ease away from your fingers as you cross over them. The art of this procedure lies in doing it so that it does not cause the woman discomfort. This requires experienced fingers and a midwife knowledgeable about what she or he is feeling. It is, therefore, not suggested for the beginner.

Procedure	Findings	Significance
3. Third maneuver (see Figure 53-3). **a.** Continue to face the woman's head. **b.** Make sure that the woman's knees are bent in order to avoid causing her discomfort during this maneuver. **c.** Grasp the portion of the lower abdomen immediately above the symphysis pubis between the thumb and middle finger of one hand. It will be necessary to press gently but firmly into the abdomen in order to feel the presenting part below and between your thumb and finger. **d.** You will feel a movable mass if the presenting part is not engaged. As in the first maneuver, palpate for shape, size, consistency, and mobility in order to differentiate if the mass you feel is the breech or head in the lower pole of the abdomen. Ask yourself: What is in the lower pole?	**(1)** The findings will be the same as for the first maneuver except they will be in the lower pole. **(2)** If the presenting part is the head, it may not be readily movable, especially if it is engaged. If the head is above the pelvic brim, it is readily movable and ballottable, as described for the first maneuver.	**(1)** Same as for first maneuver. The findings from the first and third maneuvers must be compared in order to make a final determination of the lie and presentation.

Leopold's third maneuver is also known as Pawlik's maneuver, or Pawlik's grip (see Figure 53-4). A procedure that is sometimes added to this maneuver is called the combined Pawlik grip, in which you use Pawlik's grip with one hand and grasp the fundus in the same way with the other hand at the same time. This combination enables you to compare simultaneously what is in the two poles for final determination of the fetal lie and presentation.

FIGURE 53-4 Combined Pawlik grip.

Procedure	Findings	Significance
4. Fourth maneuver (see Figure 53-3):		
a. Turn and face the woman's feet.		
b. Make sure that the woman's knees are bent in order to avoid causing her pain with this maneuver.		
c. Place your hands on the sides of the uterus with the palms of your hands just below the level of the umbilicus and your fingers directed toward the symphysis pubis.		
d. Press deeply with your fingertips into the lower abdomen and move them toward the pelvic inlet.		
e. In a breech presentation, or in a head presentation after you have palpated the cephalic prominence, continue to move your hands toward the pelvic inlet. Your hands will be unable to continue past the brim of the true pelvis because the symphysis pubis prevents further movement.	**(1)** If the head is the presenting part, one of the following will happen:	**(1)**
	a. One of your hands will make contact with a hard round mass while your other hand continues on in the direction of the pelvis.	**a.** The hard round mass is the cephalic prominence. If it is on the same side of the woman as the fetal back, the cephalic prominence is the occiput and indicates a face presentation because the head is extended. If the cephalic prominence is on the same side of the woman as the fetal small parts, it is the forehead and indicates a vertex presentation since the head is well flexed.
	b. Both of your hands will encounter simultaneously a hard round mass, which is equally prominent on both sides.	**b.** This indicates a sincipital (or military) presentation. Your hands are feeling the forehead and the occiput at the same time.
	(2) At the brim of the pelvis your hands will do one of two things:	**(2)**
	a. Converge around the presenting part so that the fingertips of your two hands touch in the abdominal midline. If the presenting part is the head, it will be readily movable. If the presenting part is the breech, it will have a feeling of give along with the trunk of the fetus.	**a.** The presenting part is not engaged. Rather, it is floating at or above the pelvic inlet (as determined by its position at or above the symphysis pubis).
	b. Diverge away from the presenting part and the abdominal midline. The presenting part will have no give or mobility.	**b.** The presenting part is either engaged or "dipping." When the presenting part is dipping, it has entered the pelvic inlet but has not yet descended to the point of engagement. If you are unable to feel the cephalic prominence because it is out of reach in the pelvis, the head is engaged.
5. Share your findings with the woman. Offer to help her feel and identify various parts of her baby if she would like.		

Location of Fetal Heart Tones

Abdominal palpation that determines the lie, presentation, position, and variety of the fetus enables you to locate the fetal heart tones. This is because the sound of the fetal heart is transmitted through the convex portion of the fetus closest to the anterior uterine wall. Therefore, you will be able to hear the fetal heart tones best through the back of the fetus in vertex and breech presentations and through the chest of the fetus in face presentations. Thus, if you know the position of the fetus you can readily locate the fetal heart tones, allowing for some variation depending on how far the fetus has descended into the pelvis (see Figure 53-5).

Conversely, location of the fetal heart tones is an additional piece of data that serves to either confirm or call into question your diagnosis of the fetal position. If you find the fetal heart tones loudest in a location different from where you expected to find them, then you must reconsider your findings or your interpretation of your findings from abdominal palpation.

The fetal heart tones of a full-term fetus with an unengaged presenting part are best heard in the general locations listed in Table 53-2, in relation to general presentations, positions, and varieties. Specific locations of the loudest fetal heart tones for specific fetal positions are shown in Figure 53-5.

Recording the fetal heart tones gives two pieces of information: the rate and the location of maximum intensity. The location is identified by dividing the abdomen into four quadrants with imaginary vertical and horizontal lines that bisect each other at the umbilicus, as follows:

RUQ	LUQ
RLQ	LLQ

RUQ = right upper quadrant
RLQ = right lower quadrant
LUQ = left upper quadrant
LLQ = left lower quadrant

You then chart the rate and location in one of the following three ways:

1. RLQ-140
2. 140 (RLQ)
3. X (RLQ), 140 (LUQ)

The latter can be the most informative, as the X in the quadrant can be placed in accord with the anterior, lateral, or flank position of the fetal heart tones.

TABLE 53-2 Locating Fetal Heart Tones in Various Fetal Presentations and Positional Varieties

Presentations and Positional Varieties	Location
Cephalic	Midway between umbilicus and level of anterior superior iliac spine
Breech	Level with or above umbilicus
Anterior	Close to abdominal midline
Transverse	In lateral abdominal area
Posterior	In flank area or close to abdominal midline on other side of abdomen

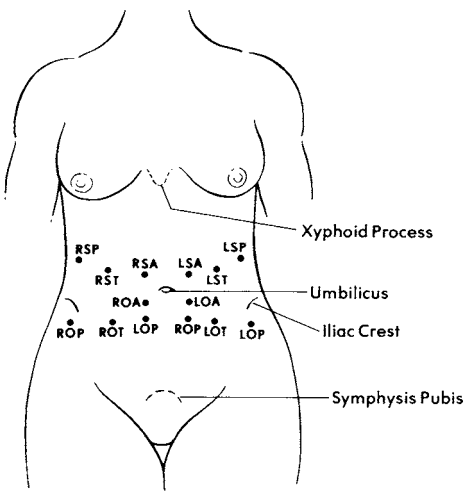

FIGURE 53-5 Location of the point of maximum intensity of the fetal heart tones for specific fetal positions.

Postpartal Abdominal Examination

The postpartal abdominal examination is done during the early postpartal period (1 hr to 5 days). It includes the following:

1. examination of the bladder
2. examination of the uterus
3. evaluation of abdominal muscle tone by determination of the degree of diastasis
4. checking for CVA tenderness (see Chapter 54)

Bladder

In examining the bladder you are looking specifically for bladder distention caused by urinary retention resulting from bladder hypotonicity because of trauma during childbirth. This condition can predispose the woman to bladder infection and be responsible for an increase in uterine bleeding. Evidence of a full bladder, therefore, should be evaluated during the abdominal examination.

Bladder distention can be seen as a bulge in the abdominal contour above the symphysis pubis extending toward the umbilicus. Sometimes the initial indication of a distended bladder is displacement of the uterus upward and to the right side. The full bladder can then be palpated in the lower abdomen.

Uterus

Examination of the uterus includes noting its location, size, and consistency. Determining the *location* of the uterus involves noting if the fundus is above or below the umbilicus and if it is in the abdominal midline or displaced to one side. Location and size overlap, since *size* is determined not only by palpation but also by measuring the height of the uterine fundus.

The fundal height of the postpartum uterus is measured by the number of fingerbreadths the top of the fundus is above or below the umbilicus. (See the first part of Chapter 42 and Figure 42-1 for norms.) As when measuring the pregnant uterus, it is essential to accurately identify the top of the fundus. Again, this can be done by placing your hands on the lateral sides of the uterus and ballotting it between your hands as you palpate up to the fundus. Your fingers will come together at the top of the fundus if you keep your hands on the lateral portion of the uterus, thereby avoiding ending on the anterior slope of the uterus and consequently obtaining an erroneous measurement. Within a few days it will be necessary to measure the top of the fundus in relation to the symphysis pubis rather than to the umbilicus; the fundus is not normally palpable after the tenth day postpartum above the symphysis pubis.

The *consistency* of the uterus is characterized as either firm or soft. *Firm* is sometimes qualified as "firms with massage" and *soft* is sometimes elaborated on as "soft and boggy." A truly firm uterus feels as hard as a rock. A soft uterus feels indentable, and you can feel it hardening beneath your fingers as you massage it. It is important to observe the perineum while feeling for the consistency of the uterus in order to evaluate the effect of uterine stimulation on the amount of lochial flow. If the uterus is firm initially, palpation will not cause an increase in the flow of lochia or expulsion of clots. If the uterus is soft initially, uterine palpation will cause contractions that will expel any accumulated blood and clots. After the uterus is emptied of this accumulation, the lochial flow normally will lessen and the uterus will become firm.

Findings obtained from examination of the uterus can be recorded in more than one way, as is illustrated in the charting of the two following sets of findings. One way, of course, is to write the findings out. The other three ways use generally accepted shorthand notations. The uterus is assumed to be in the midline unless otherwise noted. The three notation forms are presented here in the order of their frequency of use.

Findings: The fundus is firm at two fingerbreadths below the umbilicus in the midline.

1. ff @ U/2
2. ff @ 2 fb ↓ ⊙
3. ff @ ——|——    2

Findings: The fundus is soft at three fingerbreadths above the umbilicus and displaced to the right side.

1. f soft @ 3/U to the right
2. f soft @ 3 fb ↑ ⊙ to the right
3. f soft @ 3 × 
Diastasis

Determination of the amount of diastasis recti is used as an objective means of evaluating abdominal muscle tone. Diastasis is the degree of separation of the abdominal rectus muscles (rectus abdominis). This separation is measured in terms of fingerbreadths when the abdominal muscles are contracted and again when they are relaxed.

Diastasis is measured in the following manner:

1. Position the woman so she is lying on her back without a pillow under her head.
2. Place the tips of the fingers of one of your hands in her abdominal midline with the tip of your index finger just below the umbilicus and your other fingers lined up longitudinally downward toward the symphysis pubis. The sides of your fingers should be touching each other.
3. Have the woman raise her head and strive to put her chin on her chest in the area between

her breasts. (Obviously this is impossible but ensures that she will tighten her abdominal muscles, which will not occur if she merely tucks her chin down on her clavicles.) Be sure she is not pressing her hands against the bed or grabbing the mattress to help herself, as this prevents use of her abdominal muscles.

4. As the woman strains to put her chin between her breasts, press your fingertips gently a short distance into her abdomen. You will feel the abdominal muscles, like two bands of rubber, approaching the midline from both sides. If the diastasis is wide, even with the muscles contracted you will need to move your fingers from side to side in order to find the muscles. If the abdominal muscles are in good enough tone to come together in the midline when tightened, you will feel them against your fingers and then underneath your fingers as they push your fingers out of the abdomen.
5. Measure the distance between the two rectus muscles while they are contracted by placing your fingers flat and parallel to the midline and filling in the space between the rectus muscles with your fingers. Note the number of fingerbreadths between the median edges of the two rectus muscles.
6. Now place the fingertips of one hand along the median edge of one abdominal rectus muscle and the fingertips of your other hand along the median edge of the other rectus abdominis muscle. When properly positioned the backs of your hands should be facing each other in the abdominal midline.
7. Ask the woman to lower her head *slowly* to its original resting position on the bed.
8. As she lowers her head, the rectus muscles will move further apart and become less distinguishable as they relax. With your fingertips follow the rectus muscles as they move apart to their respective lateral sides of the abdomen. This maneuver enables you to still be able to identify them in their relaxed state.
9. Measure the distance between the two rectus muscles while they are relaxed the same way you did when they were contracted. Note the number of fingerbreadths between the median edges of the two rectus muscles.
10. Chart your findings as a fraction in which the numerator represents the width of the diastasis in fingerbreadths when the muscles were contracted and the denominator represents the width of the diastasis in fingerbreadths when the muscles were relaxed. For example, a diastasis that measured two fingerbreadths when the muscles were contracted and five fingerbreadths when the muscles were relaxed would be charted as follows:

Diastasis = 2/5 fb.

This measurement of course can be written out:

Diastasis = 2 fb. when muscles contracted and
5 fb. when muscles relaxed

Steps 1, 3, and 7 of the procedure for measuring diastasis comprise the chin-chest abdominal muscle tightening exercise. Thus, determining the degree of diastasis also provides an ideal situation for teaching.

Unless a woman is in the habit of exercising, she will need considerable motivation to begin and to continue a program of abdominal muscle tightening exercises. She will exercise only if she experiences a need for it, so you first have to capture her interest. You can do this by having her feel "the hole in her stomach" (she's probably already noticed that her abdomen pouches out when she moves around) and then asking her if she wants to know what it is. It is the rare woman who rejects this opportunity. Have her use the same method for feeling her abdomen as you used for determining the diastasis.

You now have her attention, and you can describe how the abdominal rectus muscles normally lie side by side (although not connected) in the midline; how, as her stomach enlarged with her pregnancy, these muscles became stretched; how, after the baby was born, her muscles collapsed; and how her abdominal rectus muscles now no longer lie side by side but instead are separated and trying to get back together again, as she can feel when she tightens them.

Next, ask her if she wants to know why it is important to get her muscles back together again. Again, it is the rare woman who answers no to this question, since this concerns her body. There are two reasons for her to work at getting the abdominal muscles back together:

1. To regain her figure. This often is an insufficient motivating factor.
2. To prevent severe backache, especially during her next pregnancy. Most women will remember having some degree of backache during their pregnancy—many women are miserable with it—and do not want it to an even worse degree the next time.

The motivating factor for many women is an explanation of how the abdominal muscles support the enlarged uterus and baby and how the pregnant

uterus will sag forward without the support of the abdominal muscles and a demonstration of the effect a sagging uterus will have on the back in the form of an exaggerated lordosis, which is what causes backache during pregnancy.

Finally, ask the woman if she wants to know how to get her abdominal muscles back together again. The vast majority of women are now experiencing a need for this information. This is your entree for teaching her the postpartal abdominal tightening exercises, starting with the chin-chest exercise she has already done. Women respond positively to your reminding them that they now know how to check their own progress and that they have reached their goal when they can no longer feel the "hole in their stomach" but can instead feel their muscles lying side by side again.

CHAPTER

54

Checking for Costovertebral Angle Tenderness

Anatomy

The costovertebral angle (CVA) is formed by the junction of the twelfth, or lowermost, rib with the paravertebral muscles, which run parallel to and on both sides of the vertebral column. The kidney is posteriorly closest to the skin surface in this area and pain is transmitted through the tenth, eleventh, and twelfth thoracic nerves. Ureter pain is transmitted through the twelfth thoracic nerve and the first three lumbar nerves.

Significance and Charting

Pain elicited in the area of the costovertebral angle is indicative of renal disease. In addition to being a routine part of the physical examination, checking for costovertebral angle tenderness (CVAT) is always indicated whenever a woman gives a history suggestive of a urinary tract infection after her initial examination.

If there is no CVA tenderness, this is noted under the examination of the abdomen as "No CVAT."

If there is CVA tenderness, this is noted under the examination of the abdomen by its location: "right CVAT," "left CVAT," or "bilateral CVAT."

Procedure and Rationale for Examination

There are several methods for eliciting CVA tenderness. All involve deep pressure or a mild blow to the area. It is important that this not be too vigorous because the woman will suffer pain if you cause trauma to the area. The point is to identify already existing pain.

Procedure	Rationale
Method A	
1. Ask the woman to sit with her entire back and trunk exposed.	**1.** The sitting position exposes the area to be examined.
2. Make a fist out of your examining hand. Use the fleshy side (ulnar surface) of your fist (the side where your little finger is) to gently hit the woman's back. Forewarn her that this is what you are going to do.	**2.** The projection of the knuckle or the thumb on the thumb side of your fist would cause pain when you hit the woman.

Procedure	Rationale
3. Gently pound down one side of the woman's back from the midportion of the scapular area to the midportion of her buttock area just lateral to her paravertebral muscles. Be sure that you hit the costovertebral angle as you move down. Repeat on the other side.	**3.** When you start and end in areas other than the costovertebral angle, the woman is not conditioned to concentrate on whether she feels pain in any one area. This method also conditions her to feel slight jars or thuds so she is not jumping from being startled by the time you arrive at the costovertebral angle.
4. Note if the woman winces, jumps, or otherwise envinces pain when you hit the costovertebral angle.	
Method B	
1. Ask the woman to sit with the area of the costovertebral angle exposed.	**1.** Exposes the area to be examined.
2. Place the palm of one hand over the costovertebral angle on one side.	**2.** to **6.** This method covers less territory than Method A and involves only one hit per side, and so would be better for thin or emaciated women who would feel discomfort from wherever hit in Method A. Method B requires closer differentiation between actual pain and being startled by the blow—both of which might cause the woman to jump—since with Method B the woman is not conditioned to being jarred, as is true in Method A. Method B, however, is useful for double-checking a positive finding elicited by Method A to make sure the pain was indeed elicited at the costovertebral angle. Method A is necessarily less precise in hitting the costovertebral angle.
3. Make a fist out of your other hand. Use the ulnar surface of your fist for striking.	
4. Strike the back of the hand that is over the costovertebral angle with the fist of your other hand.	
5. Note if the woman winces, jumps, or otherwise evinces pain. If so, ascertain if she is responding to pain or to being startled by feeling a mild blow, jar, or thud in this area.	
6. Repeat for the costovertebral angle on the other side.	
Method C	
1. Ask the woman to lie down, looking up.	**1.** to **4.** Method C is particularly useful when examining a woman who is lying in bed, for example, as a routine part of the postpartal examinations in the hospital. Method C requires close differentiation between actual pain and being startled by the blow. This differentiation can be facilitated by telling the woman what you are going to do.
2. Put your hands around the woman's waist and locate by the palpation the costovertebral angles with the flat part of your index and middle fingers on each hand.	
3. Alternately strike each costovertebral angle with your fingers by a sudden, upward motion of your hand.	
4. Note if the woman winces, jumps, or otherwise evinces pain. If so, ascertain if she is responding to pain or to being startled by feeling a mild blow, jar, or thud in this area.	

A good way to double-check a positive finding elicited by any of the above methods is by deep palpation and pressure in the costovertebral angle. This may be done with the woman either sitting or lying down. Such careful palpation in the precise area aids differentiation of CVA tenderness from pain in the immediately adjacent back muscles caused by muscle spasm. Deep palpation over these muscles will elicit any existing muscle pain.

CHAPTER

55

Checking for Deep Tendon Reflexes and Clonus

Deep Tendon Reflexes

Anatomy

Deep tendon reflexes (DTRs) are also known as stretch reflexes because they are elicited by briefly stretching a muscle by tapping its tendon briskly. The brisk tap stimulates a sensory nerve impulse that travels through the reflex arc and ends with stimulation of the muscle in a brief contraction. This brief contraction causes a corresponding brief movement, or jerk, of the anatomical body part affected by the contraction of the muscle. Therefore it is necessary, for each reflex tested, to know the name and location of the tendon to tap, the muscle in which to feel the contraction, and the anatomical body part in which to observe the jerk. Table 55-1 supplies this information for the most commonly tested reflexes.

Significance and Charting

Hyperactive deep tendon reflexes are indicative of disease of the upper motor neuron or pyramidal tract. Hypoactive or absent deep tendon reflexes are indicative of a number of diseases. If you observe either condition, you should consult with a physician.

Reflexes are evaluated on a scale of 0 to 4+ as follows:

0 = absent; no response
1+ = decreased; diminished; sluggish
2+ = normal; average
3+ = brisk
4+ = very brisk; hyperactive
(usually associated with clonus)

Reflexes designated 1+ are low-normal reflexes; 3+ reflexes are more brisk than the average reflex response and indicate the possible but not absolute presence of disease; 0 and 4+ reflexes are definitely abnormal and indicate disease requiring physician consultation. Reflexes should be symmetrical for homologous muscles and symmetry should be noted in the charting.

A stick figure is frequently used to designate the reflex findings from a routine physical examination in which all five deep tendon reflexes are evaluated. The right and left sides are marked on the figure. The figure gives a visual record of the response evaluation and symmetry of each reflex by location (Figure 55-1).

If only one or two of the reflexes is evaluated bilaterally, then the charting would reflect which one. For example:

Quadriceps and biceps deep tendon reflexes (DTR)—2+ and symmetrical
or
Quadriceps DTR—3+, no clonus, symmetrical

TABLE 55-1 Anatomy of Deep Tendon Reflexes

Reflex	Tendon	Muscle	Body Part That Jerks
Quadriceps (knee-jerk)	Ligamentum patellae—from the apex of the patella to the tuberosity of the tibia	Quadriceps femoris—the anterior thigh muscles consisting of four muscles covering the front and sides of the femur and comprising the front of the thigh; the extensor muscle of the leg	Knee extension and leg jerk
Gastrocnemius-soleus (ankle-jerk)	Tendon calcaneus (Achilles tendon)—from the middle of the posterior lower leg to the heel	Gastrocnemius and soleus muscles—the posterior leg (calf) muscles	Plantar flexion of the foot at the ankle (points the toes)
Biceps	Tendon of the biceps brachii—crosses the bend of the elbow and inserts in the posterior portion of the tuberosity of the radius	Biceps brachii—the anterior muscle of the upper arm	Flexion of the elbow, arm, and forearm; supinates the hand
Triceps	Tendon of the triceps brachii—from the middle of the posterior upper arm to the elbow	Triceps brachii—the posterior muscle of the upper arm	Extension of the elbow and the forearm; adducts the arm (toward the body)
Brachioradialis	Tendon of the brachioradialis—from the middle of the forearm to the wrist, inserting in the lateral side of the base of the styloid process of the radius	Brachioradialis—the superficial muscle on the radial (thumb) side of the forearm	Flexes the elbow and the forearm

Procedure	Rationale
1. General:	**1.**
a. Symmetry is determined by comparing the reflex response on one side with the same reflex response on the other side, *not* by comparing the response of different reflexes on the same or opposite sides.	**a.** Different tendons may vary considerably in reflex amplitude, so only the same reflexes on both sides of the body can be compared.
b. In testing reflexes, you should if possible palpate the muscle of the reflex being tested while tapping its tendon.	**b.** Palpating the muscle allows you to evaluate the vigor of the muscle contraction and the time it takes for the muscle to relax after contraction. Slow relaxation of a muscle after contraction is indicative of hypothyroidism.
c. The limb to be tested should be in a flexed or semiflexed position.	**c.** This places slight tension on the muscle to be tested by mildly stretching it and aids in eliciting the reflex.

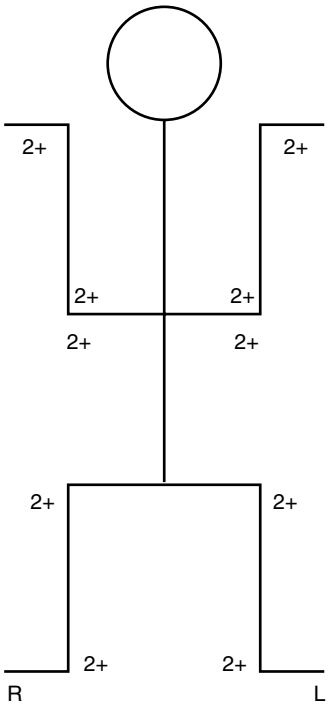

FIGURE 55-1 Stick figure for charting that all five deep tendon reflexes are normal (2+) and bilaterally symmetrical.

Procedure	Rationale
d. The woman should be as relaxed as possible. If necessary, in the event the woman's reflexes appear absent or symmetrically diminished, use the technique of reinforcement, which involves isometric contraction of muscles other than those being tested. For example, while testing leg reflexes, ask the woman to interlock her fingers and pull in opposite directions with her eyes closed; or when testing arm reflexes, have the woman clench her teeth or squeeze her thigh with the opposite hand, again with her eyes closed.	**d.** The woman must be sufficiently relaxed for a deep tendon reflex to be elicited. Reinforcement works in two ways: (1) it distracts the woman and thereby causes relaxation; (2) the deliberate contraction of different muscles from those being tested may increase reflex activity. A reflex is not considered absent unless it cannot be elicited while using the technique of reinforcement.
e. Tap the tendon briskly. A reflex hammer is most useful for this purpose. If a reflex hammer is not available the edge of your stethoscope or, for the quadriceps reflex, even the tips of your fingers suddenly striking the tendon may suffice.	**e.** A brisk tap produces a sudden additional stretch of the tendon. The reflex hammer, when held loosely and swung in an arc using wrist action, provides just the right force and briskness. Use of objects other than a reflex hammer is a makeshift way of striking the tendon that may or may not be successful, depending on a number of factors including if a woman is obese and your ability to really give a brisk tap with whatever object you are using.
f. Position the woman so her limbs are symmetrical.	**f.** This facilitates comparison of sides for each reflex.

Procedure	Rationale
2. Eliciting the biceps reflex: **a.** Feel for the tendon of the biceps brachii muscle in the bend of the elbow. This can be identified by bending the woman's arm up and down at the elbow. **b.** Place the thumb of one of your hands firmly on the tendon. **c.** Position the woman's arm so it is partially flexed at the elbow and either resting in her lap or supported on your arm (the same arm as the thumb you are using). **d.** Tap the tendon indirectly by striking your thumb with the pointed end of the reflex hammer.	
3. Eliciting the triceps reflex: **a.** Position the woman's arm so it is flexed at the elbow and resting across her chest with the palm of her hand of that arm toward her body. Lightly hold the woman's arm in this position with your hand around her wrist. **b.** Palpate for the tendon of the triceps brachii muscle on the back of her upper arm above the elbow. **c.** Directly strike the tendon just above (approximately 2 in., or about 5 cm) her elbow with either the pointed or the broad end of the reflex hammer.	
4. Eliciting the brachioradialis reflex: **a.** Position the woman's forearm so it is resting on her lap or abdomen with her arm slightly flexed at the elbow and hand slightly bent at the wrist. **b.** Palpate for the radius. Since the brachioradialis tendon inserts directly into the radius it is sufficient to strike the bone itself to elicit this reflex. **c.** Tap the radius with either the pointed or broad end of the reflex hammer approximately 1 to 2 in. (2.5 to 5 cm) above the wrist.	
5. Eliciting the quadriceps (knee-jerk) reflex: **a.** Position the woman so that her knees are somewhat flexed. If the woman is lying down, support her knees in the flexed position with your hand under her knees so her lower leg is relaxed. It is not necessary for the woman's foot to be off of the bed. If the woman is sitting, be sure that her legs dangle over the edge of the examining table or bed, that her weight is on her buttocks and thighs, and that her feet are not resting on any object or the floor.	

   b. Palpate for the patella and then identify the patellar tendon just below it.
   c. Tap the patellar tendon with the pointed end of the reflex hammer.
6. Eliciting the gastrocnemius-soleus (ankle-jerk) reflex:
   a. Position the woman's leg so it is somewhat flexed at the knee.
   b. With one hand, dorsiflex the ankle by holding the foot in a position approximating its dorsiflexion if the woman were standing.
   c. Palpate for the Achilles tendon above the woman's heel.
   d. Tap the Achilles tendon approximately 2 to 3 in. (5 to 7.5 cm) above the heel.

Clonus

Definition

Clonus is involuntary, rapid, repetitive, rhythmical contractions and relaxations of a muscle when it is sharply stretched and the stretch is maintained in either flexion or extension.

Significance and Evaluation

The midwife should always check for clonus in the presence of hyperreflexia, since extremely hyperactive reflexes are a precursor of clonus.

Clonus is indicative of upper motor neuron disease and is never present except when there is disease of the central nervous system. The presence of clonus requires that you consult with a physician.

Clonus is evaluated not only by its presence but also by counting the number of times the muscle contracts and relaxes while stretched. The sequential contractions are felt as jerks and are frequently called the number of beats. Clonus ranges from one or two beats to a sustained beating.

Procedure for Eliciting Clonus

Clonus may be elicited at a number of sites such as the wrist, knee, big toe, and ankle. The most commonly used site in obstetric care, however, is the ankle. For this reason, only the procedure for eliciting ankle clonus will be detailed here.

1. Position the woman so her knee is partially flexed. Support this position with one of your hands underneath the bend in her knee.
2. With your other hand grasping her foot, sharply dorsiflex her foot and maintain pressure to keep it in dorsiflexion.
3. You will be able to see and feel any beats of clonus, as the muscle contractions and relaxations will cause rhythmical alteration between dorsiflexion and plantar flexion. The muscles being stretched are the same as for the ankle-jerk reflex—the gastrocnemius and soleus muscles.

CHAPTER

56

Pelvic Examination

Procedures, Observations or Findings, and Significance

Preparatory and General Procedures

Procedure	Rationale
1. In general terms explain what you will be doing during the pelvic examination. If this is a woman's first pelvic examination, show her the equipment you will be using and explain its purpose. Ask the woman if she would like to learn about her own body. If she says yes, provide a mirror so she will be able to see her external genitalia and hymenal ring. Use the mirror and a flashlight to enable her to see her own cervix and vaginal walls during the speculum examination. Throughout the examination, keep the woman informed a step ahead of what you are doing. Forewarn her when you are about to touch her or insert the speculum or when something may be uncomfortable or painful.	**1.** An informed woman is more relaxed and cooperative than an uninformed woman. Explanations of what you are doing and the equipment you are using are in keeping with the philosophy of a woman's right to know what you are doing to her body.
2. Be sure the woman's bladder is empty before starting the examination.	**2.** Bimanual examination is extremely uncomfortable for a woman if her bladder is full. A full bladder also makes it difficult for you to palpate the pelvic organs.
3. Position the woman in the lithotomy position on an examining table. Be sure that her buttocks are slightly beyond the edge of the table. Help her to know how far to move down the table by telling her to move until she touches your hand (which is just beyond the edge of the table; see Figure 56-1). Her arms should be down beside her or across her abdomen. Place a pillow under her head. If there is no pillow but there is a thin mat on the table, roll up the mat behind her as she moves down to the end of the table and use the rolled mat as a pillow.	**3.** If the woman is not properly positioned, the edge of the table will be in the way of the handle of the speculum and you will have difficulty positioning the speculum. Many women automatically put their hands behind their heads when in the lithotomy position. Raising the arms stretches and tightens the abdominal muscles, making the bimanual examination more difficult and uncomfortable. You can avoid this by having the woman put her arms down (explain why) and putting something else under her head to increase comfort and relaxation.

FIGURE 56-1 Positioning the woman for a pelvic examination.

Procedure	Rationale
4. Drape the woman so she feels the minimal possible exposure and so your view of her face is not blocked when you are either sitting or standing during the examination.	**4.** Protecting the woman's modesty and privacy facilitates relaxation. You must be able to see her face at all times in order to maintain personal contact and notice any facial expressions indicative of discomfort, pain, embarrassment, or fear so you can help her. In other words, you must maintain active awareness that there is a person involved above the waist.
5. Wash your hands and put on gloves.	**5.** The old "one glove or two gloves" debate ended with the advent of HIV/AIDS. Now your decision is whether to wear one *pair* or two *pairs* of gloves. (See Chapter 45, Universal Precautions.)
6. Ask the woman to separate or spread her legs. Do not try to spread the woman's legs forcibly or even gently.	**6.** Pelvic examination is an intrusive procedure and should proceed only as the woman is ready for it. Separating her legs signals her readiness and cooperation.

7. Throughout the examination help the woman to be as relaxed as possible. It is *not* helpful to just tell her to relax; you need to tell her *how* to relax:

a. If she is familiar with breathing and relaxation techniques used in labor, have her utilize these. If not, have her concentrate on slow abdominal or chest breathing—whichever she can do most easily.

b. Ask her to think of herself as a rag doll or wet washcloth or anything else you can think of that connotes the idea of limpness.

It is vital that the woman's legs remain well separated as she relaxes and that you emphasize this point and its rationale to the woman.

7. Relaxation is essential to a pelvic examination. It ensures that the woman experiences the least possible discomfort; facilitates your ability to adequately feel and evaluate the pelvic organs; and shortens the length of time of the examination by virtue of your not having difficulty in the conduct of the examination.

It is next to impossible to conduct an adequate and accurately informative pelvic examination if the woman clamps her legs around your examining hand. You simply cannot maneuver your hand in this situation to feel and evaluate the pelvic organs and structures.

8. Your approach to the woman should be super gentle, both verbally and physically. Your touch and manipulation of the speculum should be firm but gentle (i.e., firm enough not to tickle but not so firm as to traumatize).

Remember that the woman's whole attitude toward necessary future pelvic examinations, her concept of her sexuality, her sex life, and her willingness to cooperate with any therapeutic regimen you suggest may be positively or negatively influenced by the way you conduct her pelvic examination.

8. There is no excuse for a rough pelvic examination. There is considerable difference between gently doing something that may be uncomfortable or may even hurt, such as clinical pelvimetry, and being rough. The woman knows the difference.

Pelvic examination is an intrusive procedure and women are acutely alert to your attitude of respect—or lack of respect—for their bodies. They can tolerate and cope with any necessary discomfort or pain if they are forewarned and know why it is necessary, and if procedures are done in a supportive, caring manner that expresses regret for their necessity and facilitates the woman's efforts to relax throughout.

9. If the woman gets uptight, tense, or upset during your examination, immediately stop whatever you are doing. This means holding your fingers, hand, or the speculum still—do not remove your hand or the speculum. Ascertain what the problem is. If the woman complains of pain, help her differentiate between feeling discomfort as a result of pressure, feeling actual pain, and not feeling any discomfort or pain but being fearful and tense in anticipation of feeling pain. Tell the woman that you will not proceed further until she is again in control, relaxed, and ready. Help the woman with relaxation techniques and anything else she identifies that will help her cope with this procedure.

9. The rationale is the same as for 6, 7, and 8 above.

Inspection of the External Genitalia

Procedure	Observations	Significance
1. Seat yourself on a stool at the end of the examining table so you are at eye level with the woman's perineum. Your light should already be adjusted for good visualization of the woman's perineum and your gloves should be on. Tell the woman that you are going to examine her external genitalia ("privates," "the outside down here") and that she will feel your fingers touching this area.	**1. a.** Observe the mons pubis (mons veneris) for	**1. a.**
	(1) pattern of hair growth	**(1)** secondary sex characteristic
	(2) pediculosis (lice)	**(2)** if lice are present, treatment will vary, depending on whether the woman is pregnant
	b. Inspect the labia majora and perineum for	**b.**
	(1) normal size and shape	**(1)** may vary from individual to individual
	(2) localized labial swelling, edema, or small cysts	**(2)** localized labial swelling may be caused by a Bartholin's abscess or cyst; labial edema may be due to an allergic reaction; small cysts may be sebaceous cysts
	(3) inflammation, dermatitis, irritation	**(3)** may be indicative of a vaginal infection; ask the woman if she has been itching or scratching in the area
	(4) discoloration and tenderness	**(4)** traumatic bruising
	(5) varicosities	**(5)** useful information in planning birth techniques for a pregnant woman
	(6) lesions, vesicles, ulcerations, crusting	**(6)** may be syphilitic chancre, herpes
	(7) condylomata (lata or acuminata, wartlike growths)	**(7)** condylomata lata are usually syphilitic; condylomata acuminata are caused by human papillomavirus, the most common sexually transmitted virus, and exaggerated by increased vaginal secretions during pregnancy (see Chapter 15)
	(8) old episiotomy scar or scars of repaired or unrepaired perineal lacerations	**(8)** useful information in planning birth techniques for a pregnant woman

Procedure	Observations	Significance
2. Separate the labia majora and inspect the labia minora. Then separate the labia minora and inspect the clitoris, the inside of the labia minora, vestibule, urethral orifice, and vaginal introitus.	**2. a.** Inspect the labia minora and vestibule for	**2. a.**
	(1) normal size and shape	**(1)** there is considerable variation in what is normal
	(2) inflammation, dermatitis, irritation, or caking of discharge in the fold between the labia majora and the labia minora	**(2)** may indicate a vaginal infection or poor hygiene
	(3) discoloration and tenderness	**(3)** traumatic bruising
	(4) fistulas	**(4)** physician consultation required
	(5) fissures	**(5)** physician consultation required
	(6) herpetic vesicles	**(6)** culture
	(7) chancre	**(7)** scrape lesion for darkfield examination for syphilis; serologic tests
	b. Inspect the clitoris for	**b.**
	(1) adhesions with the labia minora	**(1)** ascertain if problematic or not
	(2) enlargement	**(2)** possible masculinizing condition
	c. Inspect the urethral orifice for	**c.**
	(1) growths—polyps, caruncles	**(1)** physician consultation required
	(2) irritation, dilatation	**(2)** may be indicative of repeated urinary tract infections or insertion of foreign objects; question the woman accordingly
	(3) fistulas	**(3)** physician consultation required
	d. Inspect the vaginal introitus for	**d.**
	(1) the hymen or its remnants (myrtiform caruncles)	**(1)** an intact hymen is normal unless tight and rigid or imperforate; myrtiform caruncles are also normal
	(2) vaginal discharge	**(2)** may be indicative of a vaginal infection
	(3) discoloration and tenderness	**(3)** traumatic bruising
	(4) scars of old lacerations	**(4)** useful information in planning birth techniques for pregnant women

Procedure	Observations	Significance
	(5) abnormal growths	**(5)** physician consultation required
	(6) fistulas	**(6)** physician consultation required
	(7) fissures	**(7)** physician consultation required
	(8) uterine prolapse	**(8)** physician consultation required
	(9) note if the introitus is nulliparous, parous, or gaping	**(9)** helpful in determining what size speculum to use

Examination of the Urethra and Skene's and Bartholin's Glands

Some midwives examine the urethra and Skene's and Bartholin's glands prior to the speculum examination. Other midwives examine these after the speculum examination as the first part of their bimanual examination.

The advantage of examining the urethra and Skene's and Bartholin's glands before the speculum examination is fourfold:

1. The examination can be incorporated into the total pelvic examination during the inspection of the external genitalia.
2. It allows for immediate palpation of a suspicious labial swelling, cyst, or growth.
3. The pressure of the speculum may cause discharge from the urethra or Skene's glands, which may go unnoticed during the procedure and yield a false negative result when they are stripped afterwards.
4. It allows the midwife to also identify the position of the cervix. This information is useful to have prior to insertion of the speculum.

The disadvantage of examining these structures at this time is that you cannot use lubrication (other than water) on your examining fingers as lubricating material may interfere with the Pap smear obtained during the speculum examination.

Procedure	Findings	Significance
1. Separate the labia with the thumb and index finger of one hand. Tell the woman that you are going to insert one finger into her vagina (birth canal) and that she will feel it pressing forward. With your palm up, gently insert the index finger of your examining hand into the vagina as far as the second joint. Exerting upward pressure, strip (or milk) the Skene's gland on one side of the urethra by moving your finger alongside the urethra from inside to outside. Repeat for the Skene's gland on the other side. Then strip the urethra by again inserting your index finger and exerting upward pressure directly on the urethra itself as you move your finger from inside to outside.	**1.** Identify the urethral meatus. While stripping the Skene's glands, look for discharge either from the vestibule on either side of the urethra or from the urethra itself. Sometimes the ducts of the Skene's glands open on the posterior wall of the urethra just inside the meatus. If you observe a discharge while stripping the Skene's glands or the urethra, note its color, consistency, and odor.	**1.** Discharge from the Skene's glands or urethra is indicative of an inflammation of one or all these structures (e.g., urethritis). Usually such an inflammation is due to gonorrhea. You should obtain a specimen of any discharge from the Skene's glands and urethra for immediate diagnostic testing.

Procedure	Findings	Significance
2. Tell the woman that she will now feel you pressing around the entrance to her vagina (birth canal). With your hand in the position you used in examining the Skene's glands and urethra, sweep your finger laterally, palpating between it on the inside of the vagina and your thumb on the outside of the labia majora. Palpate the entire area, paying particular attention to the posterolateral portion of the labia majora, behind which the Bartholin's glands are located. Continue to sweep your finger and thumb across the perineum and palpate the same area on the other side. Your hand will have turned 270 degrees by the time you are finished.	**2.** Palpate for **a.** tenderness **b.** swelling **c.** masses **d.** heat **e.** fluctuation Observe for any discharge from the opening of the Bartholin's gland duct just outside the posterolateral margin of the vaginal introitus on the side of the vestibule. Palpation and observation must be bilateral because each gland is separate. If there is a discharge from either Bartholin's gland, note its color, consistency, and odor; also note any erythema of the duct opening.	**2.** Painful swelling, hot to touch and fluctuant, is indicative of an abscess of the Bartholin's gland. Such an abscess usually is gonococcal in origin and contains pus. Obtain a specimen of any discharge expressed from a Bartholin's gland duct for diagnostic testing. A nontender mass of variable size is indicative of a Bartholin's cyst, which is the result of chronic inflammation of the gland. The usual, although not only, cause of bartholinitis is gonorrhea since the Bartholin's glands are a site that harbors the gonococci.

The Speculum Examination

Description of a Speculum A speculum consists of two blades and a handle. The posterior blade of the speculum is fixed. The anterior blade is hinged and movable and is controlled by a thumb-piece attached to it. A thumbscrew on the thumb-piece, when tightened, holds the anterior blade in the position desired for intravaginal visualization. When the speculum is closed, the posterior and anterior blades come together at the distal end. From this point the anterior blade slants slightly upward away from the posterior blade and curves sharply upward at the proximal end to a distance of approximately 1 in. from the posterior blade.

When the speculum is opened with the thumb-piece, a tubelike space is created between the blades. Through this tubelike space, intravaginal and cervical observations are made and instruments are passed for any intravaginal or cervical procedures. The blades may be further separated by manipulating the thumbscrew on the handle of the speculum. Ordinarily, and always during insertion, the thumbscrew is adjusted so that the two blades are in the closest possible approximation. Once the speculum is in place and opened by use of the thumb-piece and its thumbscrew, the entire anterior blade may be elevated from the posterior blade, if need be, by sliding the anterior blade away from the posterior blade and tightening it in this position with the thumbscrew on the handle.

It is important for the inexperienced examiner to practice manipulating the speculum and become intimately familiar with how it is put together and how it operates before attempting insertion into a woman. Such practice will eliminate the possibility of hurting the woman by mishandling the speculum during examination. Also, it is not uncommon for a speculum to come apart or become malaligned during storage, and the examiner should know how to get it ready for use. The plastic disposable specula work a little differently than the metal speculum described above and require more practice to operate smoothly and avoid pinching the woman. Knowing how to handle a metal speculum does not make you facile with a plastic speculum, and vice versa. The key to smooth handling of both specula is practice.

Types of Specula There are three types of metal specula (see Figure 56-2). The variations among the three enable the midwife to select a speculum that is appropriate for the individual woman.

The smallest speculum is the *virginal speculum*. It has short, narrow, flat blades. It is used in young girls and in women who have had little or no coitus.

The *Graves speculum* is both the standard and largest speculum as it comes in these two sizes. The standard size is most commonly used, since it is most

FIGURE 56-2 Types of specula. From left to right: metal Graves (large size), virginal, Pederson, Graves (standard size), and plastic (regular size).

appropriate for women who are sexually active or who have had a baby. The large size is used with women who have collapsing vaginal walls, generally grand multiparas or very obese women. The Graves speculum varies in length from $3\,^1/_2$ to 5 in. (8.75 to 12.75 cm) and in width from $^3/_4$ to $1\,^1/_4$ in. (about 2 to 3.25 cm). The blades are curved, forming a concave space between the two blades. The posterior blade is approximately $^1/_4$ in. longer than the anterior blade to conform with the longer posterior vaginal wall and aid in visualization of the cervix.

The *Pederson speculum* is as long as the Graves speculum but has more narrow blades. Also, its blades are flat rather than curved. It is used in women who may be sexually active but tight and who have never had a baby. It is also useful for a woman whose vagina may be contracted by scars, radiation, or senescence.

Plastic specula come in regular or large sizes that are approximately the same as the metal Graves standard and large sizes.

Procedure for Speculum Examination

Procedure	Rationale
1. The woman has been properly positioned, draped, and informed as to the procedure, has emptied her bladder, and has her legs apart for the examination. You have already positioned your light source, washed your hands, and put on your glove(s).	**1.** See Steps 1 through 6 under "Preparatory and General Procedures" for the pelvic examination.
2. Select the appropriate speculum for the woman on the basis of her sexual and obstetric history and your observations during inspection.	**2.** The appropriate speculum is one that will cause the woman the least discomfort while providing adequate intravaginal and cervical visualization.
3. Lubricate the speculum with water only if you plan to obtain cytologic or other studies. If no studies are planned you may lubricate the speculum with any lubricating jelly used for a vaginal examination. However, some studies that you hadn't originally planned on may be indicated after you have visualized the vaginal walls and the cervix. For this reason most clinicians never lubricate the speculum with anything but water.	**3.** Lubricating jellies or creams may interfere with cytologic or other studies, rendering them invalid.

Procedure	Rationale
4. Warm the speculum in one of four ways: **a.** Use *warm* water to lubricate it. **b.** Hold it in your hands until it is warm. **c.** Hold it under the light source until it is warm. **d.** Some examination tables are equipped with a warming drawer. If a warming drawer is not available, a heating pad set on low may be placed in the bottom of the drawer and speculums in a towel may be set on top of it.	**4.** For comfort. This has a great effect on what the woman thinks of you and about the examination. Always be aware of the temperature of the speculum, as too hot is just as bad, or worse, than too cold.
5. Touch the woman with the warmed speculum on the inner aspect of her thigh close to the external genitalia. Ask her if the temperature of the speculum is comfortable.	**5.** This reassures you and the woman that you will neither burn nor freeze her when you insert the speculum. This also involves the woman in the procedure.
6. Help the woman to relax and tell her she will feel you touching her on the outside and then will feel the speculum going inside her vagina (birth canal).	**6.** See Steps 1, 7, and 8 under "Preparatory and General Procedures" for the pelvic examination.
7. Separate the woman's labia with a gloved hand (see Figure 56-3).	**7.** Done to expose the vaginal orifice.
8. Hold the speculum in your other gloved hand with your index finger over the top of the proximal end of the anterior blade and your other fingers around the handle.	**8.** This ensures that the blades will stay closed.
9. Insert the speculum into the vagina at an oblique angle past the hymenal ring (see Figure 56-3). *Note:* An alternative method of inserting the speculum is to insert one or two fingers of one hand just inside the vagina (to the first joint on the fingers). Then gently but firmly depress the perineal body with these fingers while the other hand guides the entry of the speculum over and past your fingers.	**9.** The oblique angle avoids pressure on and trauma to the urethra and periurethral structures.

FIGURE 56-3 Inserting a speculum.

Procedure	Rationale
10. Rotate the speculum to a horizontal angle and while pressing firmly downward, insert the speculum the length of the vaginal canal, as shown in part (a) of Figure 56-4. Avoid catching pubic hair or pinching or pushing in the labia by virtue of not having spread the labia enough during this insertion procedure.	**10.** Downward pressure again avoids trauma to the urethra. The anatomical angle of the vagina when the woman is in the lithotomy position is approximately 45 degrees downward toward the lumbar area. If the speculum is inserted straight in, the anterior vaginal wall and urethra are traumatized and the woman feels pain. (See Figure 56-4[a].)
11. Maintaining downward pressure, open the speculum by pressing on the thumb-piece. Downward pressure can be maintained either by exerting downward and outward pressure on the lower end of the speculum handle or by putting your thumb or a finger on the proximal end of the posterior blade and exerting downward pressure. Adjust your light source as needed.	**11. and 12.** These steps permit intravaginal visualization. If the speculum was directed downward firmly during insertion and this position was maintained, you are assured of finding the cervix during your sweep upward, regardless of whether the cervix is located in a posterior, midline, or anterior position. This method prevents you from having to hunt for the cervix, which would entail much maneuvering of the speculum up and down and in and out, to the discomfort of the woman and the distress of both the woman and you.
12. Sweep the open speculum slowly upward from its posterior (downward) position until the cervix comes into view, as shown in part (b) of Figure 56-4.	
13. Manipulate the speculum a little further into the vagina so the cervix is well exposed between the anterior and posterior blades, as shown in part (c) of Figure 56-4.	**13.** Adequate visualization is needed for observation and exposure of the cervical os for obtaining the Papanicolaou smear and specimens for gonoccocal and chlamydia diagnostic testing.

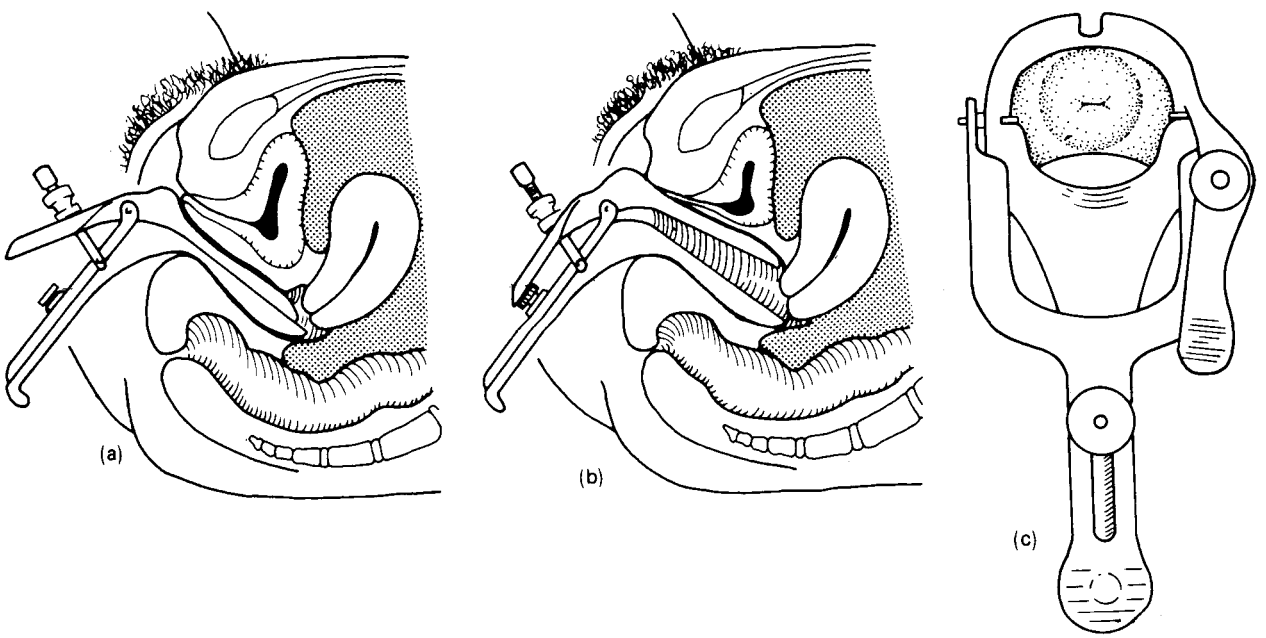

FIGURE 56-4 Placement of the speculum. (a) Speculum inserted the length of the vaginal canal; note downward angle that avoids anterior structures. (b) Open speculum positioned for visualization of the cervix. (c) View of the cervix when speculum is properly positioned.

Procedure	Rationale
14. Tighten the thumbscrew on the thumb-piece. If further exposure is needed, elevate the anterior blade by manipulating the slide and thumbscrew located on the speculum handle. Remember the comfort of the woman and do not open the speculum any wider than is absolutely necessary.	**14.** Tightening the thumbscrew frees your hand for handling other equipment. Watch that the woman does not involuntarily push the speculum back out. This is possible even with the speculum in an open position. If it looks like this may happen keep one hand on the speculum at all times to sense and prevent this from occurring.
15. If the cervix is covered with a copious amount of discharge, put a gauze 2×2 or 4×4 on a sponge stick and blot or gently wipe off the cervix.	**15.** Too much discharge will prevent you from obtaining a Pap smear representative of the tissue being scraped. Do not use a cotton ball because the cotton fibers will interfere with the wet smear microscopic examination you will want to make of the discharge.
16. Obtain specimens for Papanicolaou smears, gonococcal and chlamydia testing, and for wet smear slides of vaginal discharge, as well any other indicated tests or treatments. The procedures for obtaining these specimens are discussed in Chapters 57, 58, and 59.	
17. Before removing the speculum, gently rotate it 90 degrees while again exerting downward pressure on it. This will most likely be uncomfortable for the woman, so forewarn her of this manipulation before doing it.	**17.** This allows you to visualize the anterior and posterior walls of the vagina as well as the lateral vaginal walls.
18. Return the speculum to its horizontal position. Release the thumbscrew on the thumb-piece (and on the speculum handle, if used). While holding the blades apart with pressure on the thumb-piece, begin withdrawing the speculum until the cervix is released from between the blades of the speculum.	**18.** Avoid pinching or pulling on the cervix during removal of the speculum.
19. Release your pressure on the thumb-piece, thereby closing the blades. Avoid pinching the vaginal mucosa or catching pubic hair when the blades close. Again avoid pressure on or trauma to the urethra and periurethral structures by exerting downward pressure, rotating the speculum to the oblique angle, and making sure the blades are closed by hooking your index finger over the anterior blade as the speculum is withdrawn. Some midwives ask the woman to bear down to ease the speculum out and only guide its removal.	**19.** For the woman's comfort
20. Note the odor of any vaginal discharge pooled in the posterior blade and obtain a specimen for making a wet smear if indicated and a specimen was not already obtained.	
21. Deposit the speculum in the proper container.	**21.** For protection of yourself and others
22. Wipe any discharge from the woman's genitalia and perineum if you do not plan to do a bimanual examination.	**22.** For the woman's comfort

Observations

1. Observe cervix for
   - **a.** color
   - **b.** growth, nodules, masses
   - **c.** polyps
   - **d.** lesions, erosions, ulcerations
   - **e.** position
   - **f.** size (hypertrophy, atrophy) and shape
   - **g.** edema
   - **h.** nabothian cysts
   - **i.** inflammation (cervicitis)
   - **j.** discharge—color, amount, character, consistency, odor
   - **k.** friability (bleeding)
   - **l.** eversion
   - **m.** ectopy
   - **n.** size and shape of os and any lacerations
   - **o.** patulousness and dilatation

Significance

1. *Color* is significant in aiding in clinical diagnosis of pregnancy. A bluish color is due to increased vascularity to the cervix and is known as Chadwick's sign, a presumptive sign of pregnancy. A nonpregnant cervix is pink.

   Growths, *nodules*, *masses*, *polyps*, *lesions*, *erosions*, *ulcerations*, and *infected nabothian cysts* are all abnormal findings requiring physician consultation.

   It is useful to note the *position of the cervix* based on where you locate it with the speculum. This information serves to identify or confirm the position of the uterus during the bimanual examination. A cervix located anteriorly is indicative of a retroverted uterus; a posterior cervix indicates an anteverted uterus; a cervix in the horizontal midline indicates a uterus in midposition. Deviations of the cervix to the right or left of the vertical midline indicate the possibility of pelvic masses or uterine adhesions; these need to be carefully ruled out during the bimanual examination.

   Variations in the *size* and *shape* of the cervix give different information. The normal cervix in a woman of childbearing age is 2 to 3 cm (about $^{3}/_{4}$ to $1^{1}/_{4}$ in.) in diameter, with the exception of the larger patulous cervix of the grand multipara. A *small cervix* is seen in the postmenopausal woman and is concomitant with the endometrial and myometrial atrophy of the rest of the uterus. Normal cervical size should match the size of the nonpregnant uterus. A *hypertrophied*, *large*, or *edematous cervix* is generally an indication of cervical infection and may be observed along with the other signs of *cervicitis*. An *irregularly shaped cervix* may indicate the presence of an *infected nabothian cyst* swollen with fluid.

   Nabothian cysts may be observed as white or yellow pinpoints (1–3 mm in diameter) on the cervix. *Infected nabothian cysts* distort the shape of a portion of the cervix since they are swollen with fluid. Nabothian cysts are retention cysts arising from the occlusion of the ducts of endocervical glands extending near the surface of the vaginal portion of the cervix. They most frequently occur in the presence of chronic cervicitis.

   Cervicitis is an inflammation of the cervix usually caused by an infection (e.g., *Trichomonas vaginalis*, chlamydia, gonorrhea) but which may also be caused by irritation from injury, obstetric lacerations, mechanical devices, foreign objects, or allergic reactions.

   Note carefully whether any *discharge* is merely a continuation of a vaginal infection de-

Observations	Significance
	posited on the cervix (e.g., the plaques of a *Candida* [monilial] infection) or originates from the endocervix itself (for example, the pus of gonorrhea exuding from the external cervical os).
	Friability of the cervix, as evidenced by its bleeding easily after obtaining the Pap smear or sponging for purposes of observation, frequently accompanies cervicitis.
	Eversion of the cervix, caused by too much pressure in the vaginal fornices by the tips of the blades of the speculum, exposes the rougher and redder looking columnar epithelium of the cervical canal. Usually eversion is circumoral, showing the line of demarcation between the continuation of the stratified squamous epithelium of the vagina, which covers the vaginal portion of the cervix and extends a short distance into the cervical canal, and the columnar epithelium. Eversion is differentiated from erosions or ectopy by simply withdrawing the speculum slightly and watching the columnar epithelium disappear from view as the cervical canal returns to its correct, noneverted position.
	Ectopy, from the Greek word meaning "out of place," occurs when the columnar epithelium of the cervical canal has grown downward and outward and competes for territorial space with the squamous epithelium on the vaginal surface of the cervix. Again, the rougher, redder-looking columnar epithelium is visible. Unlike the columnar epithelium visible in eversion, however, it may be quite irregular in its line of demarcation with the squamous epithelium. Ectopy is sometimes observed in the multiparous cervix, especially if the cervix has been lacerated. Usually ectopy is also present in women who use oral contraceptives.
	Size and shape of the os largely depend on the woman's childbearing experience. A nulligravid os is small and round or oval; the typical parous os is a horizontal slit. Trauma incurred during induced abortion results in a change in the shape of the external os. Trauma incurred during difficult removal of an intrauterine contraceptive may change the shape of a nulligravid os to a slit. *Cervical lacerations* resulting from trauma during childbirth are clearly observable. Severe cervical lacerations may result in subsequent difficulty in carrying a pregnancy to term due to an incompetent cervix (see Chapter 24). Observation of the shape of the os is important in confirming the woman's obstetric history. Infrequently, a woman will attempt to conceal a previous pregnancy. In so doing she unknowingly also conceals information vital to the management

Observations	Significance
	of another pregnancy. If you observe that a woman's os does not match her obstetric history or family planning history, you should ask her for an explanation. The nulligravid cervix is closed, whereas the multiparous os is *patulous*, the degree depending on the woman's parity. The higher the parity, the more patulous the os which may be permanently open 2 to 3 cm at the external os. *Dilatation* of the os is also observable upon speculum examination; the fetal membranes may be visible when examining a pregnant woman, if they have not ruptured. The amount of dilatation is determined by manual vaginal examination.
2. Observe vagina for **a.** color **b.** inflammation/vaginitis **c.** discharge—color, odor, character, consistency, amount **d.** plaques **e.** bleeding/friability **f.** lesions and ulcerations **g.** growths or masses **h.** cysts **i.** fistulas **j.** vaginal wall muscle tone	**2.** The *color* of the vagina has the same significance as the color of the cervix. The nonpregnant vagina is pink; the vagina of pregnancy is bluish. Again, this color change in pregnancy is known as Chadwick's sign. *Growths*, *masses*, *lesions*, *ulcerations*, *cysts*, and *fistulas* are all abnormal findings requiring physician consultation. *Inflammation* and *discharge* go hand in hand as signs of *vaginitis*. Vaginitis caused by *Trichomonas vaginalis* additionally may cause red petechiae. Vaginitis due to candidiasis (monilial infection) also exhibits whitish or grayish patches, or *plaques*, which adhere to the vaginal wall and may *bleed* when scraped off. Severe vaginitis causes *friability* of the vaginal mucosa. *Blood* in the vagina must always be investigated for its source. If bleeding is not obviously caused by menstruation, a friable cervix or vagina, or trauma in these areas, physician consultation is required.

The Bimanual Examination

When clinical pelvimetry is indicated, midwives include it while doing the bimanual examination. The procedure and findings for clinical pelvimetry are described in Chapter 61. Whether or not clinical pelvimetry is performed during the bimanual examination, it is important that the midwife develop a procedure for doing the bimanual examination that (1) is the same each time, as a routine aids in not forgetting any part of it and (2) moves smoothly *once* from outside to inside and back out again, which is most comfortable for the woman (as opposed to going back and forth repeatedly). (If clinical pelvimetry is included it should be incorporated into the routine established for the combined skills.)

The woman is already properly positioned, draped, and informed as to the procedure and has her bladder empty and her legs apart for the examination. You have already positioned your light source, washed your hands, and put on your gloves. If you have done a speculum examination, it is not necessary to rewash your hands or change your gloves.

Be sure that the woman's arms are down by her sides or across her abdomen to aid relaxation of her abdominal muscles. Remember to use a firm but gentle touch and to be alert throughout the examination to any indication from the woman of discomfort or tenseness that might cause her to tighten up or move away from you. See Steps 1 through 9 under "Preparatory and General Procedures."

Procedure and Rationale	Observations and Findings	Significance
1. Lubricate the index and middle fingers of your examining hand generously.		
2. Separate the labia and insert your lubricated fingers gently into the vagina at least to their second joint, palm side down, pressing downward as you insert your fingers as you did with the speculum to avoid the anterior urethral and periurethral structures. If the introitus is small, insert only one finger.		
3. Sitting so you can easily visualize the vagina, firmly exert pressure with your fingers posteriorly against the vaginal musculature. Ask the woman to bear down or cough. (It is wise to first ask the woman if she ever urinates accidentally when she laughs, coughs, or sneezes unexpectedly. If so, position yourself accordingly.)	**3. a.** Observe the anterior vaginal wall for evidence of a cystocele or urethrocele. A urethrocele will evidence itself as the distal (vulvar) end of the anterior vaginal wall bulging downward into the vagina and outward toward the introitus. Observe for involuntary loss of urine (stress incontinence) while the woman is bearing down or coughing. A cystocele is evidenced by bulging of the upper (cervical) end of the anterior vaginal wall.	**3. a.** A first degree cystocele is evidenced by bulging of the anterior vaginal wall. In second degree cystocele the bulging reaches the vaginal orifice or introitus. A third degree cystocele is present when the bulging extends beyond the introitus. Nearly every woman who has borne a child has a first degree cystocele. It is so common that if it is not accompanied by stress incontinence it is considered a normal finding. A first degree cystocele only is significant when selecting the type of diaphragm to prescribe for a woman if she desires this method of family planning. A second degree cystocele without stress incontinence and not causing any sexual difficulties is considered asymptomatic and nothing is done except to note it. A symptomatic second degree cystocele, a third degree cystocele, or a urethrocele requires physician consultation/referral for evaluation and possible surgical repair.
	b. Observe for descensus of the uterus (uterine prolapse).	**b.** Frequently, a cystocele accompanies uterine prolapse. A first degree uterine prolapse is any minor degree of descent with the cervix remaining inside the vagina. In second degree uterine

Procedure and Rationale	Observations and Findings	Significance
		prolapse the cervix protrudes through the vaginal introitus. A third degree uterine prolapse comprises prolapse of the entire uterus outside the vulva. A second or third degree uterine prolapse or symptomatic first degree uterine prolapse requires physician consultation.
4. Continuing to press posteriorly with your fingers, now spread your fingers and again ask the woman to bear down.	**4.** Observe the posterior vaginal wall for rectocele or enterocele. A rectocele evidences itself at the lower (vulvar) end of the posterior vaginal wall by bulging upward into the vagina and outward toward the introitus. If the rectocele is severe (second or third degree) ask the woman if she has difficulty in bowel elimination, necessitating holding back the rectocele with her fingers. An enterocele is evidenced by prolapse of the upper (cervical) end of the posterior vaginal wall.	**4.** A severe rectocele requires physician consultation/referral. Rectoceles are graded in the same degrees as cystoceles are. An enterocele is almost always associated with herniation of the cul-de-sac of Douglas, which will probably contain loops of bowel. Physician consultation/referral is required.
5. Put your fingers together again and ask the woman to tighten her muscles around your fingers.	**5.** Assess the tone of the perineal muscles. Now is a good time to teach the woman perineal tightening (Kegels) exercise.	**5.** Muscle tone may affect the length of the second stage of labor, sexual satisfaction, urinary continence, and support of the pelvic organs.
6. Sweep the vagina with your fingers as you insert them the full length of the woman's vagina.	**6.** Feel for cysts, nodules, masses, or growths.	**6.** All are abnormal findings requiring physician consultation.

Note: Be careful where your thumb is during the bimanual examination. Some authorities suggest that it be tucked into the palm of your hand with your fourth and fifth fingers. However, this will cut down on the distance you can insert the length of your index finger. The principle to remember is to keep your thumb off the woman's clitoris; pressure on the clitoris is most uncomfortable.

7. Locate the cervix with your fingers and run your fingers around it circumferentially and across its vaginal end.	**7.** Feel for **a.** size (length and width)and shape	**7.** **a.** The *size* of the nonpregnant cervix should correspond with the size of the nonpregnant uterus. The *length* of the cervix is important in assessing effacement during labor. See discussion of the significance of the size and shape of the cervix under "The Speculum Examination," above.

Procedure and Rationale	Observations and Findings	Significance
	b. consistency	**b.** The *consistency* of the cervix is noticeably different when the woman is not pregnant (firm—often its consistency is compared to the tip of a nose) from when she is pregnant (soft—the consistency is more like that of the lips). A ripe cervix, a sign of approaching labor, is softer still—more like pudding.
	c. smoothness	**c.** Normally the cervix is *smooth*. The *roughness* of ectopy or erosions and bumps caused by nabothian cysts can be felt. Since roughness may be an indication of abnormality, be sure to do a speculum examination (if you have not already done one) after completing the bimanual and rectovaginal examination to visualize the cause of the roughness.
	d. position	**d.** The significance of the *position* of the cervix is discussed earlier under "The Speculum Examination." The position of the cervix is also important when evaluating the possibility that a woman is in labor.
	e. dilatation of the os	**e.** Dilatation of the os generally is a phenomenon of labor and is discussed in Chapter 26. Painless dilatation of the os without bleeding during the second trimester may indicate an incompetent cervix. The os also dilates with inevitable abortion (see Chapter 24).
8. Grasp the cervix gently between your fingers and move it from side to side.	**8.** Observe the woman for any reaction that might indicate pain or tenderness with movement of the cervix.	**8.** Pain on movement of the cervix or cervical motion tenderness (CMT; also sometimes called chandelier sign) is indicative of a pelvic inflammatory process such as acute PID (pelvic inflammatory disease). It is also a sign of a ruptured tubal pregnancy.

Procedure and Rationale	Observations and Findings	Significance
9. Palpate the uterus in the following manner: **(1)** Place your abdominal hand midway between the umbilicus and the symphysis pubis. Use the flats of the palmar surface of the first joints of your fingers to press downward and forward toward the symphysis pubis and your vaginal fingers. **(2)** With your palm upward place your two vaginal examining fingers on either side of the cervix. Bring them together on top of the cervix as you push downward on the cervix with the back of your fingers and in and upward with the tips of your fingers toward your abdominal hand. It should feel like you are trying to bring your hands together as you push down on the cervix. If the uterus is anterior or anteflexed, it will slip between the fingers of your two hands as they come toward each other. **(3)** If you do not feel the uterus with the maneuver described above, return your fingers to having one finger on each side of the cervix. Place your abdominal hand immediately above the symphysis pubis and press firmly downward. Palm up, bring your vaginal examining fingers together under the cervix, press up against the cervix and follow it inward wherever it leads. If the uterus is retroverted or retroflexed you will feel it with this maneuver. **(4)** If you still are unable to feel the uterus with either of the maneuvers above, then return your fingers to either side of the cervix. Maintaining contact with	**9.** Palpate the uterus for **a.** size, shape, and contour **b.** location	**9.** **a.** The *size* of the nonpregnant uterus in a woman of childbearing age varies according to parity. A multiparous uterus is larger in all dimensions than the nulliparous uterus, being from 1 to 4 cm (about $^1/_2$ to $1\,^1/_2$ in.) longer, 1.5 to 2.5 cm (about $^2/_3$ to 1 in.) wider, and .5 to 1.5 cm (about $^1/_4$ to $^2/_3$ in.) thicker. The normal nulliparous uterus ranges in size from 5.5 to 8 cm (about 2 to 3 in.) long, 3.5 to 4 cm (about $1\,^1/_2$ in.) wide, and 2 to 2.5 cm (about 1 in.) thick. The uterus decreases in size with the menopause, during which there is atrophy of the endometrium and the myometrium. The dimensions of the uterus give it its *shape*, which is frequently compared with a somewhat flattened pear. A uterus larger than expected in a woman of childbearing age is indicative of pregnancy or benign or malignant tumors. As the pregnant uterus enlarges, its shape changes, becoming first globular and then an ovoid of increasingly larger size. The normally smooth and symmetrical *contour* of the uterus is disrupted in the presence of a growth or a mass. Uterine myomata are felt as irregular masses on the surface of the uterus. Piskacek's sign of early pregnancy is felt as an irregularity in one of the cornual areas, causing uterine asymmetry. **b.** The *location* of the uterus is normally in the midline. Deviation of the entire corpus of the uterus to the right or left is indicative of possible adhesions or pelvic masses.

Procedure and Rationale	Observations and Findings	Significance
the cervix, press straight inward and feel as far as you can. Then slide your fingers around the uterus until one finger is on top of the cervix and one finger is underneath the cervix. Continue your inward pressure while moving your fingers in order to feel as much of the uterus as possible when it is in the middle (military) position.	**c.** position (see Figure 56-5) **(1)** military (midposition/midline) **(2)** anteverted **(3)** anteflexed **(4)** retroverted **(5)** retroflexed The prefixes *ante-* and *retro-* mean *forward* and *backward*, respectively. The suffix *-verted* indicates that the entire uterus *tilts*, either forward or backward. The suffix *-flexed* means that the uterus *bends at the isthmus* (at the level of the internal os) forward or backward. In	**c.** Knowing the *position* of the uterus is imperative prior to inserting an intrauterine contraceptive device or performing any other intrauterine procedure. The position of the uterus may be a cause of dyspareunia unless its position is compensated for by appropriate positions during sexual intercourse. The uterus is usually in a position of slight anteflexion, and the variations of anteversion, retroversion, and retroflexion are all considered normal. Slight retroversion of the

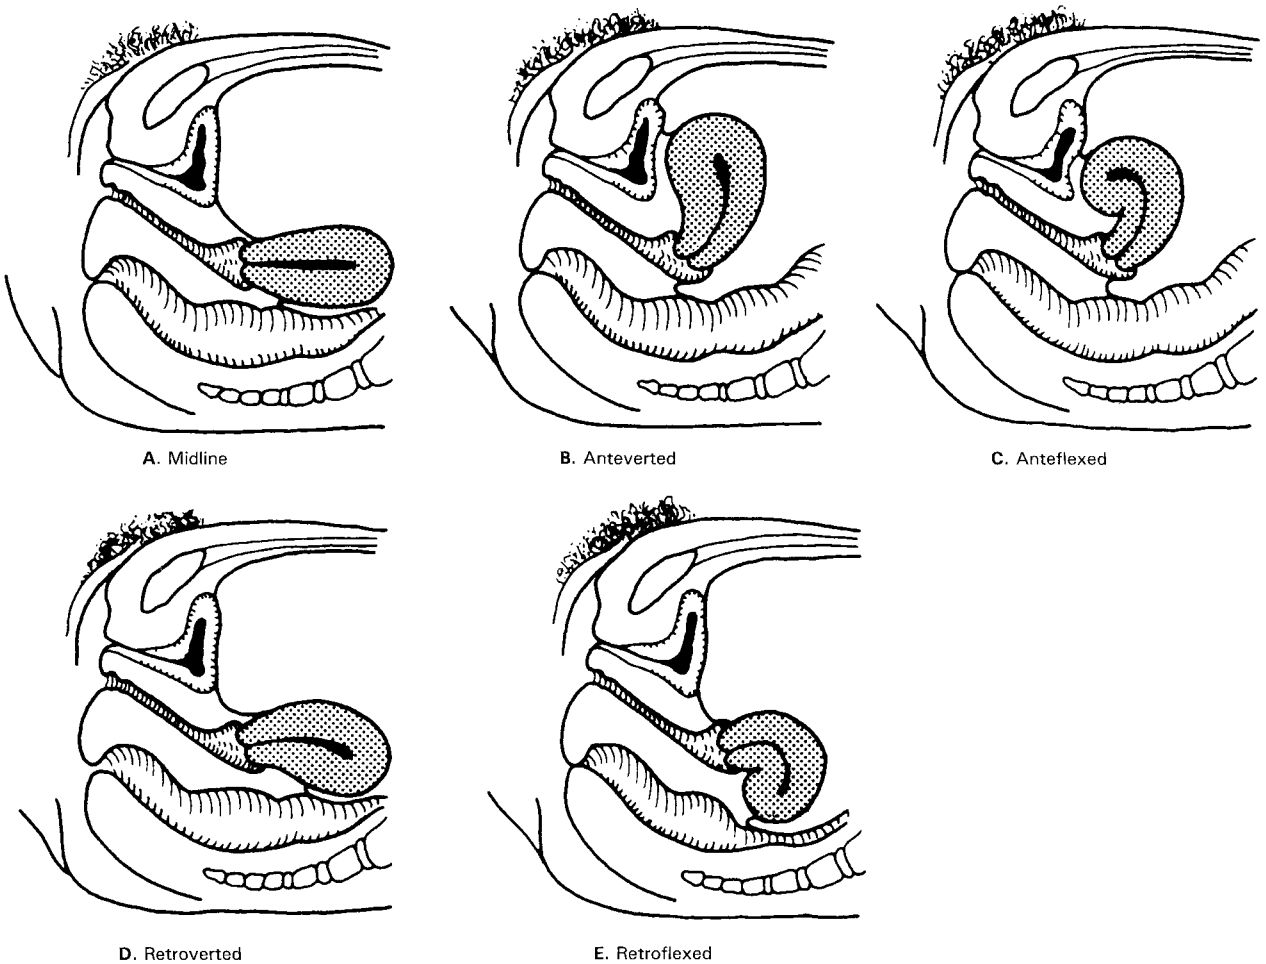

FIGURE 56-5 Uterine positions.

Procedure and Rationale	Observations and Findings	Significance
	the *military position* the uterus is perfectly straight in midposition, neither tilting nor bending forward or backward.	uterus and the so-called military position place the fundus out of reach for palpation by many examiners.
	d. consistency	**d.** The normal nonpregnant uterus is firm in *consistency*. It is somewhat softer during early pregnancy and postpartal involution when it is a pelvic organ. Hegar's sign of early pregnancy is a marked softening of the isthmus of the uterus.
	e. mobility	**e.** The normal uterus is *mobile* above the cervix in the anteroposterior plane. It is held in place laterally by the broad, uterosacral, and cardinal ligaments. Lack of anteroposterior mobility indicates adhesions, possibly resulting from infection or previous surgery.
	f. tenderness or pain	**f.** *Tenderness* or *pain* on movement of the uterus is indicative of a pelvic inflammatory process in the nonpregnant woman and of endometritis or other puerperal infections in the postpartum woman.
10. Examine the adnexal areas in the following way: **(1)** Place your abdominal hand in the area between the iliac crest of the innominate bone (hip) and the abdominal midline midway between the level of the umbilicus and the symphysis pubis. Use the flats of the palmar surface of the first joints of your fingers to press deeply downward and obliquely toward the symphysis pubis and your vaginal fingers. **(2)** With your palm facing upward, place both of your vaginal examining fingers in the lateral vaginal fornix corresponding to the side (right or left) that your abdominal hand is	**10.** Palpate the adnexal areas for **a.** size, shape, and any tenderness or pain in the adnexae	**10.** **a.** The *size* of the normal ovary during the childbearing years ranges from 2.5 to 5 cm (1 to 2 in.) long, 1.5 to 3 cm (about $^{2}/_{3}$ to $1\,^{1}/_{4}$ in.) wide, and .5 to 1.5 cm ($^{1}/_{4}$ to $^{2}/_{3}$ in.) thick. This gives it the *shape* of a small almond, with which it is often compared. The size of the ovaries diminishes markedly after menopause, frequently reducing to a mere .5 cm (less than $^{1}/_{4}$ in.) in any of the aforementioned diameters. The normal ovary is *tender* when touched, which aids in identifying the ovary when you palpate it. Normal fallopian tubes can rarely be felt because they are so narrow (from 2 to 3 mm at the most narrow portion to 5 to 8 mm at the widest portion).

Procedure and Rationale	Observations and Findings	Significance
positioned to examine. Press your fingers deeply inward and upward toward your abdominal hand as far as possible. **(3)** Palpate the entire area between the uterus and the walls of the hip bone with a sliding, gentle but firm pressing together of your two hands as they synchronously move together from the highest to the lowest level as visualized abdominally. **(4)** Reverse and repeat the manuevers in the three steps above for examination of the other adnexal area. **(5)** It helps to have formed a mental picture of the location of the adnexae in relationship to the position of the uterus before starting this part of the examination. **11.** Withdraw your vaginal examining fingers to just inside the introitus in preparation for the rectovaginal examination if you are doing one. If not, smoothly withdraw your fingers from the woman's vagina. **12.** If this ends your pelvic examination, proceed with Steps 12 through 16 under "The Rectovaginal Examination," which follows.	**b.** consistency, size, shape, and tenderness or pain of any adnexal masses The adnexae are frequently difficult to feel, even for an experienced midwife, depending on the position of the uterus and concomitant location of the adnexae and the amount of adipose tissue. If you are unable to feel anything in the adnexal areas after thorough palpation, you can assume normality in the absence of any clinical signs and symptoms. This portion of the examination is charted as "not felt." Always palpate the adnexal areas in doing a pelvic examination on a nonpregnant woman. The adnexal areas are also palpated during the initial prenatal examination if this takes place during the first trimester. However, as the pregnant uterus becomes an abdominal organ, it is futile to palpate for the adnexae. By virtue of their location and attachment in the broad ligament, the adnexae also enter the abdominal cavity along with the uterine fundus as pregnancy progresses.	**b.** Any *adnexal masses* are abnormal and require physician consultation. Their size, shape, location, consistency, and any areas of pain should be noted. Ovarian cysts and tumors usually are not tender. Generalized pain in the adnexal area may prohibit you from outlining an adnexal mass and is indicative of pelvic inflammatory disease when bilateral. If pain is unilateral, a ruptured tubal pregnancy is a possibility. In either case, such findings require physician consultation.

The Rectovaginal Examination

The rectovaginal examination is an inherent part of the total pelvic examination. The only time it is eliminated is when only a partial pelvic examination is being done for a specific reason (e.g., speculum examination for checking the strings of an intrauterine contraceptive device, vaginal examinations for evaluating labor status, speculum examination for evaluation of treatment of a vaginal infection).

Because it is an uncomfortable examination for many women, it is not uncommon for a woman to ask you to skip it. The answer is no—followed by an appropriate explanation of why not. The request usually stems from the woman's lack of understanding that there is more to the rectovaginal examination than just confirming the findings of the vaginal bimanual examination. Rectovaginal examination enables many examiners to reach almost 1 in. higher into the pelvis, an invaluable aid in evaluating pelvic organs and structures.

Procedure and Rationale	Observations and Findings	Significance
1. The bimanual vaginal examination ended with the withdrawal of your examining fingers to just inside the vaginal introitus. Keep your index finger inside the woman's vagina and remove your middle examining finger completely.		

Note: If you have observed any indication of gonorrhea during the vaginal examination, you will need to remove your examining fingers completely and change your gloves. Some midwives routinely change gloves anyway to avoid the possibility of spreading asymptomatic gonorrhea of the urinary or genital tracts to the rectum. Other midwives wash their gloves before proceeding with the rectal examination. Still others will proceed as outlined in Steps 1 and 2 in this procedure.

2. Generously relubricate your middle examining finger to allow it to slide gently into the rectum.		
3. Tell the woman that the examination may be uncomfortable and that she might feel as though she is having a bowel movement. Assure her that she will not pass stool and help her with breathing techniques to relax. Tightening her sphincter, rectum, and buttocks will make the examination more uncomfortable and will hinder your ability to examine her.		
4. After observing the anus, place your middle examining finger against the anus and ask the woman to bear down and push against your finger. As she does this, slide the tip of your finger into the rectum just past the sphincter.	**4.** Observe the anus for **a.** external hemorrhoids **b.** anorectal fistula **c.** sentinel tag or anal fissure **d.** rectal prolapse **e.** lesions	**4.** *Thrombosed external hemorrhoids*, *anorectal fistula*, *anal fissures*, *lesions*, and *rectal prolapse* are all abnormalities requiring physician consultation/referral.
5. Palpate the area of the anorectal junction and just above it. Ask the woman to tighten and relax her rectal sphincter.	**5.** Palpate for **a.** internal hemorrhoids	**5.** **a.** *Internal hemorrhoids* are difficult to feel because they are soft. History of problems with constipation, straining with bowel movements, and impactions is important. Consultation with a physician is indicated if the problem is severe. Otherwise, the woman should be instructed in measures for preventing constipation. Prescription of a laxative may be indicated.

Procedure and Rationale	Observations and Findings	Significance
	b. sphincter tone	**b.** An extremely tight sphincter may be indicative of spasticity caused by a fissure, lesion, or inflammatory process; may be caused by scarring; or may be due to extreme anxiety about the examination. A lax sphincter, unless attributable to frequent anal intercourse, may indicate neurological disease requiring physician consultation. An absent sphincter may be the result of an unrepaired or improperly repaired third degree perineal laceration most likely occurring during childbirth. A history of fecal incontinence should have alerted you to the possibility of this finding. Physician consultation is required.
6. (1) As you slide both your vaginal and rectal examining fingers as far as they will reach, palpate half of the rectal wall, sweeping your finger back and forth as you methodically cover the distance. (Decide which half you will cover as a routine based on the face of a clock—for example, between 6 and 12 o'clock or between 3 and 9 o'clock. Slightly extend the halfclock you choose so no area is missed in dividing it up, e.g., 5:30 to 12:30.) You will examine the remainder of the rectal wall as you remove your finger. **(2)** Ask the woman to bear down when you have reached as far as you can, as this will bring an additional centimeter or so within your reach.	**6.** Palpate for **a.** polyps/masses	**6.** **a.** Polyps, if felt, may be benign or malignant. *Masses* may be polyps, bowel herniation, or pelvic masses such as ovarian cysts or tumors, adnexal masses, and so forth located more posteriorly and not felt during the vaginal bimanual examination. Physician consultation is required for any of these conditions.
	b. nodules/irregularities	**b.** *Nodules* and *irregularities* may indicate the presence of an ulcerated malignancy. Physician consultation is required.
	c. strictures	**c.** *Strictures* that are causing problems with bowel evacuation require physician consultation.
	d. rectovaginal musculature	**d.** Evaluation of the thickness and tone of the *rectovaginal musculature* provides useful information in anticipating difficulties during the second stage of labor. A woman may experience problems if the musculature is too thin or if it is too thick and muscularly overdeveloped (as may be found in some female athletes).

Procedure and Rationale	Observations and Findings	Significance
7. Your abdominal hand is pressing firmly and deeply downward just above the symphysis pubis and your vaginal examining finger is located in the posterior vaginal fornix and pressing strongly upward against the posterior side of the cervix (this will move the uterus posteriorly). Palpate as much of the posterior side of the uterus as possible with your rectal examining finger. This is particularly useful in evaluating a retroverted uterus.	**7.** Palpate for confirmation of vaginal findings regarding the size, location, position, consistency, shape, contour, and any tenderness or pain of the uterus.	**7.** See Step 9 under "The Bimanual Examination."
8. If you were unable to evaluate the adnexal areas thoroughly or had any questionable findings in this area during the vaginal bimanual examination, then palpate the adnexal areas using the same maneuvers as in Step 10 of "The Bimanual Examination."	**8.** See Step 10 of "The Bimanual Examination."	**8.** See Step 10 of "The Bimanual Examination."

9. If you are doing clinical pelvimetry during your pelvic examination, you may wish to reevaluate the shape of the sacrum, the ischial spines, the sacrospinous ligaments, the sacroiliac notch, and the coccyx during your rectovaginal examination, as these structures may be more readily felt through the rectum. See the procedure for clinical pelvimetry in Chapter 61.

10. As you remove your fingers, repeat the maneuver described in Step 6 (1) above covering the remaining half of the rectal wall. For example, if you covered between 5:30 and 12:30 o'clock on your way in, you will cover the area between 11:30 and 6:30 o'clock on your way out.	**10.** Same as for 6 (a), (b), and (c) above.	**10.** Same as for 6 (a), (b), and (c) above.

11. Gently remove your examining fingers.

12. Wipe off any secretions, discharge, and lubricating jelly from the woman's perineum and external genitalia. Use a single front-to-back motion and use fresh tissue for each front-to-back stroke in order to avoid contamination from the rectum.

13. Remove your gloves and discard the tissues/wipes and gloves in a hazardous biological waste receptacle.

14. Be sure to help the woman back up on the table and into a sitting position. Some women (usually either young women having their first pelvic examination or older women) may need to sit several minutes to regain their equilibrium and composure.

15. Be sure to give the woman a sanitary pad if she is menstruating or spotting from any procedure so she will not soil her clothes; if the woman may not be expecting any bleeding, tell her to expect it, for how long, and why there is spotting.

16. If you haven't already done so, share your findings from the examination with the woman either now or after she is dressed.

CHAPTER

57

Obtaining a Specimen for Papanicolaou (Pap) Diagnostic Evaluation

There are two methods of specimen collection for Papanicolaou (Pap) screening for cancer: (1) the conventional Pap smear, in which a slide is made directly from the specimen collected at the cervix, and (2) the ThinPrep Pap Test, in which the specimen collected at the cervix is first processed in the laboratory to reduce blood, mucus, other debris, and obscuring artifacts and then a slide is made of the remaining cellular material. This material can also be used for human papillomavirus (HPV) testing. Both methods involve a speculum examination but there are variations in the collection and disposition of the specimen. The following procedure details both the commonalities and the variations in the two methods of obtaining a specimen for Papanicolaou microscopic analysis.

Procedure	Rationale
1. Before starting the procedure be sure that the specimen container label is filled out. If you are doing a Pap smear, be sure that the slide is labeled *in pencil* with the date and the woman's name and number.	**1.** Labeling before the procedure helps make sure the specimen is properly labeled with the woman's name and the date and reduces the risk in a busy office or clinic of specimens from different women getting mixed up. Ink may smear or wash off during fixation of the slide, thus making it difficult to read. The fixative also makes it difficult to label the slide after it has been sprayed.
2. Put on gloves.	**2.** Universal precaution to protect you from exposure to any body fluid/discharge or bloodborne pathogens.
3. Insert the appropriate size speculum, visualize the cervix, and fix the speculum for appropriate exposure. (See "Preparatory and General Procedures" and "The Speculum Examination" in Chapter 56.) Be sure to *gently* remove any material that obscures visualization of the cervix or may interfere with the cytological study (e.g., mucus, discharge, blood) with a 2 × 2 or 4 × 4 gauze on a sponge stick.	**3.** If a total pelvic examination is being done, inspect the external genitalia and check the urethra and the Bartholin's and Skene's glands prior to the speculum examination. The bimanual examination follows the speculum examination. It is imperative that no lubricating material except water be used prior to obtaining the Pap smear because lubricant may render this cytological study invalid. Cleaning the cervix too vigorously will remove the epithelium.

Collection and Disposition of the Specimen for a Pap Smear

4. One of four methods of specimen collection for a Pap smear may be used.

a. Place the longer portion of the slightly notched end of a wooden spatula or plastic scraper against and into the external os of the cervix and press. Scrape the cervical canal by turning the spatula firmly in a full circle. Be sure that if the squamocolumnar junction is visible, you include it and scrape it throughout the full circle.

b. Lightly moisten the cotton end of a cotton-tipped applicator with normal saline, insert the applicator into the cervical canal 2 cm, and roll the applicator between your thumb and index finger 360 degrees.

c. Insert a cervical brush 1 to 2 cm into the cervical canal and rotate it 90 to 180 degrees.

d. Use a combination of methods to include the spatula method.

5. Spread the cells on the labeled slide. If the cells were collected on a wooden spatula, place one flat side next to the label on the top half of the slide and stroke once to the end of the slide. Then turn the spatula over and place the other flat side next to the label on the bottom half of the slide and stroke once to the end of the slide. Do not stir in circles, stroke repeatedly, or stroke one side of the spatula on top of cells already spread from the other side of the spatula. If the specimen is too thick, then take the edge of the spatula and, with a single light stroke down the slide, remove the excess.

If the cells were collected on a cotton-tipped applicator or on a cervical brush, gently roll the cotton tip or the brush down the upper half of the slide from the label to the end of the slide. Repeat, rolling the cotton tip or the cervical brush down the lower half of the slide. Do not stir in circles or rub back and forth.

6. Immediately spray the slide generously with the fixative or place it in a jar of fixative solution. Speed is of the essence. Avoid waving the slide in the air or placing it under a lighted lamp prior to its being fixed.

4.

a. Pressing inserts the tip of the spatula a short distance into the cervical canal; how far depends on the patulousness of the cervix. Cells from the squamocolumnar junction should be included for cytological study because cervical cancer most frequently begins at the squamocolumnar junction.

b. Moistening the cotton-tipped applicator with saline prevents the cotton from absorbing endocervical secretions and prevents the cotton fibers from getting on the slide.

This method is often used with pregnant women to decrease the risk of bleeding resulting from increased friability of the cervix.

c. The cervical brush increases endocervical cell retrieval, expecially in women who are pregnant, postmenopausal, who have cervical stenosis, or who have had cervical procedures [1]. In women wth any of these conditions, the squamocolumnar junction has retreated within the cervical canal. Cells from this area must be retrieved for a valid Pap smear.

Rotating the cervical brush only 90 to 180° decreases bleeding, which can obscure the endocervical cells from examination.

d. A combination of methods is used if you feel the need to sample the ectocervix as well as the endocervix.

5. This procedure for spreading the cells is designed to avoid breaking and destroying the cells, which would render the Pap smear useless.

6. Drying the cells in air or with a light distorts the cells.

Collection and Disposition of the Specimen for a ThinPrep Pap Test

4. One of two methods may be used.	**4.**
a. Place the long central portion of the cervical broom into the cervical canal and press against the external cervical os. Turn the cervical broom a full circle.	**a.** Pressing inserts the cervical broom a short distance into the cervical canal; how far depends on the patulousness of the cervix. Cells from the squamocolumnar junction should be included for cytological study because cervical cancer most frequently begins at this junction.
b. Use a wooden spatula or cervical brush, as described in 4 (a) and (c) above for collection and disposition of the specimen for a Pap smear.	
5. Rinse the cervical broom (or cervical brush or wooden spatula) in the small container of liquid transport medium by gently stirring it in the solution.	**5.** Removes the specimen from the collection device into the liquid transport medium.
6. Immediately cap the container.	**6.** Prevents accidental spilling while completing the examination.
7. Proceed with the remainder of the speculum examination, making the necessary observations. Remove the speculum and deposit it in the proper container.	
8. Dispose of the spatula, cotton-tipped applicator, cervical brush or cervical broom, and your gloves in a hazardous biological waste receptacle.	

There are individual and institutional variations in the procedure for obtaining a Papanicolaou smear. The variations relate to the number of slides made with specimens from the different locations. Some protocols require two slides: one made from a specimen taken with the wooden spatula swept circumferentially at the os, and the second made from a specimen taken with the cotton-tipped applicator or cervical brush inserted into the cervical canal. Still other protocols require the examiner to make a third slide from a specimen taken from the posterior vaginal fornix or vaginal vault either by aspiration or with a cotton-tipped applicator, or with the blunt end of a wooden spatula.

CHAPTER

58

Obtaining a Specimen for Gonococcal (GC) and Chlamydia Diagnostic Testing

There are systems that collect cervical specimens for diagnosis of either or both gonorrhea and chlamydia by culture or by DNA direct probe or by DNA amplification. These systems have commonalities in the collection of the specimen but vary in the transport container, medium, or culture.

Procedure	Rationale
1. Put on gloves.	**1.** This is a universal precaution to protect yourself from any possible body fluid/discharge or bloodborne pathogens.
2. Insert the appropriate size speculum, visualize the cervix, and fix the speculum for appropriate exposure. (See "Preparatory and General Procedures" and "The Speculum Examination" in Chapter 56.)	**2.** The cervical canal is considered the best site to culture for diagnosis of gonorrhea and chlamydia. Eighty-five percent of cases of gonorrhea in the female are harbored at this site. Endocervical cells are needed for proper growth of chlamydia.
3. Gently remove any material (mucus, blood, discharge) obscuring the cervix with a sponge stick, Procto-swab, an applicator from the kit you are using, or a 2×2 or 4×4 gauze on a ring forceps.	**3.** Mucus can interfere with the growth of chlamydia.
4. Insert a sterile applicator (swab) 1–2 cm into the cervical canal. If you are collecting a specimen for chlamydia only or for both chlamydia and gonorrhea together, use a Dacron-tipped swab only. These swabs are usually provided in a specimen collection kit. If you are collecting a specimen for gonorrhea only, then you can use a cotton-tipped applicator (swab).	**4.** Natural fibers such as cotton and wood interfere with the growth of chlamydia. Synthetic fibers are thus necessary for collection of this specimen. The organisms are absorbed on the cotton-tipped applicator (swab).
5. Gently rotate the swab, being sure to move it against the sides of the cervical canal. Leave the swab in place for approximately 30 sec.	**5.** It takes time for the organisms to be absorbed on the swab.
6. Withdraw the swab carefully; avoid any contact with the vaginal mucosa.	**6.** Mucus interferes with growth of chlamydia.

Procedure	Rationale
7. The next step depends on the collection system being used.	
a. If you are using a transport system for DNA direct probe or DNA amplification, follow the directions supplied with the kit.	
b. If you are using a culturette or culture tube into which the swab is inserted, handle the specimen according to directions provided with that system.	
c. If you are using a slide method, roll the swab down the slide to place the specimen. Do not stir the swab in circles or rub back and forth, as this will damage cells. Follow directions on the specimen collection kit for fixing the specimen on a slide.	
d. If you are using a Thayer-Martin (T-M) medium culture plate to streak a culture for gonorrhea, use the following procedure:	
(1) Streak the T-M culture plate by rolling the cotton swab on the medium in a large Z pattern that covers at least three-quarters of the plate.	**(1)** T-M medium contains several antibiotics that discourage growth of the many other organisms found in the vagina and cervix, which would otherwise overgrow the *Neisseria gonorrhoeae*. Rolling the cotton swab in a large Z pattern allows the swab to be adequately exposed to the culture for maximum transfer of organisms. This pattern also allows for easier morphological study by spacing out the colonies.
(2) Cover the culture plate with its cover and turn it upside down.	**(2)** Turning the plate upside down prevents contamination by airborne organisms.
(3) The culture plate should be prepared for transport to the laboratory according to laboratory or facility protocols, i.e., use of a candle jar, jar with carbon dioxide insert, carbon dioxide bag, or Bio-bag. If a candle jar is used, place the culture plate upside down, light the candle, and replace the lid on the jar.	**(3)** The candle jar, carbon dioxide jar insert, and carbon dioxide bag all provide an atmosphere of 3 percent carbon dioxide, which is favorable for the partially anaerobic *N. gonorrhoeae*. When using only the Bio-bag it is crucial to transport the culture to the laboratory within 30 min to enhance proper growth of the organisms.
8. Properly label the transport container or T-M culture plate with the woman's name, identification number, specimen site, and date.	
9. A gonococcal and chlamydia specimen should always be obtained of any discharge elicited during examination of the urethra and Bartholin's and Skene's glands or in the event of redness and discharge from the eyes, pharyngeal soreness, or rectal pain. Specimens should also be obtained from the rectum and the throat if indicated by history or clinical symptoms. Use separate kits or T-M medium culture plates (gonorrhea only) for each site and clearly mark the site of each specimen.	
10. The indications for collecting a specimen for diagnostic testing for gonorrhea or chlamydia are the same; if a test for one is indicated, a test for both should be done.	
11. All disposables should be discarded in a hazardous biological waste receptacle.	

CHAPTER

59

Making a Wet Smear Slide of Vaginal Secretions

Procedure	Rationale
1. Put on gloves.	**1.** This is a universal precaution to protect yourself from any possible body fluid/discharge or bloodborne pathogens.
2. Obtain the specimen of vaginal discharge during the speculum examination.	**2.** The vaginal discharge in the concave posterior blade of the speculum is a good source for a specimen. Plaques of *Candida* on the vaginal walls are exposed during the speculum examination and are a good specimen source.
3. Do one of the following: **a.** Put one drop of normal saline on the middle of a clean microscope slide. **b.** Put one drop of normal saline on the left third of a clean microscope slide and one drop of potassium hydroxide (KOH) on the right third of the slide. **c.** Use two clean microscope slides and put one drop of normal saline on the middle of one slide and one drop of potassium hydroxide on the middle of the second slide.	**3.** *Candida* (monilia), *Trichomonas*, and bacterial vaginosis can all be identified microscopically when mixed with a drop of normal saline. Normal saline is used for detection of motile trichomonads. Use of potassium hydroxide facilitates identification of *Candida* because potassium hydroxide dissolves trichomonads, white blood cells, bacteria, and foreign objects. Some clinicians prefer to start with Step 3(a) and, after evaluating the slide for trichomonads and the clue cells of bacterial vaginosis, add a drop of potassium hydroxide at the edge of the coverslip. This diffuses under the coverslip, destroys the other organisms, and facilitates identification of *Candida*.
4. Roll the plain wooden end of a cotton-tipped applicator in the specimen of vaginal discharge.	**4.** Do *not* use the cotton-tipped end, as cotton filaments may be added to the specimen and be confused with or misidentified as *Candida*.
5. Mix the sample of vaginal discharge on the wooden end of the cotton-tipped applicator with the drop of normal saline on the slide. Repeat Step 4 and mix the sample with the drop of potassium hydroxide if both solutions are being used. Use both a rolling and a stirring motion to mix the vaginal discharge with the drop of solution.	**5.** Microscopic evaluation of the slide is facilitated if the sample of vaginal discharge is well mixed throughout the drop of solution, thereby avoiding thick areas of sample.

Procedure	Rationale
6. Cover the mixture of specimen sample and solution with a coverglass (coverslip) by sliding the coverslip onto and over the specimen. This is accomplished by putting the edge of one side of the coverslip into the mixed specimen/solution and drawing it to the longitudinal edge of the slide. When the specimen/solution is under the entire edge of the side of the coverslip, slide the coverslip over the rest of the mixed specimen/solution on the slide.	**6.** If the coverslip is simply dropped onto the specimen, air bubbles will be trapped between the coverslip and the specimen/solution on the slide, making microscopic evaluation difficult.
7. The wet smear slide of vaginal secretion is now ready for microscopic evaluation. (See Chapter 60, Using a Microscope.)	

CHAPTER

60

Using a Microscope

Procedure	Rationale
1. Put on gloves.	**1.** This is a universal precaution to protect yourself from any possible body fluid/discharge or bloodborne pathogens.
2. Place the slide on the stage of the microscope so that the specimen is over the opening in the stage. Secure the slide in place with the stage clips.	**2.** This properly locates the slide for viewing of the specimen.
3. Turn on the light source for the microscope and adjust the light so it reflects evenly throughout the microscopic field.	**3.** Good visualization depends on adequate lighting.
4. Do either of the following: **a.** Select the low-power objective (10×) and place it over the specimen, making sure it clicks into place. **b.** Select the high-power objective (40×) and place it over the specimen, making sure it clicks into place.	**4. a. or b.** Some midwives find it is easier to locate the proper plane of visualization by starting with the low-power objective. Other midwives prefer to start with the low-power objective because they believe it is easier to scan an entire slide under low power and then switch to high power for confirmation of findings (*Candida*, trichomonads, clue cells) and identification of clue cells, if present. Still other midwives feel that it saves time to start with the high-power objective.
5. Move the objective and the slide as close to each other as possible with the coarse adjustment knob. Watch from the side so you can see if and when the objective touches the slide. Note which way you are turning the coarse adjustment knob.	**5.** This provides a starting point for locating the proper plane of visualization without breaking the slide in the process. Watching from the side allows you to see when the objective and the slide touch and stop turning the knob. (The objective and the slide usually do not touch when starting with the low-power objective.) Noting which way you are turning the coarse adjustment knob ensures that you know which way to turn it (the opposite direction) when you are looking through the eyepiece in order to visualize the specimen and to prevent further pressure of the objective on the slide, which would break the slide.

Procedure	Rationale
6. Look through the eyepiece of the microscope and *slowly* turn the coarse objective knob in the other direction until you can see something.	**6.** If you turn the coarse adjustment knob too quickly, you will pass through the proper plane of visualization without noticing it.
7. Check to make sure you are in the right plane of visualization by moving the slide while you look through the eyepiece. Note whether what you are looking at changes position or if you see more of the specimen. If so, you are in the proper plane. If not, you are not in the proper plane and should continue with or repeat Step 6 above.	**7.** It is easy to confuse dirt, lint, and grime on the objective and eyepiece for the specimen. Such objects of vision will not change position when you move the slide.
8. When the specimen is in the proper plane of visualization, turn the fine adjustment knob back and forth while you look through the eyepiece.	**8.** The fine adjustment knob brings the specimen into sharper focus.
9. a. If you started with the high-power objective (40×), proceed with Step 11 below.	**9.**
b. If you started with the low-power objective (10×), switch now to the high-power objective. Watch from the side while changing the objective.	**b.** Switching to the high-power objective after having located the specimen in the proper plane of visualization will further magnify the specimen for ease in identification and diagnosis. If you watch from the side while changing the objective you are assured that you will not hit the slide with the objective. This might either break the slide or knock it out of position.
10. Turn the fine adjustment knob back and forth while you look through the eyepiece. Do not use the coarse adjustment knob.	**10.** Fine adjustment brings the specimen into sharper focus under the high-power objective. If you turn the coarse adjustment knob, you will lose the plane of visualization you located using the lower-power objective.
11. Systematically move the slide until you have seen the specimen in its entirety or sufficiently to make a diagnosis.	**11.** Evidence of what you are seeking may not appear in all areas of the slide. Therefore, the entire slide must be evaluated.
12. When finished with your microscopic evaluation of the slide, turn off the light source for the microscope and remove the slide from the stage.	
13. Dispose of the slide(s) and your gloves in a hazardous biological waste receptacle.	
Care of a Microscope	
1. Keep the microscope covered when not in use.	**1.** Prevents dirt and lint from collecting in and on the microscope.
2. Routinely clean the microscope of dust and lint and wipe the eyepiece and objectives with optical paper.	**2.** Facilitates proper functioning of the microscope and a clearer view of specimens.
3. Carry the microscope with two hands in an upright position or on a movable cart or table.	**3.** The microscope is a delicate instrument, which must be handled carefully if it is to function properly. It must be kept upright to prevent pieces from falling off or out.

CHAPTER

61

Anatomy of the Pelvis, Pelvic Types, Evaluation of the Bony Pelvis, and Clinical Pelvimetry

Anatomy

Pelvimetry refers to measurement of diameters of the pelvis. These diameters are most accurately measured by roentgenographic study, or x-ray pelvimetry. However, x-ray pelvimetry is rarely done today, in order not to expose the mother and baby to the potential hazards of radiation unless absolutely necessary. It is possible to measure some of the critical diameters clinically using either your hands or a pelvimeter such as Thom's pelvimeter. In addition, it is possible to evaluate the general structure (size and shape) of the pelvis by feeling certain bony landmarks. The information on pelvic diameters and structure obtained clinically is compared with the estimated size of the baby. You can then evaluate the adequacy of the pelvis for passage of a particular baby or (if you are doing the pelvimetry earlier in pregnancy) of a certain-sized baby. Generally, with cephalic presentations, a trial of labor has replaced x-ray pelvimetry when there is a question of the adequacy of the pelvis, which may indicate the need for cesarean section because of cephalopelvic or fetopelvic disproportion. Many physicians, however, will perform x-ray or computed tomographic (CT) pelvimetry on women who are primigravidas in labor with a breech presentation who plan to deliver vaginally, in order to confirm their clinical impressions of the adequacy of the pelvis, especially the inlet. X-ray or CT pelvimetry is not performed until labor has begun and the pelvis has been evaluated in relationship to the estimated actual size of the baby about to be born.

A thorough knowledge of the anatomy of the bony pelvis is an essential prerequisite not only to the performance of clinical pelvimetry and accurate interpretation of these findings but also for evaluation of the total pelvis and its adequacy to accommodate the passage of the baby.

The pelvis is comprised of four bones: two innominate bones, the sacrum, and the coccyx (see Figure 61-1). Each *innominate bone* has three parts: the pubis, the ischium, and the ilium. The *ilium* is the posterior and upper portion of the innominate bone. The two ilia form the false pelvis, share with the sacrum the important bony landmark of the sacroiliac notch, and join the sacrum at either side at the *sacroiliac synchondroses*. The *ischium* is the medial and lower portion of the innominate bone and has such important bony landmarks as the ischial spine, the ischial tuberosity, and the pelvic side-wall. The *pubis* is the anterior portion of the innominate bone. The two pubic bones join each other in the front at the *symphysis pubis* and their inferior angles from the descending rami form the important bony landmark of the pubic arch.

The sacrum and the coccyx form the posterior portion of the pelvis. The *sacrum* is formed by the fusion of the five sacral vertebrae, includes the important bony landmark of the *sacral promontory*, and joins the coccyx at the *sacrococcygeal symphysis*. The *coccyx* is formed by the fusion of four (some-

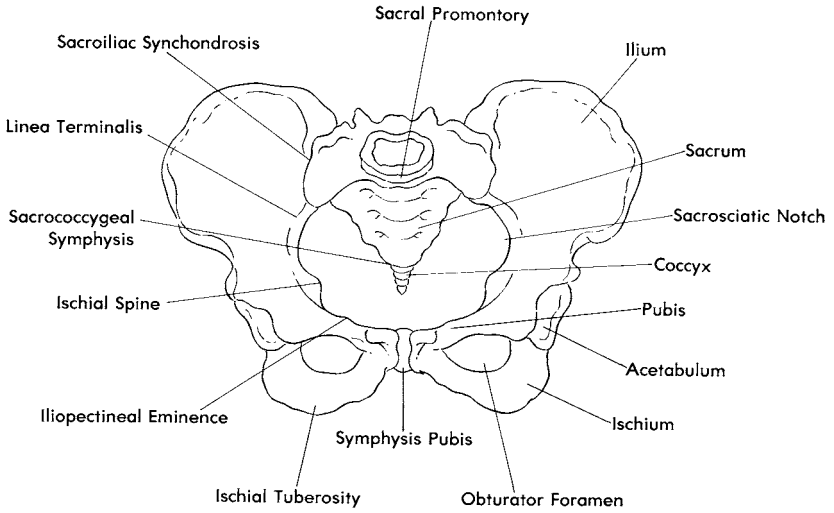

FIGURE 61-1 Bones of the pelvis.

times three or five) rudimentary vertebrae, is usually movable, and is itself an important bony landmark.

The sacrococcygeal symphysis, symphysis pubis, and the two sacroiliac synchondroses (or sacroiliac articulations) are all amphiarthrodial *joints* consisting of a network of cartilage and ligaments that join the bones of the pelvis.

The pelvis is divided by the linea terminalis into the false pelvis above this demarcation and the true pelvis below it (Figure 61-2). The *false pelvis* has little obstetric significance relevant to the passage of the fetus through the pelvis. The *true pelvis* constitutes the bony passageway through which the fetus must maneuver to be born vaginally. Therefore, its construction, planes, and diameters are of utmost obstetric importance.

The true pelvis has five boundaries:

1. *Superiorly:* the sacral promontory, linea terminalis, the upper margins of the pubic bones.
2. *Inferiorly:* the inferior margins of the ischial tuberosities and the tip of the coccyx.
3. *Posteriorly:* the anterior surface of the sacrum and coccyx.
4. *Laterally:* the sacroiliac notches and ligaments and the inner surface of the ischial bones.
5. *Anteriorly:* the obturator foramina, and the posterior surfaces of the symphysis pubis, pubic bones, and ascending rami of the ischial bones.

The *true pelvis* has three planes of obstetric significance: the inlet, the midplane, and the outlet. For each plane there are theoretically six diameters. However, not all diameters are used in measuring or discussing each of the planes or in discussion of pelvic types. Table 61-1 shows which diameters are pertinent to which planes. Those with an asterisk are considered critical to evaluation of pelvic adequacy. The sagittals (anterior and posterior) measure the distance from the midpoint of the transverse diameter to the points used in measuring the anteroposterior diameter.

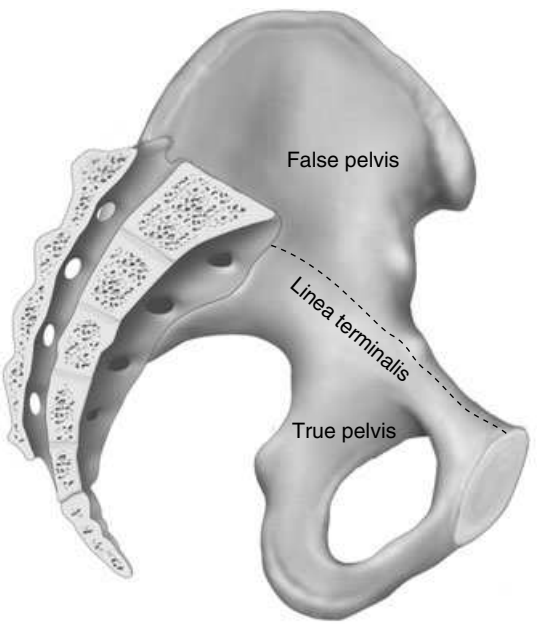

FIGURE 61-2 False and true pelvis.

TABLE 61-1	Diameters of the Three Pelvic Planes of Obstetric Significance		
Diameters	**Inlet**	**Midplane**	**Outlet**
Anteroposterior	X*	X*	X*
Right oblique	X		
Left oblique	X		
Transverse	X*	X*	X*
Anterior sagittal	X		
Posterior sagittal	X	X*	X*

* Critical to evaluation of pelvic adequacy.

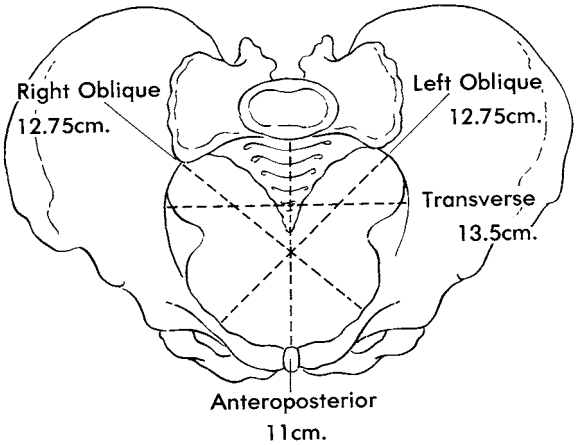

FIGURE 61-3 Diameters of the pelvic inlet.

The pelvic *inlet* (superior strait) is the upper entry into the true pelvis. Its boundaries are the sacral promontory posteriorly, the linea terminalis laterally, and the upper portion of the symphysis pubis and horizontal rami of the pubic bones anteriorly. The diameters of the inlet that are frequently referred to are discussed below (see Figures 61-3 and 61-4):

There are three *anteroposterior diameters* of the inlet:

1. *Conjugata vera:* the true conjugate of the inlet; extends from the middle of the sacral promontory to the middle of the upper margin of the symphysis pubis; normally measures 11 cm or more.
2. *Obstetric conjugate of the inlet:* extends from the middle of the sacral promontory to the middle dle of the symphysis pubis on its inner surface a short distance (several millimeters) below its upper margin. The minimum measurement of this diameter before the pelvis is considered contracted is 10 cm. This is the shortest antero-

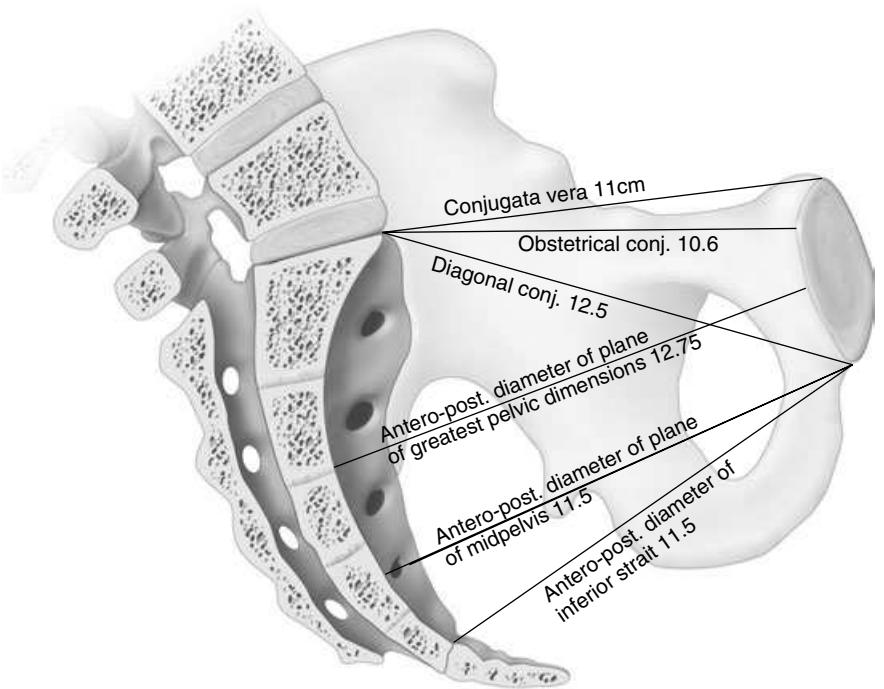

FIGURE 61-4 Diameters and planes of the pelvis.

posterior diameter because the symphysis pubis is slightly thicker at this point than at its upper or lower margin.

3. *Diagonal conjugate of the inlet:* extends from the middle of the sacral promontory to the middle of the inferior (lower) margin of the symphysis pubis. The diagonal conjugate is the only diameter of the pelvic inlet that can be measured clinically. A normal clinical measurement is considered to be at least 11.5 cm.

The *transverse diameter of the pelvic inlet* measures the greatest distance between the linea terminalis on either side of the pelvis; this distance is approximately 13.5 cm or a little less, depending on the shape of the pelvis.

The *oblique diameters of the pelvic inlet* measure the distance between the sacroiliac synchondrosis on one side of the pelvis and the iliopectineal eminence on the opposite side of the pelvis. The sacroiliac synchondrosis on the right or left of the pelvis determines whether the diameter is the right oblique diameter or the left oblique diameter. For example, if the diameter extends from the right sacroiliac synchondrosis to the left iliopectineal eminence, it is the right oblique diameter. The oblique diameters average slightly under 13 (12.75) cm each.

The *midplane* of the pelvis is the plane of least dimensions. The transverse diameter measures the distance between the ischial spines. Called the *interspinous diameter*, it normally measures about 10 cm. This measurement is critical, as it is the smallest diameter of the pelvis to which the fetus has to accommodate itself. If the ischial spines are prominent or sharp or the sidewalls converge so that the ischial spines protrude to the extent of encroaching on the space of the pelvic cavity, the interspinous measurement is diminished and pelvic adequacy for vaginal delivery of an average-sized baby is highly questionable. A contracted midplane is very often associated with a contracted outlet.

The anteroposterior diameter extends from the middle of the inferior margin of the symphysis pubis through the middle of the transverse diameter to the point on the sacrum dictated by this angle. This diameter normally measures a minimum of 11.5 cm. The posterior sagittal diameter of the midplane is usually a minimum of 4.5 cm.

It is not clinically feasible to measure the diameters of the midplane. However, its adequacy may be estimated by noting whether the ischial spines are prominent or encroaching rather than blunt, the sidewalls are convergent rather than straight, the sacrum is flat or shallow rather than hollow, and the outlet is contracted rather than measuring within normal limits.

The pelvic *outlet* can be thought of as composed of two triangles, with the transverse diameter of the outlet serving as the common base of these two triangles. The transverse diameter of the outlet is the distance between the inner aspect of the lowermost part of the ischial tuberosities (the *intertuberous*, or *biischial*, *diameter*), which usually measures approximately 10 cm. The posterior triangle has the tip of the sacrum as its apex and the anterior triangle has the middle of the inferior margin of the symphysis pubis as its apex. The anteroposterior diameter of the outlet extends from the middle of the inferior margin of the symphysis pubis to the tip of the sacrum. Unlike the anteroposterior diameter of the midplane, it does not transect the transverse diameter. It generally measures 11.5 cm. The posterior sagittal diameter of the outlet usually measures 7.5 cm. When these measurements are done clinically, a rule of thumb is that the sum of the transverse diameter and the posterior sagittal measurements must equal at least 15 cm for pelvic adequacy of the outlet.

Other anatomical features of the pelvis considered in evaluation of pelvic adequacy include the following:

Inclination of the symphysis pubis (Figure 61-5): The longitudinal axis of the symphysis pubis is normally parallel to the longitudinal axis of the sacrum. If the symphysis pubis is not at least approximately parallel to the sacrum, the anteroposterior diameters of the inlet and the outlet can be changed significantly. Tilting of the superior margin of the symphysis pubis toward the sacral promontory and of the inferior margin away from the sacrum is called *anterior inclination*. Tilting of the inferior margin of the symphysis pubis toward the sacrum and the superior margin away from the sacral promontory is called *posterior inclination*.

Angle of the pubic arch: The descending rami of the pubic bones and the inferior margin of the symphysis pubis form what is known as the *pubic arch*. The angle of this arch should be at least 90° as determined just below the symphysis pubis. An arch that is 90° a few centimeters below the symphysis pubis but narrow above that (just below the symphysis pubis) decreases the available space in the anteroposterior diameter and may indicate an inadequate outlet.

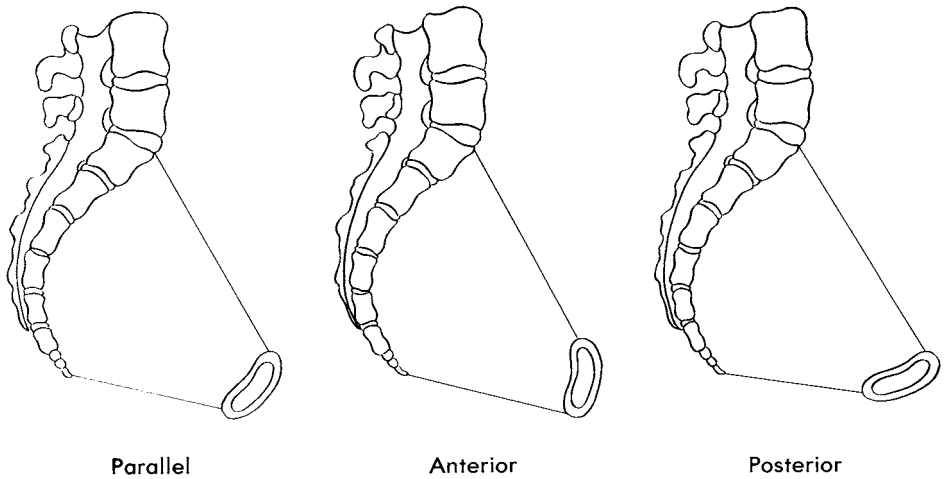

FIGURE 61-5 Inclination of the symphysis pubis.

General structure of the forepelvis: The inner aspect of the forepelvis (the anterior portion of the pelvis) should be rounded. A forepelvis that is not rounded but instead angles sharply toward the lateral portion of the pelvis decreases the oblique diameters of the inlet.

Angle of the pelvic sidewalls: The pelvic sidewalls extend from the upper anterior angle of the sacrosciatic notch at the point of the widest transverse diameter of the pelvic inlet in a downward and forward line to the ischial tuberosities at the point of the widest transverse diameter of the pelvic outlet. They are normally slightly convergent in that, if the lines of their angles were extended beyond the pelvis, they would meet at about the level of the knees. However, when felt on pelvic examination they feel generally straight. Their importance is in whether the width of the pelvis at the inlet remains the same throughout the pelvis. Divergence or convergence is based on whether the point of origin at the inlet and the ending point at the ischial tuberosities are essentially equidistant from the anteroposterior diameter of the pelvis. Convergent sidewalls usually decrease the angle of the pubic arch and may be accompanied by more prominent ischial spines. Divergent sidewalls always indicate a very wide angle of the pubic arch.

Sacrosciatic notch: The shape and width of the sacrosciatic notch are important because they affect the posterior sagittal diameter of the inlet, which combines with the shape and rotation of the sacrum to determine the amount of room in the posterior portion of the pelvis for passage of the fetus.

Types of Pelves

There are four basic pelvic types according to the Caldwell-Moloy classification: (1) gynecoid, (2) android, (3) anthropoid, and (4) platypelloid (Figure 61-6). These are determined by certain characteristics of the pelvis and classified in accord with the characteristics of the posterior segment of the inlet. Anatomical portions of the pelvis used in evaluation of pelvic types are the inlet, sacrum, sacrosciatic notch, sidewalls, ischial spines, and pubic arch.

Many pelves are not pure types but, rather, a mixture of types. For example, a gynecoid pelvis may be said to have an android tendency. This means that the posterior segment is gynecoid and the anterior segment is android or that the pelvis has certain android characteristics.

The importance of being familiar with pelvic types lies in the fact that many of the characteristics used in determining pelvic types affect the obstetric capacity of the pelvis—that is, the adequacy of the pelvis for accommodating passage of the baby. So although a pelvic type, in and of itself, may not seem too important, knowledge of the characteristics of the pelvis that are being evaluated—especially the inlet, sacrum, ischial spines, and pubic arch—is extremely valuable when combined with clinical pelvimetry for evaluation of pelvic adequacy.

Gynecoid Pelvis

The gynecoid pelvis is commonly known as the "female pelvis" because it is the type that occurs most frequently in women; 41 to 42 percent of women's

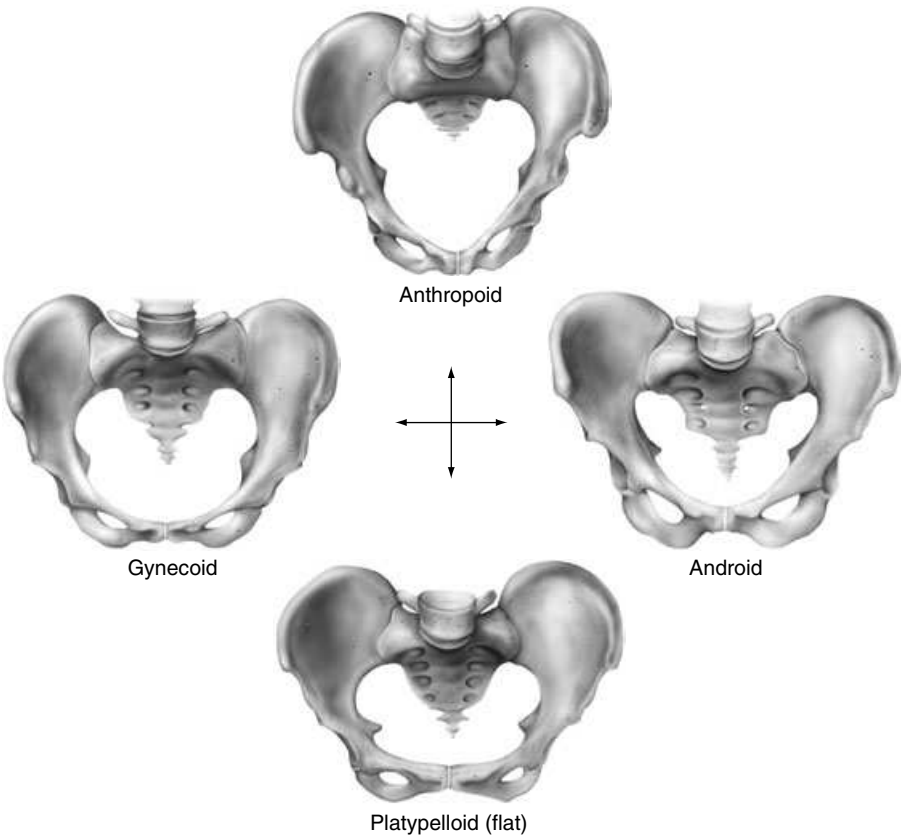

FIGURE 61-6 Four basic pelvic types. Caldwell-Moloy classification.

pelves are gynecoid. This shape is ideal for childbearing. Its identifying characteristics are as follows:

Inlet: Well-rounded anterior, lateral, and posterior segments of the pelvis, with the transverse diameter about the same or slightly greater than the anteroposterior diameter. The posterior sagittal diameter is only a little shorter than the anterior sagittal diameter.

Sacrum: Parallel with the symphysis pubis.

Sacrosciatic notch: Well rounded with an approximate distance of $2\,^1/_2$ to 3 fingerbreadths along the sacrospinous ligament, which runs between the ischial spine and the sacrum.

Sidewalls: Straight pelvic sidewalls.

Ischial spines: Blunt and neither prominent nor encroaching.

Pubic arch: A wide arch (90 degree angle or more).

Android Pelvis

The android pelvis is commonly known as the "male pelvis" because it occurs more frequently in men. However, it does occur in 32.5 percent of white women and in 15.7 percent of nonwhite women. The android pelvis is a heavy pelvis, which poses difficulty for vaginal delivery and increases the incidence of posterior position, forceps delivery, and stillbirth. The midplane and outlet contracture of the android pelvis increases the incidence of fetopelvic disproportion and cesarean sections. Characteristics of the android pelvis are as follows:

Inlet: Often referred to as heart-shaped; the posterior segment is wedge-shaped and the anterior segment (forepelvis) is narrow and triangular. The posterior sagittal diameter is quite short in comparison to the anterior sagittal diameter. This means that there is very limited space in the posterior portion of the pelvis for accommodating the fetal head.

Sacrum: Anteriorly inclined and flat, thereby contributing to the shortness of the posterior sagittal diameters throughout the pelvis.

Sacrosciatic notch: Highly arched and narrow, with an approximate distance of $1\,^1/_2$ to 2 fingerbreadths along the sacrospinous ligament between the ischial spine and the sacrum.

Sidewalls: Pelvic sidewalls that are usually convergent.

Ischial spines: Usually prominent and frequently encroaching, thereby decreasing the transverse (interspinous) diameter of the midplane.

Pubic arch: Narrow, with an acute angle of much less than 90 degrees.

Anthropoid Pelvis

The anthropoid pelvis is most common in the nonwhite races, occurring in 40.5 percent of nonwhite women as compared to 23.5 percent of white women. The shape of the anthropoid pelvis favors a posterior position of the fetus. It is adequate for vaginal delivery if it is on the large size.

Inlet: Characteristically oval with an anteroposterior diameter much larger than the transverse diameter. The anterior segment of the pelvis (forepelvis) is somewhat pointed and narrower than the posterior segment.

Sacrum: Posteriorly inclined, so, although flat, the posterior sagittals are long throughout the pelvis. Therefore, there is more space in the posterior portion of the pelvis for accommodating the fetal head. The anthropoid pelvis has the longest sacrum of the four types of pelves, and hence, is the deepest pelvis.

Sacrosciatic notch: Of average height but quite wide; has an approximate distance of 4 fingerbreadths along the sacrospinous ligament between the ischial spine and the sacrum.

Sidewalls: Frequently somewhat convergent.

Ischial spines: Usually prominent but not encroaching, so the transverse (interspinous) diameter of the midplane is generally less than that of the gynecoid pelvis but not as contracted as the android pelvis.

Pubic arch: May be somewhat narrow, but the potential problem of outlet contracture generally is counterbalanced by the lengthy anteroposterior diameter's having a long posterior sagittal, thus providing room in the posterior portion of the pelvis for the baby.

Platypelloid Pelvis

Fortunately the platypelloid pelvis is rare, because it is not particularly conducive to vaginal delivery. It occurs less than 3 percent of the time in both white and nonwhite women.

Inlet: Has been likened to a flat gynecoid pelvis. It is the opposite of the anthropoid pelvis, having instead a short anteroposterior diameter and a wide transverse diameter. The anterior segment of the pelvis (forepelvis) is quite wide.

Sacrum: Inclined posteriorly and quite hollow, thereby creating a short sacrum and shallow pelvis.

Sacrosciatic notch: Wide and flat with an acute angle between the ischial spines and the sacrum.

Sidewalls: Slightly convergent.

Ischial spines: The ischial spines are somewhat prominent but, because of the flattened character of the pelvis and wide transverse diameters throughout the pelvis, this prominence has no effect. The transverse diameter of the midplane of a platypelloid pelvis is the widest of all the pelves.

Pubic arch: Quite wide; this pelvis is the widest of all the pelvic types.

Procedure, Rationale, and Description of Findings

Before doing clinical pelvimetry it is important that you measure your fingers and your fist because they will become your instruments of measurement. Specifically, you should measure the length of the reach of your examining fingers—that is, from the tip of your longest finger to the juncture of your first finger (palm) and your thumb. This length should be measured both with the measurer just resting against this juncture and with the measurer pressed into this junction with the same degree of force you use against the perineum when reaching for the diagonal conjugate. Pressing usually adds 0.5 to 1 cm to your reach.

Even if you have access in your setting to a Thom's pelvimeter for measuring the diameters of the outlet, it is wise to have measured your fist, as not many settings have a Thom's pelvimeter. Measure your fist from the outer (ulnar) aspect to the outer (radial) aspect of the tops of the knuckles of your fingers where they attach to your hand. If this does not measure at least 8 cm, then position your thumb in a way that you will position it each time and add the joint or knuckle of your thumb into the measurement.

Clinical evaluation of the pelvis and pelvimetry are usually included as part of the initial antepartal examination and, depending on circumstances, repeated again either late in the third trimester or at the time of the initial intrapartal bimanual pelvic examination. (See "The Bimanual Examination" in Chapter 56.) It is important to develop a routine procedure for performing clinical evaluation of the

bony pelvis so that you will remember and include all aspects and so the procedure progresses as smoothly and comfortably for the woman as possible.

The woman is prepared for this procedure as for the pelvic examination: empty bladder, lithotomy position, careful draping, and instruction about both the procedure and relaxation techniques to help her cope with the examination. (See "Preparatory and General Procedures" in Chapter 56.)

One useful way to explain to the woman how it will feel to have you pressing against her pelvic bones is to hold one of her arms and press firmly with your thumb against her wrist bone while explaining that any discomfort she will feel will be like this and will be due to pressure.

Procedure and Rationale	Description of Findings
1. Put on gloves.	**1.** This is a universal precaution to protect you from any possible body fluid/discharge or bloodborne pathogens.
2. Insert your two vaginal examining fingers, palmar surface up, just inside the woman's vagina. Slightly separate your fingers and gently palpate the inner surface of the symphysis pubis. Separating your fingers places them on either side of the urethra, thus sparing it any trauma and the woman any additional discomfort while you are palpating.	**2.** Note any abnormal thickening of the symphysis pubis that would decrease the obstetric conjugate diameter of the pelvic inlet. Note if there is any separation of the symphysis pubis. Also note the position of the symphysis pubis so that after palpating the sacrum you can determine if the symphysis pubis is parallel with the sacrum or if it has either anterior or posterior inclination.
3. Move your fingers to either side of the symphysis pubis, palpating the horizontal rami of the pubic bones toward the lateral portion of the pelvis.	**3.** Evaluate the curvature of the upper portion of the forepelvis for round and roomy or angular structure, which would decrease the oblique diameters of the inlet.
4. Follow the horizontal rami of the pubic bone on one side of the pelvis to the lateral portion of the pelvic inlet. Then palpate down the pelvic sidewall to the ischial spine. Be sure to get to the lateral portion of the pelvis before beginning your descent from the inlet to the midpelvis. Otherwise, by starting your descent too early, you will end up at the ischial tuberosity rather than at the ischial spine. This maneuver is used not only for evaluation of the pelvic sidewalls but also as a means of locating the ischial spine.	**4.** Evaluate the pelvic sidewall and determine if it is straight, convergent, or divergent.
5. Palpate the ischial spine.	**5.** Evaluate the ischial spine for its protuberance and determine if it is blunt (or flat), prominent (or sharp), or encroaching.
6. Sweep your fingers across the pelvic cavity to the ischial spine on the opposite side of the pelvis, palpate it, and sweep your fingers back to the first spine.	**6.** This is done to estimate the distance between the ischial spines. While the interspinous (transverse) diameter cannot be clinically measured, you can get an impression of its adequacy. This impression improves in accuracy with experience, comparing clinical findings with x-ray or CT pelvimetry whenever circumstances provide this opportunity, and practicing on objects whose diameters you can measure.
7. Starting at the ischial spine, outline the sacrosciatic notch and return to the ischial spine.	**7.** Note the shape and height of the sacrosciatic notch.
8. Now palpate across the sacrosciatic notch, following the sacrospinous ligament from the ischial spine to the sacrum.	**8.** Measure the width of the sacrosciatic notch, which is the same as the length of the sacrospinous ligament, in terms of fingerbreadths.

Procedure and Rationale	Description of Findings
9. From where you ended on the sacrum after following the sacrospinous ligament over, move down the sacrum to the coccyx. Press firmly on the coccyx. (See Step 18 if you are not sure of mobility.)	**9.** Note whether the coccyx is mobile. The coccyx is described as movable or fixed.
10. Now walk your fingers up the sacrum (palpating its width as you go) as far as you can reach.	**10.** Determine whether the sacrum is hollow, flat (or straight), or J-shaped (Figure 61-7). Note if the sacrum is in alignment with the sacral promontory or instead is either anteriorly or posteriorly inclined. Also note the longitudinal axis of the sacrum and correlate it with the position of the symphysis pubis you have already felt in order to determine if the symphysis is parallel with or has either anterior or posterior inclination in relation to the sacrum.
11. The diagonal conjugate is measured next. You can reach the sacral promontory in one of two ways. The first is a continuation of the preceding step in which you walk your fingers up the sacrum to the sacral promontory. However, if the sacrum is hollow it is possible that you might lose contact with the sacrum as it may become too far away for you to reach. It is possible to extend the normal reach of your fingers by depressing the perineum by exerting pressure against it. This also exerts pressure on the juncture of your first finger (palm) with your thumb, which additionally extends your reach. You can exert maximal pressure against the perineum by supporting the elbow of your examining hand against either your hip or your thigh (which is elevated horizontally by placing your foot on a stool) and using this as a brace to further exert pressure against the perineum. Reaching for the sacral promontory involves having your examining hand at the proper angle and in the proper location. It helps to visualize mentally where the sacral promontory is in relation to the vaginal introitus. The tips of your examining fingers should be in the posterior fornix of the vagina. Then drop your wrist (it helps to lower your elbow) and press against the perineal body with the knuckles of your last two fingers. Dropping your wrist changes the direction of your fingers from horizontal to angled upward. This angle needs to be approximately 45 degrees. If you feel the sacral promontory, maintain contact with it while raising your wrist until your hand touches the inferior margin of the symphysis pubis. With your other hand, mark on your examining hand the point that is touching the symphysis pubis. After removing your hand from the vagina, measure the distance from the tip of the finger that was touching the sacral promontory to the mark indicating where your hand was touching the symphysis pubis.	**11.** If you felt the sacral promontory, then you can chart whatever measurement you obtain for the diagonal conjugate. If you did not feel the sacral promontory, then chart the diagonal conjugate as greater than whatever you have measured the length of your examining fingers to be.

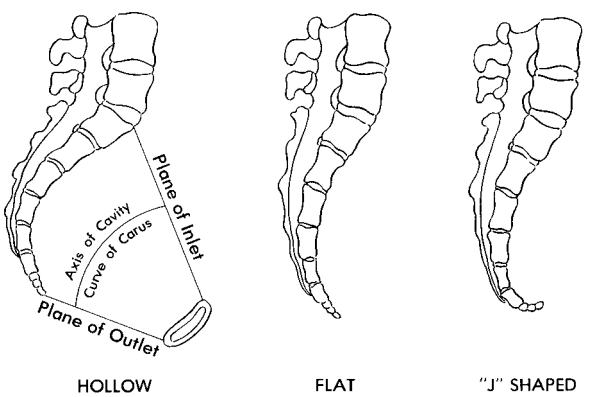

FIGURE 61-7 Sacral shapes.

Procedure and Rationale	Description of Findings
If you are unable to feel the sacral promontory, you know that the diagonal conjugate is greater than the length of your examining fingers, which you have already measured. Measurement of the diagonal conjugate is the last of the internal evaluations of the bony pelvis to be done, as it is the most uncomfortable. The woman should be forewarned that this maneuver may be uncomfortable for her.	
12. As you withdraw your fingers from the woman's vagina, turn them so that they are horizontal and place them against the inferior margin of the symphysis pubis.	**12.** If your fingers fit comfortably in this location, the pubic arch is probably at least a 90 degree angle. If you cannot fit your two fingers in this location, the pubic arch is probably less than a 90 degree angle.
13. With the thumbs of both of your hands palpate the pubic arch by following it down the descending rami of the pubic bones.	**13.** The arch should become progressively wider from a rounded apex. Visualize the angle of the arch immediately below the symphysis pubis as you palpate and combine these findings with those of Step 12 to finalize your determination of the angle of the pubic arch.
14. Continue your palpation down the pubic rami to the ischial tuberosities. Measure the transverse diameter of the outlet (intertuberous diameter; biischial diameter) either by using a Thom's pelvimeter or by placing your premeasured fist between the tuberosities.	**14.** Chart your measurement of the intertuberous diameter either as what it measured if you used a Thom's pelvimeter or as greater or lesser than the measured width of your fist. If you use your fist, it is important to recognize that the thickness of the tissue between your bones and the woman's bones will make the actual bony measurement approximately 1 cm greater. This centimeter, however, is not added to your measurement but should be considered in evaluating the adequacy of the intertuberous diameter.
15. If you have a Thom's pelvimeter, measure the posterior sagittal diameter. The anterior sagittal diameter is not generally measured. It is not possible to measure either of these diameters with your hands.	**15.** The posterior sagittal diameter of the pelvic outlet should measure 7.5 cm.
16. It is possible, although not usually done, to measure the anteroposterior diameter of the pelvic outlet with your hands. If this measurement is done, it should be done after doing the diagonal conjugate and before removing your examining hand from the vagina. Simply come down the sacrum from the promontory until you locate the tip of the sacrum and place the tip of one of your examining fingers on the tip of the sacrum (at the sacrococcygeal junction); then raise your examining hand until it touches the inferior margin of the symphysis pubis, while maintaining contact with the tip of the sacrum with the tip of your finger. With your other hand, mark on your examining hand the point that is touching the symphysis pubis and measure the distance between that point and the tip of the finger that was on the tip of the sacrum.	
17. If you have had difficulty evaluating middle and lower pelvic structures vaginally, end your examination of the pelvis during the rectovaginal examination to confirm your vaginal findings, as it is easier to feel these structures through the rectum. This includes palpation of the coccyx, ischial spines, sacrospinous ligament, and the lower sacrum.	
18. If you are unsure of coccyx mobility, test for it during the rectovaginal examination by holding the coccyx between your rectal finger and your thumb, which is positioned externally. Now attempt to move it back and forth between your finger and your thumb.	
19. Some midwives believe that it is necessary to palpate and evaluate completely both sides of the bony pelvis. Other midwives believe that, with the exception of sweeping across the pelvic cavity to feel the opposite ischial spine and estimate the transverse diameter of the midplane, it is sufficient to actually feel	

only one side of the bony pelvis, unless an obvious pelvic deformity is observed during the physical examination from the woman's posture, stance, and position of the lower spinal column. In such rare cases both sides of the bony pelvis should be evaluated. Otherwise, you can assume that the two sides of the pelvis are equilateral and thus reduce the amount of discomfort to the woman by palpating only one side.

The procedure described above is in accord with the latter viewpoint. Those who believe in complete examination of both sides of the pelvis can do so either by turning their examining hand over or by switching hands for palpation of the second side.

20. If evaluation of the bony pelvis was incorporated as part of the total pelvic examination, you now proceed with the remainder of the pelvic examination. If clinical pelvimetry was done as an isolated procedure, then the procedure ends with giving the woman wipes with which to clean off, disposing of the wipes and your gloves in a hazardous biological waste receptacle, and sharing your findings with her as outlined in Steps 12 to 16 in "The Rectovaginal Examination" in Chapter 56.

Evaluation of Findings

The following is a listing of generally accepted findings from clinical evaluation of the bony pelvis that indicate pelvic adequacy:

forepelvis: rounded
sidewalls: straight
ischial spines: blunt
sacrospinous ligament: $2\,^1/_2$ to 3 fingerbreadths
coccyx: movable
sacrum: hollow
diagonal conjugate: 11.5 cm or greater
pubic arch: 90 degrees or greater (2 fingerbreadths)
intertuberous diameter: 8 cm or greater

Variations of the above findings in and of themselves would not indicate pelvic inadequacy. It is well to remember that these rather precise findings must be combined with the other findings regarding inclination of the symphysis pubis, depth and angle of the sacrosciatic notch, alignment of the sacrum, and roominess of the posterior portion of the pelvis. The sum of all these findings gives a composite mental image of the total pelvis and its general type.

The individual pelvic architecture is then weighed against the estimated size of the fetus at term, the type of presenting part, and its position. A determination of pelvic adequacy is made from these findings. Often when evaluation of the bony pelvis is done early in pregnancy, the pelvis is deemed adequate for a certain size baby. This specificity is helpful if there is a question of adequacy when the baby ends gestation larger than that size. For example, charting may include a summary statement such as "adequate for a $7\,^1/_2$-pound baby"; if the estimated fetal weight at term is 8 pounds, the midwife is alerted to a potential problem requiring reevaluation of the pelvis and evaluation of labor status.

CHAPTER

62

Breast Massage, Manual Expression, and Nipple Rolling

Breast massage, manual expression, and nipple rolling are skills a mother can use while initiating breastfeeding and during the entire period she breastfeeds her baby. These skills also increase the woman's familiarity with her breasts and comfort and naturalness in touching and caring for them.

Breast massage and manual expression initially promote the flow of breast milk by clearing the lactiferous sinuses and ducts of the early viscid colostrum and establishing the free flow of the later, less viscid, colostrum. They also are used for relieving engorgement, helping the baby latch on, and collecting breast milk for bottle feeding (e.g., of preterm babies or when the mother will not be available).

Nipple rolling strengthens the erector muscles of the nipples, thereby providing an erect nipple for the baby to latch on to. If a woman has flat or inverted nipples, it should be remembered that how the nipple looks is not predictive of how well it will function if it is placed well back in the baby's mouth [1].

Breast massage and manual expression should not be done prior to delivery for two reasons:

1. Antepartal breast stimulation may cause the release of oxytocin, which may in turn cause the initiation of preterm labor.
2. The viscid colostrum serves as a barrier to bacteria antepartally. Removing colostrum would leave the breasts susceptible to possible infection.

Nipple rolling, along with breast foreplay and sexual intercourse, should be prohibited if the woman has a history or any signs and symptoms of preterm labor.

Breast massage and manual expression are done in that order, because massage increases circulation and facilitates the flow of milk through the ductal system of the lactiferous sinuses. Manual expression then expresses the milk out of the sinuses and through the ducts in the nipple to the surface of the nipple. The application of warmth to the breasts prior to massage increases the circulation and the flow of milk.

Instruct the woman to first do the following before starting breast massage and manual expression or nipple rolling:

1. Wash your hands.
2. Be comfortably seated.
3. Remove clothing covering your breasts.
4. Protect other clothes by covering them; cover your lap with a bath towel.
5. Lubricate your hands with some form of lubricant—e.g., hand lotion or cream, mineral oil, baby oil, or cocoa butter for the breast massage; and baby-safe lubricant or nipple cream for manual expression and nipple rolling.

Procedure for Breast Massage

The following is the procedure for breast massage:

1. Visualizing the breast as the face of a clock, place one hand, palmar side down, at 12 o'clock just above the upper margin of the breast. Place the other hand, palmar side down, on top of the first hand.

2. Apply firm, even pressure while drawing the two hands apart laterally so that one hand goes down each side of the breast.
3. As the hands go down the sides of the breast, keep the thumbs on the upper portion of the breast as the fingers again meet and cover each other under the breast, thereby cupping the breast.
4. Continuing the firm, even pressure, draw the breast upward and forward as the fingers press up toward the areolae and nipple and the thumbs press down toward the areolae and nipple.
5. Without touching the areolae and nipple, allow the breast to slip between the fingers and thumbs as they slide off of the breast.
6. Repeat steps 1 to 5 in sequence 10 to 15 times, relubricating the hands as needed.

Procedure for Manual Expression

The following steps are used for manual expression:

1. Support a breast with one hand.
2. Use the thumb and index or middle finger of the other hand and place them across from each other on opposite sides of the nipple at the outer margin of the areola. (The lactiferous sinuses are located in the area beneath the outer edge of the areola.)
3. a. Using a milking motion, press backward (away from the areola), then inward (down into the tissue), then forward (toward the nipple), and then release the pressure.
   b. Apply gentle yet firm pressure. Undue pressure could traumatize the tissue, yet the pressure must be firm enough to actually compress the sinuses.
4. Observe for beads of colostrum or milk on the nipple surface where the duct openings are. A mother may not observe beads of colostrum or milk when first doing manual expression. However, with repeated expression, all of the ducts will soon become free-flowing, and not only will she see colostrum or milk, but she will observe little squirts or streams with each milking motion.
5. Gently wipe or blot the colostrum or milk off the nipple surface with a clean washcloth.
6. Methodically move the thumb and finger around the areola, repeating steps 2 to 5 for each location. There are 15 to 20 lactiferous sinuses, all of which should be emptied. This means that the entire process will involve eight to ten thumb and finger placements, with the thumb having covered one half of the areola and the finger the other half of the areola by the end of all the placements.
7. When first doing manual expression, perform the milking motion no more than twice for each location in order not to traumatize tissue while the technique is being learned. After all ducts have become free-flowing and the woman has become adept with the technique, manual expression can be done until the flow of colostrum or milk ceases.

Procedure for Nipple Rolling

The following procedure can be used for nipple rolling:

1. Support a breast with one hand.
2. Place the nipple between the thumb and the index finger of the other hand. Proper placement of the thumb and index finger on the nipple avoids the nipple surface (end) where the ducts open and includes the entire side of the nipple down onto the adjacent aspect of the areola.
3. Apply gentle pressure and roll the nipple back and forth as far as it will go between the thumb and finger without moving the placement of either on the nipple.
4. Roll the nipple for approximately 30 sec.
5. Repeat steps 1 to 4 for the other breast.
6. Avoid skin friction with light lubrication on the thumb and index finger, yet not so much lubrication that the nipple becomes too slippery to manipulate.

CHAPTER

63

Injection of Intradermal Sterile Water Papules for Relief of Low Back Pain in Labor

SARASWATHI VEDAM, CNM, MSN

Back pain in labor, especially when caused by an occiput posterior position, is one of the most challenging conditions for the midwife to treat effectively. The tension caused by this pain has been associated with prolonged labor, increased need for pain medication, and prevention of the spontaneous rotation of the vertex to an anterior position. Several techniques have been reported to be helpful, including massage, counterpressure, applied heat or ice, transcutaneous electrical nerve stimulation (TENS), and hydrotherapy. However, most of these offer only partial relief with constant application by another person.

Methods of counter–irritation, acupuncture, and sterile water or saline injections have been used for many years to effectively treat back pain associated with renal colic, sacral pain, and whiplash injuries [1–6]. These techniques have been recently adapted for use in labor. A few controlled studies of intradermal sterile water injections have reported significant analgesic effects lasting 2 to 3 hours in 85 to 90 percent of women [7–11]. This technique offers the advantages of needing minimal, readily available equipment, adaptability to any setting, simplicity of application, and nearly immediate relief with lasting effects. The main disadvantage is the sensation of intense burning or stinging at time of application. This effect lasts 30 to 90 seconds.

The onset of relief occurs within 2 minutes of injection and usually lasts 2 to 3 hours. The technique may be repeated up to three times, but some women will decline reapplication because of the initial burning. Some women will experience no relief or only partial relief. The exact location of the injected papules can influence the effectiveness. Hence, prior to injection, the midwife should assess both fetal position and individual preferred focal points for pressure.

Method

1. Explain procedure to woman and support persons, including benefits, risk, expected onset of relief, and side effect of burning at site for 30 to 90 seconds. Prepare woman and support persons with methods of maintaining an immobile position and coping with discomfort during procedure.

Rationale

1. Informed consent is recommended for any obstetrical procedure. Prior understanding of the method may facilitate acceptance and tolerance of side effect as well as ease of application.

Method	Rationale
2. Place woman in a sitting, kneeling, or standing position, stabilizing herself with her arms and hands as she leans forward slightly. Expose her lower back enough to visualize the sacral dimples which correspond to the dorsal sacral foramina.	**2.** The injection sites in the sacral area will be more visible when the woman leans forward and flattens her back. She is most capable of providing an immobile surface when she supports herself.
3. Place and press the pads of your index fingers and thumbs into the sacral dimples so that your fingertips touch the corners of a trapezoid (see Figure 63-1). Move them very slightly laterally and vertically until the woman indicates the points of greatest relief.	**3.** The degree of relief provided by this pressure can indicate the best location for injection sites.
4. Have an assistant draw a half-circle around your fingertips while they remain in place. If you are alone you can ask a support person for help or use your own hands alternately.	**4.** The injection site must be exactly over the points of pressure that bring the woman relief. When you remove your fingers you may not be able to recognize the points without a landmark.

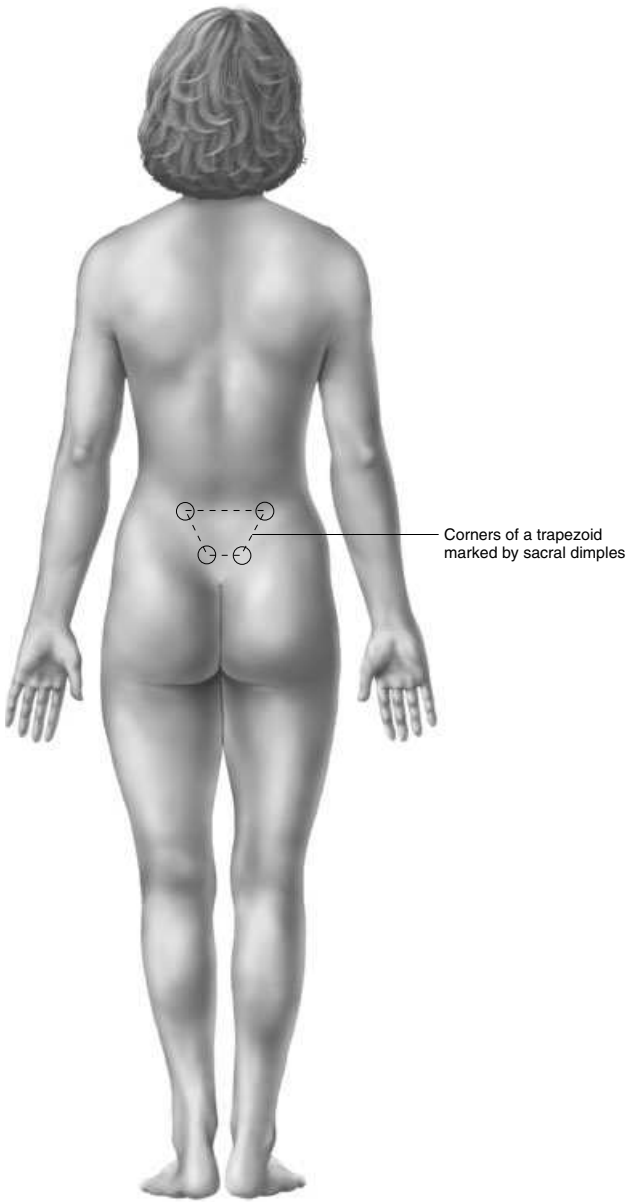

FIGURE 63-1 Injection sites for sterile water papules.

Method	Rationale
5. Draw up or have an assistant prepare a 1-cc syringe with 0.6 mL of sterile water and a 25-gauge needle.	**5.** You will create a papule with 0.1 to 0.15 mL of injected sterile water at each of 4 sites.
6. Remind the woman that she will feel temporary burning and stinging as you place the papules.	**6.** Preparation may enhance her ability to keep still for the procedure.
7. Clean the sites with an alcohol swab, taking care not to erase the marks. Inject 0.1 to 0.15 mL intradermally in each of the 4 points you have delineated (within the half-circle mark) until the distended skin forms a blanched 1-cm bleb or papule. If you have an assistant, two papules may be injected simultaneously to reduce the burning episodes by half.	**7.** The papules will provide the pressure or counter-irritation analgesia. Simultaneous injection may enhance the woman's willingness to repeat the procedure if necessary.
8. The onset of relief should occur within 2 minutes. If the relief is uneven the woman can usually tell you which side needs to be replaced. Once the effects have worn off (in 1 to 3 hours depending on the woman and the baby's position and station), the papules may be replaced with the woman's consent. More than three applications may not be advisable.	**8.** If the relief is uneven, the area of less analgesia is often consistent with a bleb that is noted to absorb too quickly, is misplaced, or was injected too deeply. Replacing the papule slightly laterally or vertically often achieves the desired effect. The cumulative local irritation may make the reapplication more uncomfortable and the available sites for injection will be reduced with successive applications.
9. Dispose of the needle(s) and syringe(s) in a biological hazardous waste disposal receptacle.	**9.** Protect yourself and others from needle injury or bloodborne pathogens.

CHAPTER

64

Inserting an Intrauterine Pressure Catheter; Amnioinfusion

The intrauterine pressure catheter (IUPC) is used for two different purposes: internal monitoring of the contractions for evaluation of the fetal heart, and amnioinfusion. Use of an intrauterine pressure catheter requires that there be an indication for an invasive procedure, spontaneous or artificial rupture of the membranes, and at least 1- to 2-centimeters cervical dilatation.

You need to become familiar with the type of internal monitoring device used in your practice or institution, as there are many different makes and models. Some of the newer catheters are made of a firmer plastic, do not require fluid filling or a guide, and may be zeroed while inserted. The procedure for insertion of these newer catheters is the same as the procedure described here except the catheter acts as its own guide and there is nothing to remove after insertion.

Most catheters have built-in ports for amnioinfusion, which allow for simultaneous instillation of fluid and monitoring. You will need an assistant to help you with this procedure, especially if using a fluid-filled catheter.

Procedure	Rationale
1. Explain to the woman why you wish to place an intrauterine pressure catheter. Discuss the information you hope to gather from the use of the monitor, what the woman will feel during and after insertion of the catheter, and the benefits and risks of internal monitoring, and answer any questions the woman or her partner or support person may have. Get the woman's consent for the procedure and chart the content of this discussion and her agreement to the procedure.	**1.** Your goal is to elicit cooperation and make the woman a participant in her health care decisions. Informed consent ensures that she understands and agrees to the procedure. Charting your discussion and her agreement is good risk management for you.
2. Gather all necessary equipment and ensure it is in working order. You will need the following: **a.** the catheter **b.** sterile gloves **c.** adhesive tape **d.** an electronic fetal monitor with the capability for internal monitoring **e.** if the catheter is fluid-filled, you will also need the following:	**2.** Gathering all equipment before you begin allows you to proceed smoothly and ensure that sterility is maintained.

Procedure	Rationale
(1) sterile normal saline or bacteriostatic water	**(1)** used to flush and fill the catheter
(2) 10-mL syringe	
(3) appropriate connecting devices	**(3)** see manufacturer's instructions for details on assembling the particular catheter you will be inserting
3. See steps 2 through 9 under "Preparatory and General Procedures" for the pelvic examination (Chapter 56, pages 1169–1171).	**3.** Following these steps makes the procedure as comfortable as possible and protects the woman's privacy and modesty.
4. Place the woman in a supine position with the head of the bed slightly elevated and a small pillow or rolled towel under her right hip.	**4.** The pillow or towel provides a left tilt to relieve pressure on the aorta and inferior vena cava and avoid supine hypotension [1].
5. Have the woman separate her knees and let her legs drop to the sides as far as comfortable/possible.	**5.** This signals her readiness for the procedure and makes the examination and procedure easier for both of you.
6. Position yourself for comfort and maintenance of sterility.	**6.** A sterile insertion is essential to prevent infection.
7. Put on sterile gloves.	**7.** This is a sterile procedure to prevent intrauterine infection.
8. Establish a sterile field. Have sterile equipment unwrapped and placed on the field. If the catheter you will be inserting is fluid-filled, hand the end to an assistant to be flushed and filled with sterile normal saline or bacteriostatic water. The assistant then continues to hold the now nonsterile end of the catheter so it does not contaminate the sterile field.	**8.** This will maintain sterility of the procedure.
9. Perform a sterile vaginal examination, placing the fingers of your examining hand inside the internal os of the cervix. Note cervical effacement and dilatation and station of the presenting part.	**9.** Assessing the cervical status at the same time you are inserting the intrauterine pressure catheter decreases the number of vaginal examinations. Insertion of your fingers through the internal os, when possible, facilitates correct direction and proper placement of the catheter.
10. Place the catheter inside the guide and insert the guide into the cervical os. Be careful not to extend the tip of the guide beyond the tips of your examining fingers (see Figure 64-1).	**10.** Placing the catheter no further than the tips of your examining fingers ensures that the rigid guide, which is made of firm plastic, will not cause injury to the fetus, uterus, or placenta.
11. Hold the guide in place and advance the flexible catheter approximately 18 inches into the uterine cavity. You will know the catheter is in 18 inches when a mark on the catheter reaches the vaginal introitus.	**11.** Inserting 18 inches of catheter ensures that the catheter will reach the contractile uterine fundus.
12. The catheter should advance smoothly and easily with firm pressure. If you encounter resistance, *STOP*. Redirect the catheter by either changing the angle of the guide or moving the guide and the catheter 90° to a different cervical location [2]. Try again.	**12.** Resistance to the advance of the catheter may be due to fetal parts, the uterine wall, or the placenta. Use of excessive force could result in fetal injury, placental separation, or uterine rupture.
13. When the catheter is in place, hold it with your fingers while sliding the guide out of the vagina.	**13.** Holding the catheter prevents it from being pulled out with the guide.

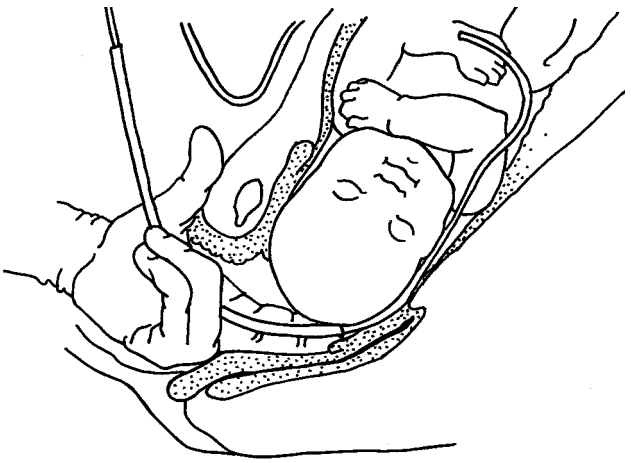

FIGURE 64-1 Insertion of intrauterine pressure catheter.

Source: From Freeman, R. K., Garite, T. J., and Nageotte, M. P. *Fetal Heart Rate Monitoring*, 2nd ed. Baltimore, MD: Williams and Wilkins, 1991, p. 47. Reprinted by permission.

Procedure	Rationale
14. Observe for return flow of amniotic fluid. If no fluid flows from the catheter, reevaluate placement.	**14.** Intraamniotic placement of the catheter will return at least a small amount of fluid. If no fluid return occurs, the catheter may be placed outside of the amniotic sac [3].
15. Flush the catheter and connect it to the monitor in accord with the manufacturer's directions.	
16. Tape the catheter to the woman's leg.	**16.** Prevents the catheter from being dislodged with maternal movement
17. Help the woman clean up and assist her into a comfortable position.	
18. Discard all materials, your gloves, and the guide in a hazardous biological waste receptacle.	
19. Evaluate the findings obtained by the intrauterine pressure catheter, readjust the monitor if necessary, then explain the results to the woman.

CHAPTER

65

Attaching a Fetal Scalp Electrode

Use of a fetal scalp electrode requires that there be an indication for an invasive procedure, spontaneous or artificial rupture of the membranes, and at least 1- to 2-centimeters cervical dilatation.

Because the tip of the electrode penetrates the fetal scalp, there is the possibility of trauma, bleeding, and infection. Attaching a fetal scalp electrode thus should be avoided, if possible, with unknown fetal presentations or presenting parts, with face presentations, or in the presence of a known vaginal infection (e.g., herpes, gonorrhea, chlamydia, HIV) or unexplained bleeding (may be placenta previa) [1–3]. Attachment of a fetal scalp electrode is always done under aseptic conditions to prevent both infection of the fetal scalp and intrauterine infection.

Procedure	Rationale
1. Explain to the woman why you wish to place a fetal scalp electrode. Discuss the information you hope to gather, what the woman will feel during and after the procedure, and the benefits and risks of fetal scalp monitoring, and answer any questions the woman or her partner or support person may have. Get the woman's consent for the procedure and chart the content of this discussion and her agreement to the procedure.	**1.** Your goal is to elicit cooperation and make the woman a participant in her health care decisions. Informed consent ensures that she understands and agrees to the procedure. Charting your discussion and her agreement is good risk management for you.
2. Gather all necessary equipment and ensure it is in working order. You will need the following: **a.** the fetal scalp electrode assembly **b.** sterile gloves **c.** an electronic fetal monitor with the capability for internal monitoring **d.** leg plate with Velcro strap or adhesive patches and cable to fetal monitor **e.** conductive jelly	**2.** Gathering all equipment before you begin allows you to proceed smoothly and ensure that sterility is maintained.
3. Attach the leg plate to the woman's thigh.	**3.** The leg plate is now ready for you to attach the wires from the spiral electrode.
4. See steps 2 through 9 under "Preparatory and General Procedures" for the pelvic examination (Chapter 56, pp. 1169–1171).	**4.** Following these steps makes the procedure as comfortable as possible and protects the woman's privacy and modesty.

Procedure	Rationale
5. Place the woman in a supine position with the head of the bed slightly elevated and a small pillow or rolled towel under her right hip.	**5.** The pillow or towel provides a left tilt to relieve pressure on the aorta and inferior vena cava and avoid supine hypotension [1].
6. Have the woman separate her knees and let her legs drop to the sides as far as comfortable/possible.	**6.** This signals her readiness for the procedure and makes the examination and procedure easier for both of you.
7. Position yourself for comfort and maintenance of sterility.	**7.** A sterile insertion is essential to prevent infection.
8. Put on sterile gloves.	**8.** This is a sterile procedure to prevent fetal scalp and intrauterine infection.
9. Perform a sterile vaginal examination.	**9.** A sterile exam is necessary to prevent infection.
a. Note cervical effacement and dilatation, and station of the presenting part.	**a.** Assessing the cervical status at the same time you are attaching a fetal scalp electrode decreases the number of vaginal examinations.
b. Identify the presenting part. If the presenting part is vertex, locate the suture lines and fontanels. If the presenting part is the breech, assess for location of the genitalia.	**b.** The electrode should be attached over cranial bones, not on suture lines or fontanels. In a breech presentation, the electrode may be attached to the fetal buttocks but not on the genitals.
10. Advance the guide tube between your examining fingers. Be sure the spiral end of the electrode within the drive tube is withdrawn 1 inch inside the guide tube (see Figure 65-1).	**10.** Advancing the tube between your fingers avoids injury to maternal tissue by the guide tube and by the spiral electrode during insertion through the vaginal and cervical canals. This technique also ensures that the spiral electrode that is to be inserted into the fetal scalp remains sterile.
11. Place the guide tube firmly against the fetal presenting part where you are going to attach the fetal scalp electrode at a right angle.	**11.** and **12.** This ensures firm and complete attachment of the spiral electrode into the fetal presenting part.
12. Stabilize the guide tube between your two internal examining fingers. Grasp the drive tube with your external hand. Advance the drive tube containing the fetal scalp electrode until the drive tube and electrode reach the presenting part.	
13. Rotate the drive tube clockwise one full turn until you feel mild resistance and the drive tube recoils. One full turn (360°) is enough.	**13.** Rotating the drive tube causes the tip of the spiral electrode to penetrate the fetal scalp and be attached. Turning the drive tube more than 360° may cause tissue injury [1]. The electrode penetrates the presenting part 1.5 millimeters [3].

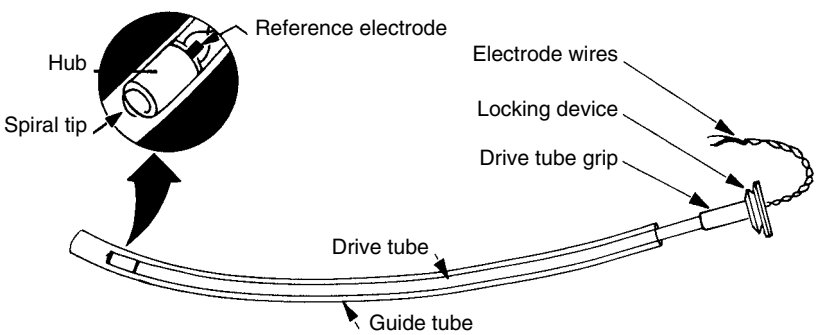

FIGURE 65-1 Fetal monitoring spiral electrode assembly.

Source: Adapted from *Disposable Spiral Electrode for Fetal Monitoring: Instructions for Use*. Andover, MA: Hewlett Packard. Reprinted by permission.

Procedure	Rationale
14. Release the locking device on the drive tube.	**14.** This will free the electrode from the drive tube.
15. Carefully remove the drive and guide tubes so as not to disturb the attachment of the electrode.	**15.** This will free the electrode wires so they can be attached to the leg plate and allows for disposal of the drive and guide tubes.
16. Attach the electrode wires to the leg plate and the cable from the leg plate to the fetal monitor.	**16.** This allows for direct monitoring of the fetal heart tones.
17. Help the woman clean up and assist her into a comfortable position.	
18. Discard all materials, your gloves, and the guides in a hazardous biological waste receptacle.	
19. Evaluate the findings obtained by the spiral electrode, then explain the results to the woman.

CHAPTER

66

Perineal Prep (Cleaning)

The perineal cleansing prep is a procedure for making the perineum and surrounding region as clean as possible. The same basic procedure is followed regardless of when it is done for whatever reason (e.g., birth, sterile vaginal examination).

This procedure follows the principle of going from inside to outside (from a central point to the periphery), with inside being the area that requires cleaning and outside being the periphery or adjoining region. The inside therefore becomes the point of emphasis for both cleansing and avoiding contamination.

The purpose of this procedure is to clean, and merely passing lightly over the skin surface with cotton balls or 4 × 4s thwarts this purpose. Scrubbing—not so vigorous as to be painful but vigorous enough to cleanse—is called for.

The solutions used for the perineal cleansing prep vary, and therefore this discussion will not elaborate on them; rather, it will deal only with the mechanics of the actual cleaning itself. The use of cotton balls or gauze 4 × 4s also varies from setting to setting. This discussion will refer to 4 × 4s, with the understanding that cotton balls can be used instead.

The procedure is actually a series of steps to be gone through in the sequence presented. The sequence is important in order to avoid contamination of the perineal area. Dry 4 × 4s are held over the introitus during the first three series of scrubbing strokes.

1. The first series of scrubbing strokes begins at the level of the clitoris and moves back and forth across the mons pubis upward onto the lower abdomen (see Figure 66-1).
2. The second series of scrubbing strokes begins in the crease of the groin between the thigh and the lateral edge of the labia majora on one side and moves back and forth across the width of the inner thigh to midway up to the knee.
3. The third series of scrubbing strokes is the same as the second series only on the opposite side.

These first three series of scrubbing strokes direct any excess cleansing fluid to the outside and also ensure that contamination from the outside is not brought to the inside.

4. With very short back-and-forth motions (approximately 1 inch in length), scrub the labia majora on one side from the level of the clitoris downward past the level of the anus to the level of the bed or table.
5. Do the same on the opposite side.
6. With a single downward motion from front to back (or top to bottom) cleanse the vulva, perineum, and anus.

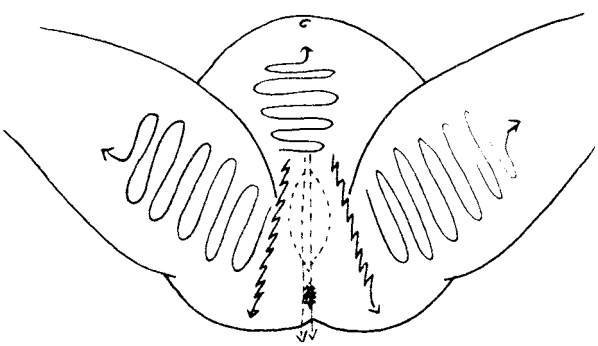

FIGURE 66-1 Cleaning the perineal area.

7. Repeat step 6 with a fresh 4 × 4. This is the one area cleansed twice.

Steps 4, 5, 6, and 7 are designed to avoid any contamination of the perineum or vulva from the anal area. In all of the above steps more than one 4 × 4 may be used at a time but none is reused. They are used once for a step and then discarded.

8. If any remaining solution is poured over the area it should be poured at the level of the vulva downward in order to avoid the contamination that would occur if the solution were poured higher over surrounding skin surfaces.
9. The wet underpad beneath the woman is removed and replaced with a dry sterile underpad.

CHAPTER

67

Second Stage Pushing

There are three reasons why it is important that a woman know how to push effectively during the second stage of labor. First, although maternal pushing effort is normally a natural response to a reflex mechanism, it is at times necessary for the woman to push without the benefit of the stimulating reflex mechanism. Second, a woman may feel like pushing but pushes so ineffectually that progress is inhibited. Third, a woman with epidural analgesia/anesthesia, which blunts the natural urge to push, will need assistance with pushing.

A number of techniques can enhance the maternal pushing effort and can change ineffectual pushing into effective maternal pushing.

Breath Control

The woman should be told either to push while exhaling, or to push after expiration as a forced exhalation, for short periods of time (5 to 6 seconds). This latter type of pushing often will be accompanied by a grunt. In such an effort the glottis is at least partially open, the abdominal muscles are shortened and contracted against the uterus, and the intrathoracic pressure doesn't increase to interfere with the venous return to the heart and produce its resulting effect on cardiac output and arterial pressure.

In contrast, the closed glottis type of pushing occurs when a woman is instructed to take a deep breath and hold it while she pushes for as long as she can—usually to a count of 10. However, it is possible that this kind of breath holding combined with prolonged bearing down may produce fetal hypoxia and acidosis, because holding her breath closes the mother's glottis and bearing down increases the intrathoracic pressure. This combination results in a drop in arterial pressure caused by decreased cardiac output due to diminished venous return to the heart. Decreased arterial pressure has two effects: it decreases blood flow to the placenta and decreases oxygen content in the blood that does circulate to the placenta. Fetal hypoxia may be prevented if the woman is given the open glottis pushing instructions.

Body Position

A woman can push in any position—on her back, on her side, on her hands and knees, kneeling, standing, or squatting. Her position depends on her preference and on the baby's and her own condition or situation. Squatting has the advantage of adding the effect of gravity to the bearing down effort. Upright positions (squatting, sitting, standing) may shorten the total length of labor. Second stage is facilitated because of the increased pressure of the fetal head on the pelvic floor and the improved alignment of the fetus with the pelvis (see Chapter 28).

Several techniques for effective pushing can be instituted best or only when the woman is in an elevated (reclining) position on her back. The following instructions are to be used when the woman is on her back. All of them must be done in order to enhance pushing effectiveness. Using one alone will not accomplish the desired effect.

When the woman starts her breathing for pushing, she brings her legs up and apart. She raises up

and curves her back, tucks her chin down onto her chest, and grasps either her knees or behind her thighs with her hands. Pillows, backrests designed for this purpose, or an arm placed underneath her shoulders help her get into the raised, curved-back position. In out-of-hospital settings the woman's partner or a support person may sit behind the woman. The importance of this position is that it directs the woman's pushing effort in the right direction. Many women arch their backs rather than curving their backs. This wastes their pushing effort because it decreases the force they could get behind the push if they were properly positioned.

Many women spoil their effort by letting their heads hang back. This posture diverts some of the pushing effort to the throat; in addition, it is distracting, since this is an uncomfortable position. If the woman starts a contraction with her head back and is unable to change and tuck her chin onto her chest, lift and support her head with a hand behind her head.

Grasping either her knees or behind her thighs with her hands serves two purposes: it helps her get into and maintain the curved position of her back and it provides her with something to pull back on as she pushes down. Another option to counterbalance her push, when in a standing or squatting position, is to pull down on an overhead rope or bar or press down on supportive arms.

Arm Position and Action

The maternal pushing effort is greatly facilitated if the woman has something to pull back on while she pushes down; this gives her a counterforce to push against. If grasping her knees or behind her thighs is not feasible, there are other means of providing a counterforce. In the hospital, the handlebars on the delivery room table serve this purpose, as do the bars on the side rails of her hospital bed. The best alternative in all settings is to have two people stand or sit on the bed on either side of the woman, below the level of her hips, facing her, and each extend a hand to her underneath her leg to grasp. As she pulls against these hands the two people also pull sufficiently to maintain their position and provide a counterbalance to her pulling.

How the woman pulls back is also important. Pulling straight back tends to throw her body out of its curved position and may cause her to arch her back. Therefore, her elbows should be bent and out from her sides as though she were rowing a boat. This will maintain her proper body position.

Pubic Pressure

This technique is done by someone other than the woman. It is used if the woman seems to be having some difficulty in pushing in the right place. The admonition to "bear down as if you were having a bowel movement" not only lacks in aesthetic quality but also misdirects the pushing effort more posteriorly than is optimal.

With the edge of your slightly cupped hand, apply mild pressure immediately above the symphysis pubis and instruct the woman to push against your hand. This directs her pushing effort more properly anteriorly and involves the maximum use of her abdominal muscles. The woman's bladder should be empty.

Vaginal Stimulation

This technique is also done by someone other than the woman. In instances when it is mandatory for the woman to push but she does not feel the urge to push, it is possible to stimulate the perineal floor reflex mechanism by simulating the pressure of the presenting part with your fingers. As the woman pushes, you insert two or three fingers into her vagina and firmly press down on the posterior vaginal wall. In keeping with the philosophy of nonintervention in normal processes and the principle of as little vaginal manipulation and examination as possible in order to reduce the possible introduction of infection, this technique is used only when absolutely indicated. Generally it is quite effective.

CHAPTER

68

Pudendal Block

Pudendal block is a regional anesthesia in which the pudendal nerve is blocked, or anesthetized. Pudendal block has these advantages:

1. It anesthetizes the perineum and vulva including the clitoris, labia majora, labia minora, perineal body, and rectal area.
2. It has no effect on the uterus or its contractions.
3. It poses minimal potential danger to the mother, provided the proper medication is used in proper amounts and is not inadvertently given intravenously.
4. It poses minimal potential danger to the baby if care is taken not to inadvertently give the anesthetic agent intravenously.

With the exception of local infiltration of the perineal body, as described in Chapter 69, pudendal block is by far the safest obstetric anesthesia known.

The anesthetic agent usually used in pudendal block is 1% lidocaine hydrochloride (Xylocaine), 10 mg/mL, although a number of other local anesthetics can be used. The length of effect of the anesthesia depends on the success of the pudendal block and on the medication. An effective block with lidocaine will last approximately $1\frac{1}{2}$ hours. Lidocaine has the advantage of being fast-acting. The amount used is 10 mL (100 mg) per side. The maximum safe total dosage of lidocaine is 500 mg. If you use 200 mg for the pudendal block, you will be able to use another 100 mg for a quick local infiltration of the perineal body if the pudendal block failed, and have some remaining, if needed, for further local infiltration for repair of the episiotomy or lacerations.

The pudendal nerve arises from the pudendal plexus, which is formed by branches of the second, third, and fourth sacral nerves. The pudendal nerve is the largest branch of the pudendal plexus and leaves it as a single nerve trunk. The pudendal nerve passes across the posterior surface of the sacrospinous ligament just as this ligament attaches to, or within 0.5 to 1.0 centimeters of, the ischial spine as the nerve momentarily leaves the pelvic cavity from the greater sciatic foramen and reenters the pelvic cavity in the lesser sciatic foramen (Figure 68-1). It is helpful to remember that it is the projection of the ischial spine that divides these two foramina. As the pudendal nerve enters the lesser sciatic foramen, it enters Alcock's canal, which directs the pudendal nerve anteriorly to the inferior ramus of the ischium and pubis. As it courses through Alcock's canal, the pudendal nerve divides into three main branches: (1) the inferior hemorrhoidal nerve, (2) the perineal nerve, and (3) the dorsal nerve of the clitoris. Each of these branches further subdivides to become the primary nerve supply of the perineum.

Thus the art of successfully performing a pudendal block lies in three things:

1. Knowing the pertinent anatomy
2. Identifying accurately, by palpation, the ischial spine and also, ideally, the sacrospinous ligament
3. Placing the anesthetic agent properly in relation to the ischial spine

The technique of pudendal block described here is the transvaginal route. A long, 12- to 15-centimeter (5- to 6-inch) 20- or 22-gauge needle is used, with or

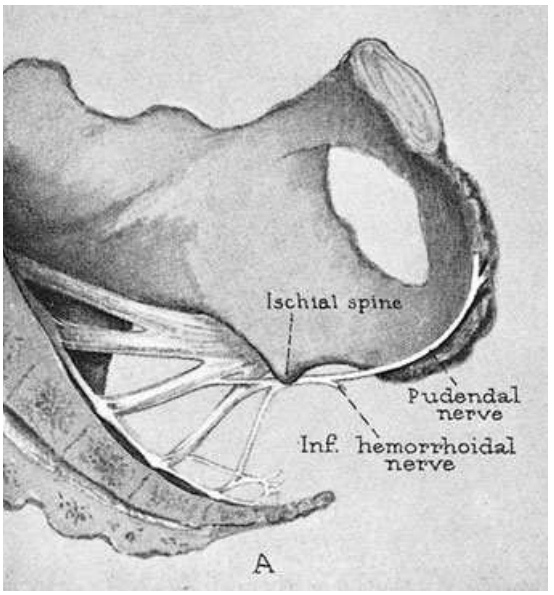

FIGURE 68-1 Relationship between the pudendal nerve and the bones of the pelvis.

without a needle guide (see Figure 68-2). A needle guide is usually used if one is available; the most commonly used guide is an Iowa trumpet. Whatever is used, the needle guide should allow for the needle to protrude 1.5 centimeter beyond the end of the needle guide. A 10-mL syringe with a Luer-Lok attachment completes the necessary equipment in addition to the medication (poured into a medicine glass).

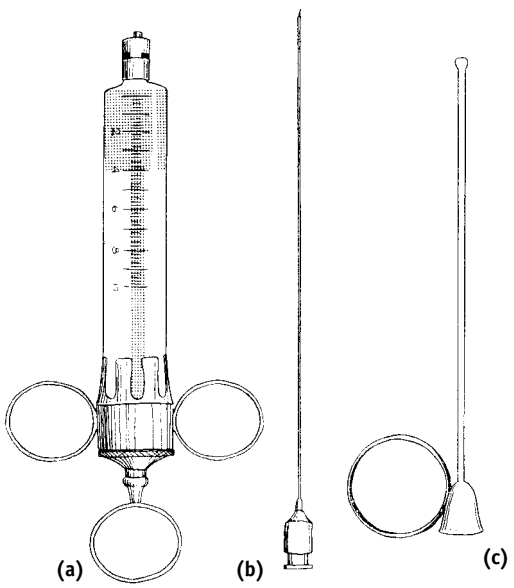

FIGURE 68-2 Equipment used for pudendal block: (a) 10-mL syringe; (b) 6-inch, 20-gauge needle; and (c) Iowa trumpet needle guide.

Source: From Bonica, J. J. *Principles and Practice of Obstetric Analgesia and Anesthesia*, Vol. 1. Philadelphia, PA: Davis, 1967, p. 495. Reproduced by permission.

If there is no needle guide, you can prevent the needle point from catching on the vaginal mucosa during insertion by holding the needle parallel in the groove between your two examining fingers with the point between your fingertips. If an Iowa trumpet is used, it is inserted first once your examining fingers have located the ischial spine, positioned, and then the needle with the syringe attached is inserted through this needle guide.

First you palpate the ischial spine. Use your left hand as the vaginal hand when palpating the woman's left ischial spine and your right hand as the vaginal hand when palpating the woman's right ischial spine. Then you insert the needle guide and position the end of it immediately beneath and medial to the inferior, medial border of the ischial spine (see Figure 68-3). Palpate the sacrospinous ligament. The protrusion of the needle is then inserted posterior to the ischial spine, through the sacrospinous ligament to the space occupied by the pudendal nerve and vessels. You will feel a slight give as the needle exits from the sacrospinous ligament and enters this space. This is a distance of approximately 1 to 1.5 centimeters (around $^1/_2$ inch) from the end of the needle guide.

Aspirate. Turn the needle 180° and aspirate again in order to assure yourself that the needle is not in a blood vessel and that the lack of blood return on the first aspiration was not merely caused by the bevel of the needle being snug against the inner wall of the vessel. This careful aspiration is a safeguard to ensure the safety of the procedure and must be performed deliberately as part of the procedure. This precaution is necessary because the internal pudendal artery and internal pudendal vein are immediately adjacent to the pudendal nerve, with the pudendal nerve actually lying between the posterior surface of the sacrospinous ligament and the internal pudendal vessels.

Intravenous injection of any of the local anesthetics will most probably cause maternal toxic reactions (possibly including respiratory depression, convulsions, and death) and fetal distress or neonatal depression. Great care must be taken to prevent inadvertent intravenous administration of the local anesthetic while performing a pudendal block. After assuring yourself that you do not have the needle point in a blood vessel, inject 10 mL of 1% lidocaine (100 mg).

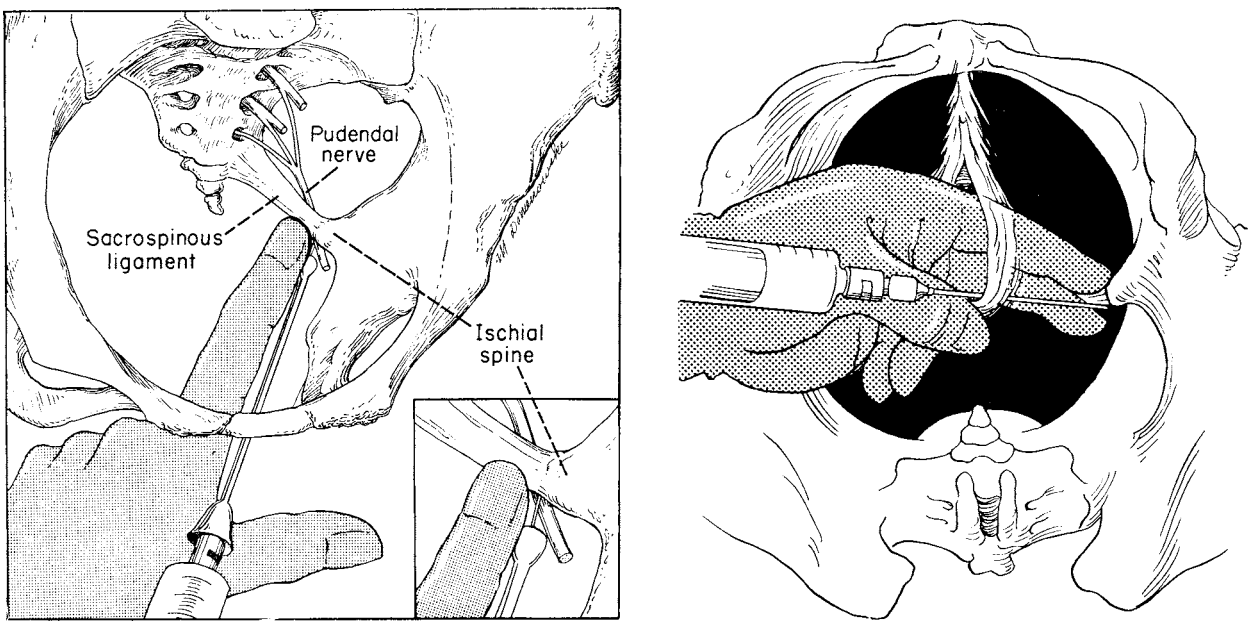

FIGURE 68-3 Position of the needle for pudendal nerve block using the transvaginal approach. (a) Superior view of the pelvis showing how the index finger is used to direct the needle point as it approaches the ischial spine. The figure illustrates the use of the Iowa trumpet guide. (b) The syringe is directed downward and laterally to pierce the vagina just below the projection of the ischial spine. In the final position the needle is parallel with the mother's longitudinal axis.

Source: From Bonica, J. J. *Principles and Practice of Obstetric Analgesia and Anesthesia*, Vol. 1. Philadelphia, PA: Davis, 1967, pp. 494, 495. Reproduced by permission.

Repeat the entire procedure for the other side. After injecting both sides and waiting a few minutes, test the effectiveness of the block by using a sharp object, such as a needle, to scratch along each side of the perineal area (both sides need to be evaluated). Confirmation of effectiveness for each side is from two sources: (1) the woman's lack of verbal complaint even when asked and (2) visual observation of a lack of anal sphincter or vaginal orifice contraction.

If the pudendal block is ineffective and you plan to cut an episiotomy, do a local infiltration as described in Chapter 69.

This page intentionally left blank

CHAPTER

69

Local Infiltration

Perineal local infiltration before birth is done to anesthetize the area to be cut for an episiotomy and its subsequent repair. Local infiltration done after birth but before or during repair of an episiotomy or lacerations is to anesthetize the area to be repaired. At times the effects of a local infiltration done before birth may last throughout any repair work. At other times the effects may have worn off before the repair is completed or even begun, or the laceration may extend beyond the area originally anesthetized. Local infiltration of the unanesthetized area is then necessary.

Local Infiltration Before Birth

Local infiltration prior to birth is usually chosen as the method of anesthetizing the perineal body in the following circumstances:

1. When administration of a pudendal block has failed
2. When second stage has been so rapid as not to allow time for performance of a pudendal block
3. When the decision to perform an episiotomy is a last-minute decision, reversing an earlier decision not to do an episiotomy, and the fetal head is too low to do a pudendal block
4. When the woman has stated a preference for this mode of anesthesia if any anesthetic is indicated at all

Local infiltration is a second choice; a pudendal block is preferable. The primary reason is that a pudendal block anesthetizes a larger area (including the lower vaginal tract as well as the perineum) and provides anesthesia that does not distort the tissues for repair.

There are two techniques for local infiltration of the perineal body. Both techniques use a 22-gauge, $1\,^1/_2$-inch (4-centimeter) needle attached to a syringe that holds at least 10 mL. Longer needles and larger syringes can be used but the gauge should not be any larger. The medication is usually 1% lidocaine hydrochloride (Xylocaine), 10 mg/mL, although a number of other local anesthetics can be used.

The standard (but not necessarily always the most efficacious) technique is to insert the needle point at the center of the fourchet and then fan the injection centrally, to both sides of center, and in both the anterior and the posterior planes of the perineal body. The disadvantage of this technique, when compared with the other possible technique, is that it takes more time to perform, is more awkward for learners, and entails considerable relocating of the needle, which involves much backing up and repositioning of the needle and can increase the need for multiple sticks.

The second technique is simply to insert the needle at the center of the fourchet and direct the needle straight down the midplane toward the rectum without puncturing into that orifice. Then, after aspirating, up to a maximum of 10 mL (100 mg) of lidocaine is injected as the needle is slowly withdrawn. The desired effect is to create a large, visible, and palpable perpendicular wheal approximately $^3/_4$ to 1 inch wide and extending from top to bottom in the center of the perineal body (see Figure 69-1). If the plan is to cut a mediolateral episiotomy, then the direction of the needle and resultant wheal are in accord with the path this cut will

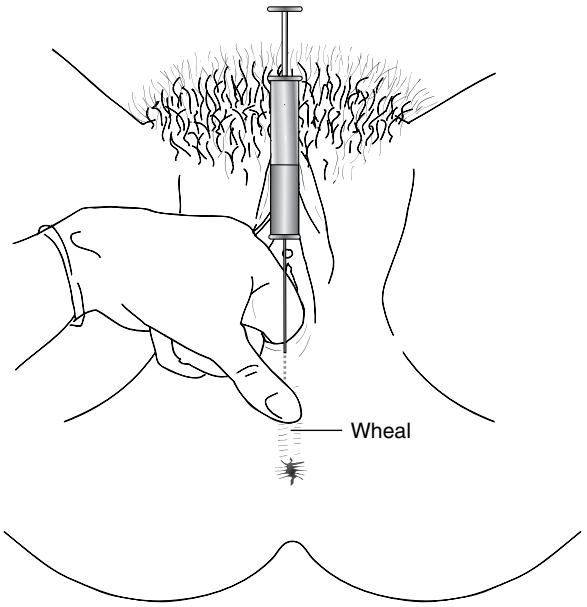

FIGURE 69-1 Local infiltration: central wheal.

take. This technique is very quickly performed and involves just one needle thrust.

The second technique is ideal because in the majority of cases when local infiltration is used it is done just shortly before birth, when the perineal body has thinned and flattened considerably. This allows for ready development of a broad wheal since there is little anteroposterior tissue and only one plane. In fact, this poses the one difficulty with performing a local infiltration: The perineal body is so flattened that it is easy to pierce the posterior wall and insert the local anesthetic uselessly into the vagina. This problem can be avoided by observing carefully and positioning a finger posterior to the insertion line to detect if this happens. To rectify the problem, merely withdraw the point of the needle until it is again within tissue and redirect it so it will stay within the tissue of the perineal body.

Local Infiltration for Repair After Birth

Local infiltration is used when anesthesia is needed for repair of a laceration or episiotomy and either (1) predelivery anesthesia has worn off, (2) a postdelivery pudendal block has failed, or (3) local infiltration is the mode of choice. The primary disadvantage of local infiltration for repair is that it distorts the tissue, thereby making tissue approximation and judgment of the tightness of the sutures more difficult.

The gauge and length of the needle and the amount of anesthetic agent used depend on the laceration. A 22-gauge, $1\,^1/_2$-inch needle is fine for infiltrating an episiotomy cut, a lacerated extension of one, or a vaginal sulcus tear. However, a smaller gauge needle should be used for smaller lacerations in more sensitive areas. For example, a 25-gauge, 1-inch needle would be the needle of choice for anesthetizing a clitoral laceration. The midwife must exercise judgment in making this selection.

The technique of local infiltration is to insert the needle point at the end or corner of the laceration or cut and run it the length of the wound along the line where the suture needle will be either entering or exiting. Then, after aspirating, the anesthetic agent is injected as the needle is withdrawn to the point of insertion. Injection of the medication is stopped while the needle is redirected along another line of projected suturing, and the process is repeated until the entire area of possible pain is anesthetized.

CHAPTER

70

Hand Maneuvers for Birth with the Mother in Lithotomy or Modified Lithotomy Position

The most comprehensive and precise hand maneuvers are for birth of the baby in the birth position of occiput anterior (OA) when the mother is in lithotomy position or a modified lithotomy semi-sitting position with the labor/delivery table/bed broken or at the edge of a bed (end or side) with her feet on chairs. These hand maneuvers are designed to (1) effect a safe, atraumatic birth for the baby, (2) facilitate the mother's efforts in giving birth to her baby with minimum possible trauma to herself, and (3) give you a feeling of absolute security and control in handling the baby, confidence in what you are doing, and free you from fears of the baby slipping out of your hands.

The following pages and Figure 70-1 describe in detail what to do with your hands every moment of the actual birth of the baby. It is strongly suggested that before you help a mother give birth to her a baby, you practice these hand maneuvers until you are comfortable with them, can readily adjust them to whichever way the baby's head rotates during restitution and external rotation, and can use them smoothly no matter how fast the baby might come. For practice you need someone else to serve as the power to manipulate a doll through a pelvis or anything with a hole large enough to simulate a pelvis and accommodate the doll. Have this person vary the rate of speed of birth and the direction of restitution and external rotation.

These same hand maneuvers are applicable for babies who birth in the occiput posterior position, with the exception of the direction of pressure exerted for control of the birth of the head. This is also true for babies who birth with a face presentation; once the head is out, the remaining hand maneuvers are the same.

The hand maneuvers differ after birth of the baby's head if the mother is in a dorsal position. The dorsal position hand maneuvers are detailed in Chapter 71. Knowing the comprehensive hand maneuvers for the lithotomy or modified lithotomy position and for the dorsal position enables you to adapt them to facilitate the birth of babies with mothers in side-lying, hands and knees (see Chapter 72), squatting (see Chapter 73), or any other position.

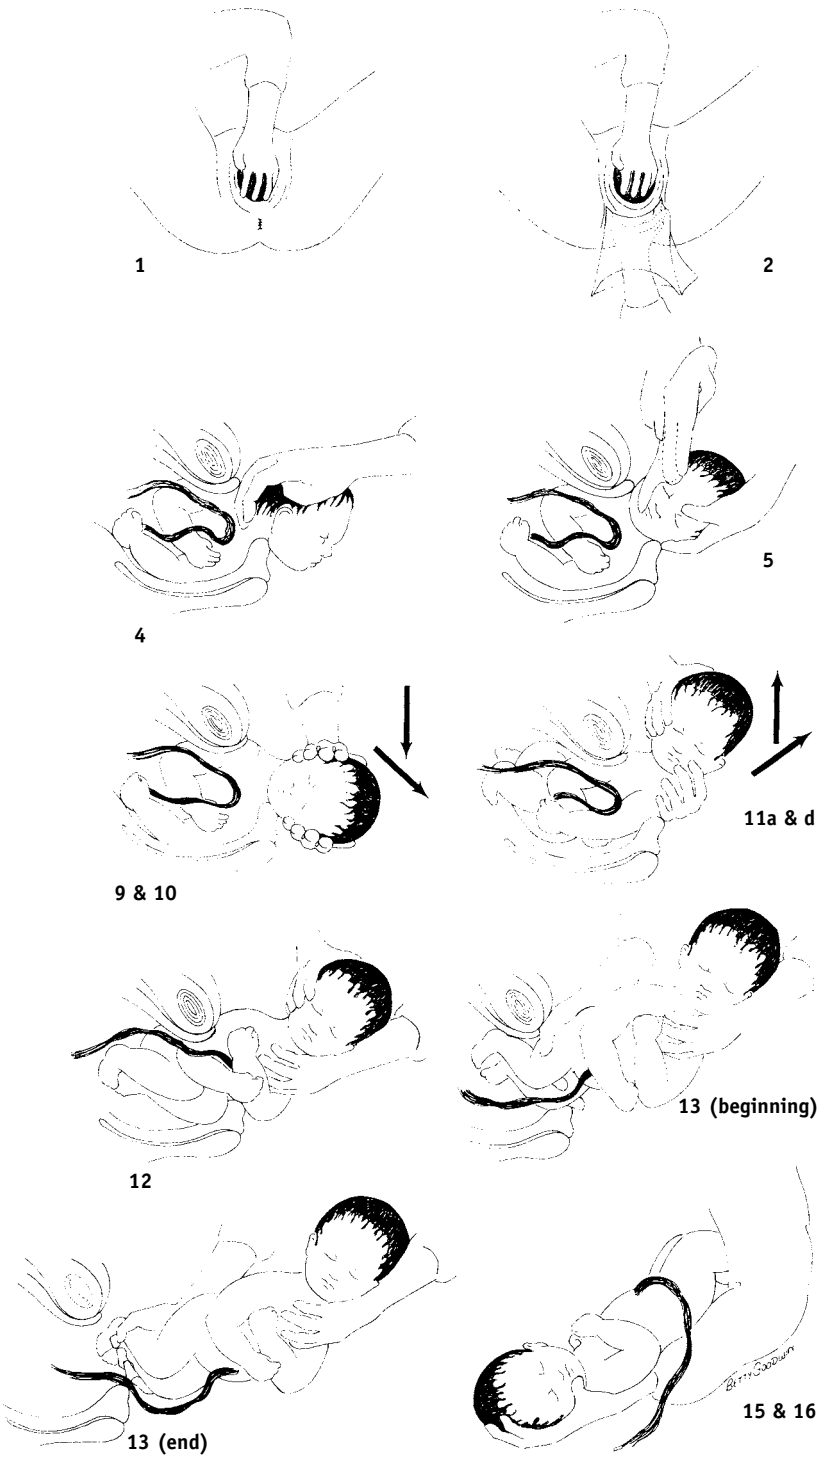

FIGURE 70-1 Hand maneuvers for birth of the baby in occipital anterior position with the mother in lithotomy or modified lithotomy position. Numbers correspond with the numbered paragraphs in the narrative text on the hand maneuvers and their rationale.

Hand Maneuver	Rationale
Stand or sit between the woman's legs at the foot or side of the delivery table or birth bed. The baby is in an occipital anterior position.	
1. For control of the baby's head place the pads of your fingertips on the portion of the vertex showing at the vaginal introitus. Be careful not to let your fingers slip inside the vagina alongside the head. As more of the head is accessible at the vaginal introitus, spread your fingers over the vertex of the baby's head with your fingertips pointing toward the as yet unseen face and your elbow pointing upward toward the mother. Allow the head gradually to extend beneath your hand by exerting a controlling, but not prohibitive, pressure with your hand. Use the length of your fingers in doing this and not just your fingertips. For head control, use the hand most comfortable for you. Most practitioners use their nondominant hand, leaving their dominant hand to handle any equipment or supplies that may be suddenly and quickly needed. For example, a right-handed person would use the left hand on the head, thereby leaving the right hand free for other actions.	**1.** Letting your fingers slip inside the vagina increases the possibility of introducing infection and increases the risk of tearing. Spreading your fingers over the vertex evenly distributes the pressure you are exerting, thereby avoiding any possibility of intracranial injury. Pressure applied at this time keeps the head flexed until the suboccipital region impinges under the symphysis pubis and extension begins. If the head is allowed to extend too soon, the result often is periurethral lacerations. Gradual extension of the head as the diameter changes from the suboccipitobregmatic diameter of 9.5 centimeters to the occipitofrontal diameter of 11.5 centimeters and then to the occipitomental diameter of 12.5 centimeters prevents the baby's head from popping out, which can cause intracranial injury, and reduces the possibility of trauma (lacerations) to the mother. Using the length of your fingers rather than just your fingertips more evenly distributes the pressure and also enables you to have better control, as you are in contact with more of the head and you can better adjust the pressure as needed.
2. Some midwives believe that proper control of the head will preserve the perineum and result in birth over an intact perineum. Others believe that it is necessary to support the perineum in addition to controlling the head in order to achieve this result. If you want to try supporting the perineum in order to make up your own mind about the efficacy of this technique, it is most important that you do it correctly. It is incorrect simply to place your hand against the perineum and press. The correct method is as follows:	**2.** Pressing on the perineum serves only to place additional stress on the perineum and to obliterate your view of the perineum.
a. Cover the hand not being used on the baby's head with a towel.	**a.** The towel prevents your hand from being contaminated by accidentally brushing against the rectal orifice.
b. Place your thumb in the crease of the groin midway on one side of the perineum.	**b.**, **c.**, and **d.** Placing your thumb and middle finger in the crease of the groin on either side of the perineum (perineal body) avoids placing stress on the perineum itself. The downward pressure includes more tissue in the action, and the inward motion distributes any additional tissue toward the crucial midpart of the perineum, thereby providing a little give to relieve the strain there.
c. Place your middle finger in the crease of the groin midway on the other side of the perineum.	
d. Apply pressure with the thumb and finger downward and then inward toward each other and the middle of the perineum (perineal body).	
e. Be sure to keep your hand parallel to the perineum while doing this in order to be able to observe the perineum in the space between your thumb and middle finger and your hand.	

Hand Maneuver	Rationale
3. Watch the perineum while the head extends and is born.	**3.** You should be sure to observe the final stretching of the perineum. Thin white lines appear immediately prior to the perineum tearing. This would be an indication to increase perineal support. Some clinicians would cut an episiotiomy. Watching the perineum also keeps your other hand away from the perineum if you're not supporting the perineum, thereby preventing the possibility of contaminating it on the anal opening and causing subsequent infection.
4. As soon as the head is born, place the fingertips of one of your hands on the occiput and then slide them down the curve of the baby's head to the baby's back at the level of the top of the shoulders and sweep them in both directions, feeling for the umbilical cord. Most midwives use their dominant hand for this maneuver, as it is the hand most accustomed and sensitive to touch.	**4.** This maneuver is done to determine if the umbilical cord is around the baby's neck and, if it is, to judge how tight it is as a basis for deciding how to manage the situation. Starting at the occiput helps locate where you are on the baby. It is easy for inexperienced fingers to get confused and have difficulty identifying what they are feeling during this maneuver because the neck of a baby is short. Sliding your fingers down from the occiput to the top of the back ensures that you will feel a nuchal cord if one is present. Sweeping your fingers from side to side picks up a cord over a shoulder. It also enables you to identify the position of the shoulders.
Management of a nuchal cord is as follows:	
a. If the cord is loose, slip it over the baby's head (cord reduction).	**a.** and **b.** A loose cord may tighten as the baby's body is born unless it is slipped away from the baby's neck.
b. If the cord is too tight to slip over the baby's body but not tight around the neck, slip it over the shoulders as the baby's body is born and deliver the baby through the cord.	
c. If the cord is too tight to slip back over the shoulders but has a little give to it, somersault the baby out, as follows [1]: **(1)** Slowly deliver both shoulders without manipulating the cord. **(2)** As the shoulders are delivered, flex the baby's head so the face is pushed toward the mother's thigh. **(3)** Keep the baby's head next to the perineum while the body is delivered (somersaults out). **(4)** Unwrap the umbilical cord.	**c.** The somersault maneuver does not require equipment, can be performed regardless of the number of times the cord is looped around the baby's neck, can be used with the mother in any birth position, and allows the cord to be cut under more calm and less risky circumstances [1].
d. if the cord is tight, immediately double clamp and cut the cord between the clamps at the neck before the baby's body is born. Tell the mother to pant while you are clamping, cutting, and unwinding the cord.	**d.** A tight cord may cause hypoxia or anoxia. Having the mother pant will keep her from pushing the remainder of the baby out (tightening the cord still further and defeating your efforts) before you are through clamping, cutting, and unwinding the cord and before your hands are in position for the next maneuver.

Hand Maneuver	Rationale
5. Wipe off the baby's face and head and wipe off fluid from the nose and mouth with a soft, absorbent cloth.	**5.** and **6.** Drying the baby's face and head prevents loss of body heat from these surfaces. Wiping away fluid from the nose and mouth and aspirating the nasal and oral passages clear the baby's airway, thereby preventing aspiration of fluid into the lungs with the baby's first breath.
6. Suction the baby's nasal and oral passages with a soft rubber bulb syringe.	
7. Wait for a contraction and watch the head return to anatomical alignment with the body (restitution) and external rotation.	**7.** Watching may inhibit any inclination to interfere, gives the shoulders time to rotate internally to the anteroposterior diameter of the pelvic outlet, confirms or refutes your prebirth judgment regarding the fetal position, and prepares you to place your hands for the subsequent hand maneuver.
Place a hand underneath the upper half of the baby's head while watching. Unless the cord has been cut, there is no need to hurry or interfere by rotating the shoulders manually. If the cord has been cut and external rotation is not yet completed, assist rotation of the shoulders, as described in the management of shoulder dystocia in Chapter 30, into the anteroposterior diameter of the pelvis.	This provides support to the head. Keeping your hand under just the upper half of the head keeps your fingers away from the rectum, thereby avoiding contamination.
8. Adjust your position by shifting a little to the right or left as indicated. If the head rotates to the LOT, then shift your body toward the mother's left. If the head rotates to the ROT, then shift your body toward the mother's right.	**8.** Shifting your position enables you to place your hands correctly and comfortably for the next hand maneuver.
9. Place one hand on each side of the baby's head so that your fingers point toward the baby's face and your little fingers are closest to the mother's perineum ("pinkies to perineum"). This means that for a baby in the LOT position, your left hand will be the bottom hand underneath the baby's head and your right hand will be the hand on top of the baby's head; for a baby in the ROT position, your right hand will be the bottom hand underneath the baby's head and your left hand will be the hand on top of the baby's head.	**9.** This places your hands in a position to avoid contamination from the rectum. The natural inclination is to place the bottom hand so the fingers are pointing toward the rectum, but invariably in so doing, the fingers inadvertently touch the anus or even slip inside slightly while you are concentrating on the birth of the baby. Deliberate placement of the hands sideways prevents this possibility. This placement of your hands also provides for the correct hand to be in the correct location for the hand maneuvers in 11d, 12, and 13 below.
10. Exert downward and outward pressure on the side of the baby's head with your top hand until the anterior shoulder has impinged beneath the symphysis pubis and can be seen.	**10.** Placing your hands on the sides of the baby's head keeps your fingers from pulling anywhere under the mandible or pressing in or on the neck, thereby avoiding injury to the cervical or brachial nerve plexus. (Steps 10 and 11 reflect the mechanism of labor called *birth of the shoulders and body by lateral flexion via the curve of Carus*.)
11. a. Apply upward and outward pressure on the side of the baby's head with your bottom hand, and with both hands lift the baby's head toward the ceiling.	**11. a.** See Step 10 above. The direction of this maneuver follows the curve of Carus.
b. While doing this, bend over sufficiently to watch the perineum during the birth of the posterior shoulder.	**b.** Observe the perineum for rapidity of birth and to see if there is a hand of the baby alongside the shoulder that needs to be controlled.

Hand Maneuver	Rationale
c. If the baby is coming too rapidly, you can slow it down by telling the mother to pant and by applying controlling pressure with the side of your bottom hand to the top of the posterior shoulder.	**c.** You want the shoulders to ease out over the perineum and to have control of the upper arm, elbow, and hand as described in d. below. This will help prevent perineal laceration.
d. As the baby is being born, slide your bottom hand under the baby's head from the side of the baby's head, across the neck and onto the shoulder and upper arm of the baby as they clear the perineum. In effect, you slide your hand down until the side of it rests against the top of the perineum at the fourchet. Then as the shoulder is born the upper arm is actually born into the palm of your hand while your ring finger, little finger, and the edge of your hand control the baby's elbow and hand as they clear the perineum.	**d.** This hand maneuver is *absolutely essential* for control of the upper arm, elbow, and hand of the posterior shoulder as they are being born. Otherwise, the hand or elbow can flip out and cause a perineal laceration. Perineal laceration is prevented if your hand keeps the upper arm pressed against the body until the elbow and hand have cleared the perineum.
12. As the upper half of the baby's body is born and the elbow and hand have cleared the perineum, "shake hands" with the baby's body with your bottom hand by having your thumb on the baby's back, your fingers across the baby's chest, the baby's neck in the V created between your thumb and fingers, and the baby's head supported on your wrist.	**12.** This gives you a hold on the baby, which gives you complete control of the remainder of the birth of the body and places the baby securely in your grasp without any possibility of the baby slipping past you or through your hands or fingers.

Note: Control of the baby's birth has gone from your top hand for birth of the head and the anterior shoulder to your bottom hand for birth of the posterior shoulder and body. The controlled birth of the posterior shoulder and the body has been accomplished with one smooth movement of your bottom hand from the side of the head in 9, down to the perineum in 11d, and into the "handshake" in 12 above.

13. As the baby's body is being born, slide your top hand down the baby's back, slip your index finger between the baby's legs as the buttocks clear the perineum, curve your middle finger and thumb around the legs, and continue running your hand down the legs until you can grasp the baby around the ankles. At this point, close your thumb and middle finger onto your index finger, thus totally encircling and enclosing the legs in your grasp. One foot of the baby will rest in the V created between your thumb and index finger, and the other foot will rest in the V created between your index and middle fingers.	**13.** This hand maneuver, combined with 12 above, gives you an absolute hold on the baby. No baby, no matter how slippery with fluid and vernix, can slip out of this hold. The baby is securely held in your two hands and there is no chance of the baby's "falling in the bucket," which is the primary fear of the inexperienced student helping a mother in a lithotomy position give birth to her baby.

Then do either 14 and 15 or 16 and 17.

14. Move the baby in a smooth arc onto the mother's abdomen. Be sure of the following as you place the baby on the mother's abdomen:	**14.** Placement on the mother's abdomen gives the mother immediate contact with her baby and causes the uterus to contract.
a. The baby's head is lower than the baby's body.	**a.** This allows drainage of fluid from the baby's body oral and nasal air passageways.
b. The baby is placed on her or his side or the baby's head is turned to the side if the baby is in a prone position.	**b.** This will maintain a patent oropharyngeal airway.

Hand Maneuver	Rationale
c. There is no tension on the umbilical cord.	**c.** This prevents tearing the cord from its insertion in either the placenta or the baby.
15. Keep one hand on the baby as you use your other hand to reach for necessary supplies and equipment for suctioning, drying the baby, clamping and cutting the cord, and so forth.	**15.** This is a safety measure that protects the baby from sliding, falling, or flipping off the mother's abdomen.
16. Move the baby in a smooth arc into the football hold, as follows:	**16.** The football hold is known as a safety hold in nurseries. Putting the baby into a football hold keeps the baby at the same level as the placenta.
a. Let the baby's head and shoulders pivot in your bottom hand so that the head is now supported by the palmar surface of your outstretched index and middle fingers, the suboccipital region and back of the neck are in the palm of your hand, and your thumb and remaining fingers are *resting*, not pressing, against the sides of the neck. Your top hand continues its grasp around the ankles during this maneuver.	**a.** The thumb and fingers resting against the neck serve as a barrier to movement between the mandible and the shoulders. If the baby slides either way, it will go no further than the fingers. Do *not* close your thumb and fingers around the baby's neck. The baby's head is supported and you have control over the position of the baby's head for suctioning. Your continued grasp on the ankles absolutely ensures that the baby will not fall.
b. Place the baby's legs between the elbow and upper arm of your bottom hand and your body at waist level and remove your top hand from around the baby's ankles. The baby's back is supported on your lower arm and the bottom part of the baby's body is tucked securely between your elbow/upper arm and your body.	**b.** This completes getting the baby into the football hold and frees one hand for subsequent actions of suctioning, drying the baby, clamping and cutting the cord, and so forth. *Note:* If the baby was born from a LOT position, the baby will end up under your left arm. If the baby was born from a ROT position, the baby will end up under your right arm. If you are unable to use your minor hand for the necessary subsequent actions, then you will need to switch the baby from under one arm to under the other arm. If you are inexperienced in handling babies and do not know how to get a baby into a football hold or how to transfer football holds from one side to the other, go to a normal newborn nursery and practice until you are comfortable.
17. *Be sure* as the baby is born in 11d and 12 and placed in safety holds in 13 and 16 that you do the following:	**17.**
a. Keep the head of the baby in a downward, dependent position, and turned somewhat to the side.	**a.** This allows drainage of fluid from the oral and nasal air passageways and maintains a patent oropharyngeal airway.
b. Exert no tension on the umbilical cord.	**b.** This prevents tearing the cord from its insertion in either the placenta or the baby.
c. Keep the baby well supported at all times.	**c.** The baby will not feel a frightening loss of support.

The hand maneuvers for the actual birth of the baby end with placing the baby on the mother's abdomen or with the baby being held securely in the football hold.

You will see many other methods, or variations of this method, used in helping a mother in lithotomy or modified lithotomy position give birth to her baby. Before trying variations or alternatives, the inexperienced student should learn one method, whatever it is, that is guaranteed to be safe and atraumatic and that will foster self-confidence. This one is recommended. In considering another method, or variations of this one, the student should scrutinize and analyze the method for valid rationale and for safety and security features.

CHAPTER

71

Hand Maneuvers for Birth with the Mother in Dorsal Position

If you have been accustomed to helping a mother give birth to her baby when she is in the lithotomy or modified lithotomy position and are now preparing yourself to be able to help a mother give birth to her baby when she is in the dorsal position, the most important thing for you to realize is that the hand maneuvers you used for birth in the lithotomy or modified lithotomy position, as described in Chapter 70, will not work when you are standing beside the mother in the dorsal position. The maneuvers have certain similarities, but it is unsafe even to think of running from one side of the table or bed to the other side (depending on the direction of restitution and external rotation of the baby's head) at the very time your hands should be facilitating and controlling the birth of the baby's shoulders and body. On the other hand, it is possible for you to use some of those hand maneuvers if you are seated cross-legged in front of a woman in dorsal position.

If you are learning birth of babies with the mother in the dorsal position, you must realize that when you later learn birth in the lithotomy or modified lithotomy position, you will need to learn a different set of hand maneuvers.

The hand maneuvers described below and illustrated in Figure 71-1 describe in detail what to do with your hands every moment of the actual birth of the baby when you are standing beside a mother in dorsal position. Although there is no danger of dropping the baby any great distance when the mother is in the dorsal position, it is still important to practice these maneuvers before actually helping a mother give birth to her baby in order to effect an atraumatic birth for both the baby and the mother. For practice you need someone else to serve as the power to manipulate a doll through a pelvis or anything with a hole large enough to simulate a pelvis and accommodate the doll. Have this person vary the rate of speed of birth.

These same hand maneuvers are applicable for all babies who birth from a cephalic presentation once the head is born. Prior to that time the hand maneuvers vary in accord with the indicated direction of pressure exerted for control of the birth of the baby's head.

Hand Maneuver	Rationale
The baby is in an occipital anterior position.	
1. Position yourself on one side of the table or bed. If you are right-handed, you will be positioned on the mother's right side. If you are left-handed, you will be positioned on the mother's left side.	**1.** Proper positioning in accord with your dominant hand is important for your own comfort and ease in doing examinations and in managing the situation and relevant supplies and equipment.

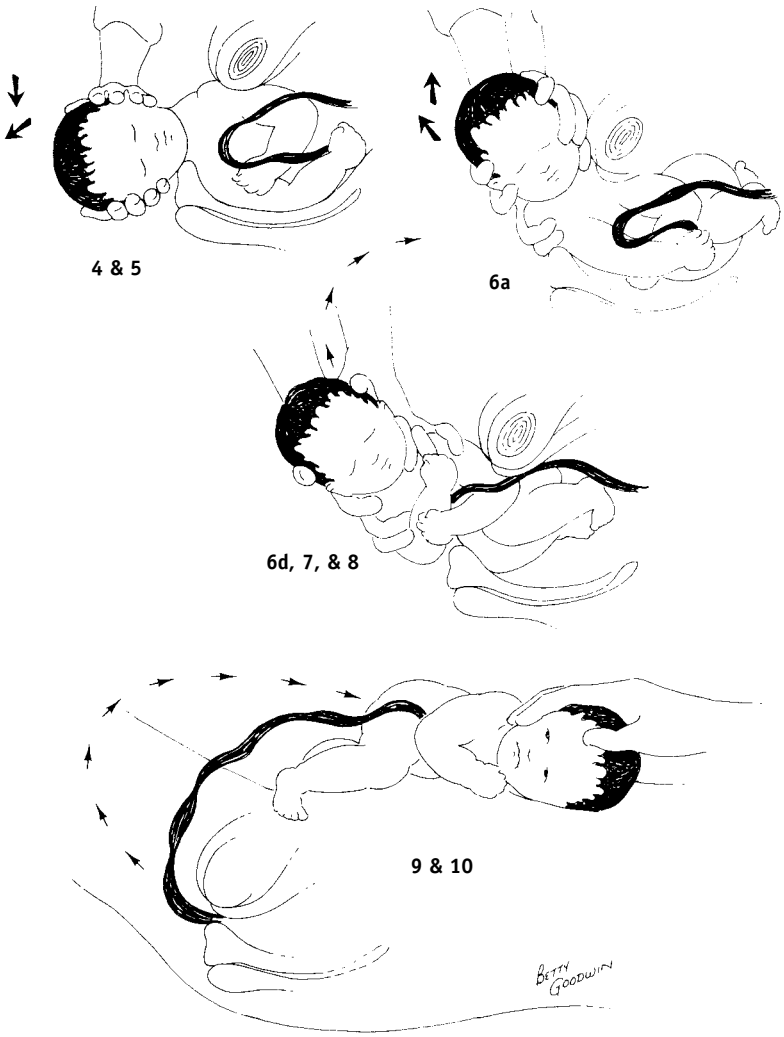

FIGURE 71-1 Hand maneuvers for the birth of a baby in occipital anterior position with the mother in dorsal position. Numbers correspond with the numbered paragraphs in the narrative text on the hand maneuvers and their rationale.

Hand Maneuver	Rationale
2. You should be positioned just below the level of the mother's knees, which are flexed and well separated out to the sides. From this position you reach over her leg to function in the area between her legs, reaching upward toward the perineum to assist the mother with birth of her baby and downward toward the foot of the table or bed to where your supplies and equipment are located.	**2.** Working inside her leg keeps the mother's knee from getting in your way; gives you an element of control, if necessary, of the mother's legs; and positions you in a way that guarantees access to both the baby and the necessary supplies and equipment.
3. The hand maneuvers involved in control of the birth of the baby's head, checking for a nuchal cord, wiping the baby's head, suctioning, and watching for restitution and external rotation are the same as the hand maneuvers for birth of the baby with the mother in lithotomy or modified lithotomy position (Steps 1 to 7) described in Chapter 70.	**3.** See the rationale for Steps 1 to 7 described in Chapter 70.

Hand Maneuver	Rationale
4. Place one hand on each side of the baby's head. If you are standing on the right side of the mother, your left hand will be on top of the baby's head and your right hand will be underneath the baby's head. If you are standing on the left side of the mother, your right hand will be on top of the baby's head and your left hand will be underneath the baby's head. This positioning of your hands will be true regardless of which direction restitution and external rotation take. Be sure that the palms of your hands are on the baby's head with your fingers pointing toward the mother's opposite leg ("pinkies to perineum"). This places the sides of your hands at right angles to the perineum.	**4.** This placement of your hands is designed to accomplish three things: **a.** Prevent contamination of your bottom hand through contact with the rectum. **b.** Prevent grasping the baby under the mandible or around the neck for birth of the shoulders and body. **c.** Prevent damage to the cervical or brachial nerve plexus.
5. Exert downward and outward pressure on the *side* of the baby's head with your top hand until the anterior shoulder has impinged beneath the symphysis pubis and can be seen.	**5.** Same as for 4b and 4c above. (Steps 5 and 6 constitute the mechanisms of labor called *birth of the shoulders and body by lateral flexion via the curve of Carus*.)
6. a. Apply upward and outward pressure on the side of the baby's head with your bottom hand and with both hands lift the baby's head toward the ceiling.	**6. a.** This is same as for 4b and 4c above. The direction of this maneuver follows the curve of Carus.
b. Watch the mother's perineum during the birth of the posterior shoulder.	**b.** Observe the mother's perineum for rapidity of birth and to see if there is a hand to be controlled alongside the baby's posterior shoulder.
c. If the baby is coming too rapidly, you can slow it down by telling the mother to pant and by applying controlling pressure with the side of your bottom hand to the top of the posterior shoulder.	**c.** You want to ease the shoulders over the perineum and to have control of the posterior upper arm, elbow, and hand in order to prevent perineal lacerations.
d. As the baby is being born, slide both your top and bottom hands, with the exception of your index fingers, down from the sides of the baby's head onto the baby's shoulders and upper arms as they clear the mother's perineum and are born. The index fingers of both of your hands remain on the parietal bones on either side of the baby's head. During this maneuver your bottom hand slides down until the side of it rests against the top of the perineum at the fourchet. Then as the posterior shoulder is born the upper arm is actually born into the palm of your hand while your ring finger, little finger, and edge of your hand control the baby's elbow and hand as they clear the perineum.	**d.** This positions your hands for the next hand maneuver, described in Step 7. Your index fingers on the parietal bones steady and support the baby's head between them. This action of your bottom hand is essential for control of the upper arm, elbow, and hand of the posterior shoulder as they are being born. Otherwise, the hand or elbow can flip out and cause a perineal laceration. If your hand keeps the upper arm pressed against the body until the elbow and hand have cleared the perineum, then perineal laceration is prevented.
7. As the upper half of the baby's body is born, grasp the baby's body around the upper arms, upper chest, and upper back. Your thumbs will be on one side of the baby's body, your index fingers will be on the parietal bones, and your remaining fingers will be on the other side of the baby's body.	**7.** This provides you with a secure hold of the baby's body and also enables you to guide the direction of the remainder of the birth of the body via the curve of Carus.

Hand Maneuver	Rationale
8. Guide the baby's body upward and outward in a smooth arc for the birth of the lower half of the baby's body.	**8.** This follows the curve of Carus.
9. Continue your arc and place the baby on the mother's abdomen.	**9.** Placement on the mother's abdomen gives the mother immediate contact with her baby, causes the uterus to contract, and keeps the baby out of the fluids that have now accumulated on the table or bed in the area between the mother's legs.
Be sure of the following as you place the baby on the mother's abdomen:	
a. The baby's head is lower than the baby's body.	**a.** This allows drainage of fluid from the oral and nasal air passageways.
b. The baby is placed on his or her side or the baby's head is turned to the side if the baby is in a prone position.	**b.** This will maintain a patent oropharyngeal airway.
c. There is no tension on the umbilical cord.	**c.** This prevents tearing the cord from its insertion in either the placenta or the baby.
10. Keep one hand on the baby as you use your other hand to reach for necessary supplies and equipment for suctioning, drying the baby, clamping and cutting the cord, and so forth.	**10.** This is a safety measure that protects the baby from sliding, falling, or flipping off the mother's abdomen.

The hand maneuvers for the actual birth of the baby end with the placing of the baby on the mother's abdomen.

CHAPTER

72

Hand Maneuvers for Birth with the Mother in the Hands and Knees Position

SARASWATHI VEDAM, CNM, MSN

Hand maneuvers for the birth of a baby with the mother in a hands and knees position are designed to provide the midwife with a safe and efficient method of receiving the baby and, subsequently, transferring the baby to the mother's arms. The issues of assessing fetal well-being and maintaining perineal integrity are addressed by steps that are very similar to those for other maternal positions. While the mechanisms of labor are not changed by maternal position, the reversed and delayed appearance of the emerging vertex necessitates alterations in timing and in placement of the hands.

Visibility and access to effect maneuvers are enhanced in this position. However, the inability to establish eye contact with the mother during delivery requires a greater emphasis on anticipatory guidance as well as a birthing environment that allows for undisturbed verbal contact between woman and midwife at the time of birth. If the woman is hearing impaired, one of her support persons may have to relay your words by sight.

Stress on the anterior labia and on the periurethral area is slightly increased when the mother assumes a hands and knees position for pushing. Hence, methods of perineal support must focus on the prevention of lacerations in those areas. Finally, as in lithotomy or supported squat positions, the baby will emerge suspended above the surface of the bed or floor. A secure hold on the baby is essential.

The following hand maneuvers are one approach to managing the birth of a baby with the mother in the hands and knees position. Each midwife will develop her or his own style for conducting a birth.

Hand Maneuver	Rationale
The baby is in an occipital anterior position.	
1. Sit, kneel, or stand to one side of the mother's hips as you begin to notice rectal bulging with pushing. Your shoulders and body should be parallel to her side as you visualize the rectal and perineal area.	**1.** Rectal bulging and gaping will be the first apparent sign of fetal descent to the perineum in this maternal position. It is easier to establish timely communication with the woman if you can see both the woman's face and perineum.
2. Establish eye contact with the mother (moving yourself into her line of vision if necessary), and explain that if she delivers in the hands and knees position, you will need to hand the baby to her from behind through her bent legs, after which she can simply sit down with the baby on her abdomen.	**2.** When the plan is to cut the cord after the mother has received the baby, the cord length is generally inadequate to circumvent the mother's leg.

Hand Maneuver	Rationale
Remind her not to sit back or down immediately after delivery before she has received the baby.	Upon delivery many women will naturally lower their haunches to sit back. If she sits before passage of the baby to her arms, she may sit on the cord or baby and make receiving the baby more complicated.
3. Encourage her, her supporting family, and nursing staff to facilitate communication between you and the woman at the time of delivery. Delegate someone to lift or remove her garment as the baby is delivering so that it does not obstruct the path between the perineum and the mother's arms.	**3.** She will not be able to see you, the baby, or the perineum during delivery so you must communicate instructions, requests, and reassurances verbally or through an assistant. The baby or the mother can get tangled in the clothes as the baby is passed to the mother or she changes position from hands and knees to sitting after the birth.
4. Watch for the roundness of the brow to distend the rectal and perineal wall. Place the pads of your fingertips, palm up, on the crown of the head with the fingertips pointing toward the mother's abdomen. As the head begins to emerge, spread the fingers slightly and exert a slight upward pressure with the length of the fingers on the vertex. Be careful to avoid pressure on the clitoris. Allow the head to extend gradually into your hand maintaining a steady but gentle counterpressure until the biparietal diameter is delivered and you can visualize the ears.	**4.** The ability to visualize the emerging head at the introitus is somewhat reduced. A rounded distention of the perineum will be the first sign that crowning is imminent. Maintaining flexion until the suboccipuit passes under the symphysis pubis and extension begins will reduce the possibility of perineal trauma. Flexion must be effected in accordance with fetal position. In hands and knees maternal position, the baby in an OA position appears face up. Gradual extension prevents the head from popping out, which can cause perineal lacerations and may be more traumatic for the baby.
5. It is possible to support the perineum with the other hand alone or with a warm moist towel. Many women appreciate moist heat on the rectal area as the head crowns and delivers. Review the correct procedure and rationale for perineal support in the section on hand maneuvers for delivery in the lithotomy or modified lithotomy position. (See Step 2, Chapter 70.)	**5.** See rationale for Step 2, Chapter 70.
6. If necessary, guard or reduce the stress on the anterior labia and periurethral area with your fingertips. Use the same technique of providing support with your thumb and middle fingers that is described above only with the placement of fingertips on either side of the anterior apex of the introitus.	**6.** When the vertex emerges with the woman in a hands and knees position, the pressure exerted on the perineum is distributed anteriorly. Lacerations along the anterior labial borders or periurethral area are more common but tend to be shallow if the delivery of the vertex is controlled.
7. The hand maneuvers involved in checking for a nuchal cord, wiping the baby's head, watching for restitution and external rotation are the same as the maneuvers for delivery of the baby in lithotomy or modified lithotomy position described in Chapter 70 (Steps 4–9). In the hands and knees maternal position, the checking hand will be palm up and sliding under the head. Wiping the baby's face and suctioning, if necessary, will be easier to effect as the face is up.	**7.** See rationale for Steps 4–10 described in Chapter 70.
8. a. Exert downward and outward pressure on the side of the baby's head with your top hand until the posterior shoulder is visible.	**8. a.** Follows the Curve of Carus and effects birth of the posterior shoulder and body by lateral flexion.

Hand Maneuver	Rationale
b. Apply upward and outward pressure on the side of the baby's head with your bottom hand, and with both hands lift the baby's head toward the mother's back. As the anterior shoulder emerges, slide your bottom hand down along the neck and shoulder keeping the anterior arm close to the baby's body as it emerges at the perineum.	**b.** This motion will assist the anterior shoulder to pass under the mother's symphysis pubis. The arm will have a tendency to abduct from the body as the shoulder delivers and its motion and dimension can contribute to periurethral lacerations if not controlled.
c. As the upper half of the baby is born and the elbows and hands have cleared the perineum, you can "shake hands" with the baby's body with your bottom hand by having your thumb on the baby's back and your fingers across the baby's chest, while placing your top hand in the same position on the other side of the baby. Alternatively, you can place your hands, fingers together, under the baby's armpits and across the chest, thumbs supporting the back, as you lift the baby while the mother spreads her legs. Or you can follow Steps 13–15 in Chapter 70 to place the baby in a football hold until the mother is ready to reach for the baby.	**c.** The baby will be slippery and in motion. It is important to find a hold on the baby that gives you control of the remainder of the delivery of the body and places the body securely in your grasp as you lift and give the baby to the mother. You goal is to support the baby's body without squeezing or poking the soft parts.
9. Pass the baby to the mother through her legs, keeping a secure hold on the baby until she has a firm grasp. Then assist her to sit down and back, while you move to her front to assess and care for the baby. Alternatively, the mother can carefully lift one leg while you pass the cord under it as she turns to sit down facing you. She is then ready to receive the baby, which you can place on her abdomen.	**9.** When the plan is to cut the cord after the mother has received the baby, the cord length is generally inadequate to circumvent the mother's leg. Upon delivery many women will naturally lower their haunches to sit back. If the mother sits before passage of the baby to her arms, she may sit on the cord or baby and make receiving the baby more complicated. Placing the baby on the mother's abdomen gives her immediate contact, places the baby on a warm surface, and keeps the baby within reach for assessment and care.
10. Place the baby stomach down, head turned to face you, on the mother's abdomen as you instruct her to sit down. Keep your hands on the baby until the mother is stable enough to replace your hands with her own. Be conscious of the length of the cord, and adjust the height of the placement of the baby so there is no tension on the cord.	**10.** A dependent position of the head allows for drainage of fluid from the oral and nasal passageways. The mother will need to sit and find a stable position for herself before she can use her arms to support the baby. If the cord is too taut, it will pull on the insertion site on the baby and/or cause maternal discomfort at the introitus.

The hand maneuvers for the actual birth of the baby end with the placing of the baby on the mother's abdomen.

CHAPTER

73

Hand Maneuvers for Birth with the Mother in the Squatting or Supported Squat Position

SARASWATHI VEDAM, CNM, MSN

Hand maneuvers for the birth of a baby with the mother in a squatting position combine elements of the hand maneuvers for the lithotomy position and those for the dorsal position. The issues of maintaining perineal integrity, visibility, and safety for the baby vary slightly, depending on whether the mother is in a true squat with her perineum close to the bed or floor, or in a supported squat with her perineum suspended above the floor or foot of the bed.

In a true squat, the mother's legs are bent and abducted. Weight bearing is distributed between her legs and feet. She may stabilize her upper body by resting her arms on a support person sitting behind her or by holding onto a rope or bar in front of her. This position brings the perineum close to the surface she is squatting on, so the baby emerges just inches above the surface. Moreover, the curve of Carus parallels the surface at the introitus, so the natural arc of the baby's path would serve to deposit the baby along his or her back onto the surface. Hence, the hand maneuvers are designed mainly to follow this process while preserving perineal integrity and assisting the mother to receive her baby on the warm surface of her abdomen.

In the supported squat, the mother's buttocks are partially supported by the edge of a broken birthing bed or a birthing chair or stool. The mother may place her hands on a squatting bar or on handles on the stool. The weight bearing is distributed between her hands, buttocks, legs, and feet. The perineum is suspended 6 to 18 inches above the surface of the bed or floor. Securing a good hold on the emerging baby becomes more important as there is a risk of dropping the baby.

The following hand maneuvers are one approach to managing the birth of a baby with the mother in the squatting position. Each midwife will develop her or his own style for conducting a birth.

Hand Maneuver

The baby is in an occiput anterior position.

1. Sit or squat on a low stool or on the floor between the woman's legs, facing the perineum, with your shoulders at or below the level of the mother's bent knees.

2. As the vertex appears at the vaginal introitus, place the pads of your fingertips on the crown of the head with the fingertips pointing toward

Rationale

1. Placing yourself low and between her legs allows you greater visibility, access, and control during the delivery. Your shoulders also provide a passive barrier to prevent the mother's knees from adducting during pushes.
2. It is difficult to twist the elbow and exert a controlling pressure with the fingertips pointing downward when the woman is squatting above

Hand Maneuver	Rationale
the mother's abdomen and your elbow pointing to the floor. As the head begins to emerge, spread the fingers slightly and exert a slight downward pressure with the length of the fingers on the vertex. Be careful to avoid pressure on the clitoris. Allow the head to extend gradually into your hand maintaining a steady but gentle counterpressure until the biparietal diameter is delivered and you can visualize the ears.	you. The ability to visualize the emerging head is enhanced with the fingertips spread. Maintaining flexion until the subocciput passes under the symphysis pubis and extension begins reduces the possibility of perineal trauma. Gradual extension prevents the head from popping out, which can cause perineal lacerations and may be more traumatic for the baby.
3. It is possible to support the perineum with the other hand alone or with a warm moist towel, but this support will be by feel, not by sight, in this position. Review the correct procedure and rationale for perineal support in the section on hand maneuvers for delivery in the lithotomy or modified lithotomy position. (See Step 2, Chapter 70.)	**3.** See the rationale for Step 2 in Chapter 70.
4. Watch the introitus while the head extends and is born, paying attention to the labial borders. If the labial edges appear taut or blanched, provide support by placing a thumb and middle finger just below and just above the strained area and exerting pressure with an inward motion toward each other.	**4.** When the vertex emerges with the woman in a true squatting position, the pressure exerted on the introitus is distributed between the labia and the perineum. Lacerations along the labial borders are more common but tend to be shallow if the delivery of the vertex is controlled. This pressure includes more tissue in the action and the inward motion distributes the additional tissue toward the strained area of the labia, thereby relieving some of the stress and reducing the possibility of a laceration.
5. The hand maneuvers involved in checking for a nuchal cord, wiping the baby's head, watching for restitution and external rotation, and delivery of the anterior shoulder are the same as the hand maneuvers for delivery of the baby in the lithotomy or modified lithotomy position described in Chapter 70 (Steps 4–10). Suctioning, if necessary, will be easier to effect once restitution has occurred.	**5.** See the rationale for Steps 4–10 in Chapter 70.
6. a. Apply upward and outward pressure on the side of the baby's head with your bottom hand, and with both hands lift the baby's head toward the mother's abdomen.	**6. a.** Follows the curve of Carus and effects birth of the posterior shoulder and body by lateral flexion.
b. As the posterior shoulder emerges, slide your bottom hand down along the neck and shoulder keeping the posterior arm close to the baby's body as it emerges at the perineum.	**b.** The arm will have a tendency to abduct from the body as the shoulder delivers and its motion and dimension can contribute to perineal lacerations if not controlled.
c. As the upper half of the baby is born and the elbows and hands have cleared the perineum, you can "shake hands" with the baby's body with your bottom hand by having your thumb on the baby's back and your fingers across the baby's chest, while placing your top hand in the same position on the other side of the baby. Alternatively, you can	**c.** The baby will be slippery and in motion. It is important to find a hold on the baby that gives you control of the remainder of the delivery of the body and places the body securely in your grasp as you lift and give the baby to the mother. Your goal is to support the baby's body without squeezing or poking the soft parts. Placing the baby on the

Hand Maneuver	Rationale
place your hands, fingers together, under the baby's armpits and across the chest, thumbs supporting the back, as you lift the baby onto the mother's abdomen.	mother's abdomen gives her immediate contact, places the baby on a warm surface, and keeps the baby within reach for assessment and care.
7. Place the baby stomach down, head turned to face you, on the mother's abdomen as you instruct her to sit down. Keep your hands on the baby until the mother is stable enough to replace your hands with her own. As she repositions herself, assess the baby's need for suctioning or respiratory support as you dry the baby. Be conscious of the length of the cord, and adjust the height of the placement of the baby so there is no tension on the cord.	**7.** A dependent position of the baby's head allows for drainage of fluid from the oral and nasal passageways. The mother will need to sit and find a stable position for herself before she can use her arms to support the baby. It is possible to complete immediate assessment of the baby at this point. The cord will pull on the insertion site on the baby or cause maternal discomfort at the introitus if too taut.
The hand maneuvers for the actual birth of the baby end with the placing of the baby on the mother's abdomen.

Inspection of the Placenta, Membranes, and Cord

The placenta, membranes, and cord are inspected in order to diagnose the normality of the placenta, umbilical cord insertion, and cord; to screen for abnormality; and to ascertain whether the placenta and membranes have been completely delivered.

In order to diagnose normality of the placenta and cord insertion, the midwife must know the parameters of normal. Screening for abnormality then encompasses anything not within the parameters of normal; however, it is useful to know and be able to recognize the more common deviations from normal. The causes of these deviations are not always known, and the significance of deviations from normal may lie not in their cause but instead in pointing to potential problems their existence may have created. All of this information makes up the necessary database for inspection of the placenta and membranes.

Database

Normal Placenta, Cord Insertion, and Cord

The normal term placenta weighs approximately 500 grams (just under 1 pound 2 ounces), which is roughly one-sixth of the weight of the newborn. It varies in shape, usually being discoid (flattened and circular) with an average diameter of 15 to 20 centimeters (roughly 6 to 8 inches) and an average thickness of 1.5 to 3 centimeters (about $^{2}/_{3}$ to $1^{1}/_{4}$ inches).

The maternal surface of the placenta is the side of the placenta that was attached to the uterine wall. Normally it is dark red (primarily as a result of fetal hemoglobin), covered with a grayish film of decidua basalis, soft, and friable if torn. It evidences a variable number of cotyledons separated by decidual septa composed of fibrous tissue and interwoven with innumerable blood vessels (see Chapter 21).

The fetal surface of the placenta is the side that was next to the fetus; it is thus covered with the shiny fetal membranes that extend beyond the placenta to form the two-layered membranous sac in which the fetus was enclosed. The outer layer, or chorion, and the inner layer, or amnion, are separable up to the insertion of the umbilical cord. It is difficult to impossible to separate the chorion from the fetal surface of the placenta. The chorion is more easily torn, more opaque, and thicker than the inner, glistening, transparent amnion. The fetal surface of the placenta is irregular because of the branching of the placental blood vessels from the umbilical cord. The color is grayish, although the redness of the placenta can be seen through the membranes except where there are infarcts.

Degenerative changes in the placenta are normally observed as infarcts. These are hard, nodular, whitish areas, which may be found on either the maternal or the fetal surface, or both. They vary in size from a few millimeters to several centimeters. Frequently small calcifications are also observed on the maternal surface of the placenta. These feel gritty to touch and normally may be spread all over the maternal surface to a moderate degree. Developing a reasonable amount of these degenerative changes (in-

farct formation and small calcifications) is a normal part of the aging process of the placenta.

The umbilical cord inserts into the placenta on the fetal surface and the insertion is usually somewhat eccentric—that is, the cord inserts somewhere between the center and the margin. A central cord insertion is normal but much less common. The umbilical cord normally averages approximately 55 centimeters (22 inches) in length and thus is slightly longer than the total length of the average term newborn. The amount of Wharton's jelly supporting and protecting the blood vessels in the cord varies considerably but the cord is normally full and firm to touch. The normal number of blood vessels in the umbilical cord is three: two arteries and one vein. Although these vessels collapse after the cord is cut, they can be easily identified because the vein has a larger aperture than either of the two arteries.

Placental Variations, Anomalies, and Abnormalities

All abnormal placentas indicative of a disease process require consultation with a physician and should be sent to pathology for detailed examination. Placental variations, anomalies, and abnormalities include the following.

1. Larger and heavier than normal placentas may occur with excessively large fetuses, fetal syphilis, or erythroblastosis.
2. Smaller and lighter than normal placentas may occur with maternal general systemic diseases or local uterine conditions causing undernourishment of the placenta and usually resulting in intrauterine growth retardation.
3. Placental tissue that is obviously lighter in color than normal is caused by fetal anemia such as is found in erythroblastosis.
4. Extensive infarction of entire cotyledons is abnormal and usually is the result of disease processes such as severe chronic maternal hypertension or severe preeclampsia or eclampsia. Such extensive infarcting reduces effective placental functioning, which may result in intrauterine growth retardation or (if a substantial portion of the placenta is infarcted) fetal death.
5. Cysts are most frequently observed on the fetal surface. Smaller cysts, a few millimeters in size, are more common than the very uncommon larger cysts of up to 8 to 10 centimeters in diameter. Cysts are usually not significant except in the occasional instance in which the cyst contains a blighted twin.
6. With edema of the placenta, the placenta is mushy, thick, and pale, and fluid can be squeezed from it. Edema may be caused by severe maternal heart disease, diabetes, or nephritis, and by severe erythroblastosis. The fetus usually dies in utero either as a stillbirth or earlier as an abortion.
7. Tumors may be found in association with prematurity and polyhydramnios. Perinatal mortality and maternal hemorrhage are both increased.
8. A syphilitic placenta is abnormally large and pale yellowish-gray; expect a syphilitic fetus.
9. With a lobulated placenta, there appear to be multiple placentas for a single baby. In fact, it is one placenta that is divided into two or more parts that are either completely separated or joined in part. Either way, the lobes are held together by the one set of membranes and by the blood vessels (which may extend from one lobe to another or may be separate and distinct, uniting just before entering the cord, which is not inserted into any lobe). The number of lobes determines the name, for example, placenta duplex (two), placenta triplex (three). This anomaly is thought to be due to abnormalities in the blood supply to the decidua. Its main significance is that you need to be alert to make sure that all lobes have been expelled from the uterus.
10. A succenturiate placenta (placenta succenturiata) is a not uncommon placental anomaly in which one or more separate accessory lobes are in the membranes a variable distance away from the main placental mass. These accessory lobes are usually connected to the main placental mass by blood vessels extending out from the main placental mass. When there are no connecting blood vessels, the anomaly is called placenta spuria.

    The primary significance of a succenturiate placenta lies in the possibility that the succenturiate lobe(s) will be retained in the uterus after expulsion of the main placental mass. Retained succenturiate lobes may cause severe postpartal hemorrhage.

    The retention of succenturiate lobes can be detected during inspection of the placenta and membranes by noting the following:

    a. There are torn blood vessels at the margin of the maternal surface of the placenta with the fetal membranes, or the extension of blood vessels into the membranes. (This may also be noted from the margin of the fetal surface of the placenta.)
    b. There are rough or torn roundish defects in the membranes a short distance from the placenta; occasionally these may have a fragment of decidua attached on the periphery of the defect.

Manual exploration of the uterus and removal of the succenturiate lobe(s) is indicated if retention has occurred.

11. Extrachorial placenta is a placental anomaly observed on the fetal surface as a thick, white ring, which gives the impression that the central portion of the placenta is somewhat depressed. Within this depression the fetal surface looks as usual with the insertion of the umbilical cord. However, all the large blood vessels pass into the depths of the placenta before reaching the ring, instead of coursing over the totality of the fetal surface as they usually do.

There are two varieties of extrachorial placenta, which are determined by the location of the ring. Both may be complete or incomplete, as dictated by whether the ring circumscribes a full circle:

a. In placenta circumvallata (circumvallate placenta), the ring is situated a variable distance between the margin and the middle of the placenta. The ring is formed by a double fold of both the chorion and the amnion doubling back on themselves, with fibrin and degenerated decidua interposed between the folds of the membranes. This gives the ring its raised effect.

b. In placenta marginata (circummarginate placenta), the ring is located at the edge, or margin, of the placenta and is raised by the presence of degenerated decidua and fibrin interposed between the membranes and the placenta at the edge of the placenta; the membranes do not fold back on themselves.

The etiology of extrachorial placentas is not known. Their incidence and significance are a subject of controversy in the literature. At any rate, any significance occurs prior to the time of delivery of the placenta (e.g., antepartal hemorrhage), so an extrachorial placenta may answer some diagnostic questions but there is no indication for clinical action.

Variations, Anomalies, and Abnormalities of the Umbilical Cord and Its Insertion

1. Battledore placenta is a variation in which the umbilical cord inserts in the edge, or margin, of the placenta. Although considered a normal cord insertion, marginal insertion of the cord occurs in less than 10 percent of placentas.

2. Velamentous insertion of the cord is when the blood vessels in the umbilical cord separate and leave the cord prior to insertion into the surface of the placenta (the three vessels course between the chorion and amnion for a variable distance before each enters the placenta surrounded by only amnion). Velamentous insertion occurs approximately 1 percent of the time, with an increased incidence in the event of multiple gestation.

A velamentous insertion of the cord is fraught with danger for the fetus. Rupture of the membranes may also rupture a fetal blood vessel, because their protection is flimsy since they are covered only with amnion. A ruptured vessel may cause hemorrhage in, and exsanguination of, the fetus. The vessels are also liable to compression, which would cause fetal anoxia.

By the time you note such an insertion on inspection of the placenta after its delivery, any disaster that might have happened will have already happened. In such an event, noting a velamentous insertion would be of diagnostic value. Fortunately such circumstances are rare.

3. Vasa previa—a dangerous anomaly with a high perinatal mortality if rupture occurs—is when unprotected blood vessels, covered only with amnion and coursing between the chorion and the amnion, present first at the cervical os by crossing the os ahead of the fetal presenting part. With fetal descent and rupture of the membranes, the vessels are subject to compression and rupture with resulting exsanguination and anoxia of the fetus.

Vasa previa usually occurs in conjunction with a velamentous insertion of the cord. However, vasa previa may also occur when there is a succenturiate placenta since the vascular connections to the succenturiate lobe are also unprotected vessels coursing between the chorion and amnion.

Vasa previa occurs in less than 0.2 percent of pregnancies. Although it is extremely rare, it should be thought of as a possibility any time you are not positive of what you feel presenting at the cervical os. Your examination should include feeling for pulsations synchronous with the fetal heart rate in the questionable presenting entity. It is not always possible, however, to feel a vasa previa during examination. Consultation with the physician is mandatory whenever you cannot identify the presenting part or believe it to be abnormal.

4. An abnormal number of blood vessels in the umbilical cord is an abnormality that has a high correlation with fetal anomalies. About one-third of infants born with only one umbilical artery will have multiple, severe malformations.

5. A short cord may be classified as relative or absolute. An absolute short cord is one that is short in length; a relative short cord is one of average length (or, more likely, one that is ex-

cessively long) that has become looped around the body or neck of the fetus so that it is too short to reach from its placental insertion to the newborn's umbilicus outside the maternal vulva, as is necessary for normal birth.

A short cord, although unusual, may be the causative factor in failure of the fetus to descend. In such an event, it might additionally cause abruptio placentae, umbilical hernia, fetal distress, rupture of the cord, shoulder dystocia, or a combination of these.

A short cord usually is not recognized until there is evidence of a problem. Therefore, it should be considered as a possibility whenever descent is not occurring normally in the presence of an adequate pelvis and good contractions. Fetal distress enhances the accuracy of the diagnosis and compounds the urgency for action, which will require a physician.

6. An excessively long cord is more common than a short cord. Of itself, it has no significance. However, a long cord is of great clinical significance if it becomes looped around the fetal body or neck, thus causing a relative short cord. It can also become knotted or prolapse in front of the presenting part.
7. Cord looping is usually the result of a cord that is longer than average (50 to 55 centimeters, or about 20 to 22 inches). A vast majority of cords longer than 100 centimeters (39 inches) will be looped. Looping occurs in approximately 20 percent of all pregnancies. Single or multiple looping may cause a short cord with all its possible complications. In addition, looping of the cord around the neck may cause fetal distress (although rarely death) as a result of either compression of the cord between the clavicle and the mandible during flexion or tightening of the cord around the neck during descent, especially if the distance is short between the loop and the placental insertion. Therefore it is important to check for a cord around the neck as soon as the baby's head is born.
8. True cord knotting must be differentiated from false knotting. False knotting of the cord occurs when the cord appears to be knotted but instead the blood vessels within the cord are kinked. A true knot occurs when the fetus has passed through a loop in the cord and a real knot has been created (see Figure 74-1). True knotting is most apt to occur in one of two situations:
   a. There is a small fetus, long cord, and large amount of amniotic fluid. The higher ratio of amniotic fluid to fetal size in early pregnancy makes this the time of greatest incidence. True knots, although usually benign because the pulsations in the blood vessels may keep the knot from tightening, may be the cause of intrauterine death at any gestational age.
   b. There is a multiple gestation within a single amnion. All sorts of cord entanglements and knots are possible because the fetuses have greater freedom of movement within the fetal sac, thereby increasing both the chance of a knot's forming and the chance of its tightening. Mortality rate is high.
9. A markedly decreased amount of Wharton's jelly may be seen in malnourished and postmature newborns.
10. Rarities that may occur in the umbilical cord are hematomas, tumors, cysts, and edema. Hematomas usually are the result of rupturing of the umbilical vein. Edema is not uncommon with an edematous or macerated fetus.

Procedure

A gross inspection can be done as the placenta is delivered. Obvious immediately is whether the membranes trail, with or without tearing; the general appearance and characteristics of the cord; the general size, wholeness, health, and characteristics of the placenta; and the type of cord insertion. A thorough inspection is done as follows:

1. Umbilical cord
   a. Count the number of cord vessels (see Figure 74-2). To do this, take a gauze 4 × 4 and wipe off the cut end. Apply pressure and the apertures of the vessels will be visible. If for some reason time has passed and the vessels

FIGURE 74-2 Counting the number of cord vessels.

FIGURE 74-3 Midwife examining the fetal side of the placenta. The membranes are incomplete.

have collapsed beyond your being able to identify them, reclamp and recut the cord and look for them at the site of the new cut, where they will be readily visible.

b. Measure the length of the cord. Whether the cord is measured usually is dictated by institutional policy and not every institution requires it. Regardless of policy, if the cord appears abnormally long or short it should be measured. Remember to include the length of cord cut off the baby's end when the baby's cord was finally clamped and cut.

c. Inspect the cord for knots, hematomas, tumors, cysts, edema, and the amount of Wharton's jelly.

2. Cord insertion. Inspection of the cord insertion includes the following:

a. location of normal cord insertion, that is, eccentric, central, or marginal (Battledore placenta)

b. abnormal cord insertion (velamentous cord insertion)

3. Membranes. Inspect the membranes for the following:

a. Completeness. This is done by placing the placenta maternal side down, then placing a hand inside the membranes on the fetal surface of the placenta and holding the membranes up to simulate the sac they once were (see Figure 74-3). If the membranes do not form a sac, they are incomplete and most likely ragged. Your hand will have gone inside the membranes in the opening created when the membranes ruptured. This is also the opening the placenta will have come through if delivered via the Schultz mechanism of expulsion. If so delivered, the sac will have been inverted and will need to be turned right side in again for this inspection.

b. Succenturiate lobes, defects, or blood vessels.

4. Placenta. The following steps are involved in inspecting the placenta:

a. Inspect the placenta for meconium staining and areas of calcification.

b. Inspect the fetal side for cysts and to determine if this is an extrachorial placenta (either a placenta circumvallata or a placenta marginata). If necessary, tear or invert the membranes in order to see the entire fetal surface. The fetal surface should also be examined closely for torn or intact blood vessels leading into the membranes in order to identify a missing or intact succenturiate lobe (see Figure 74-3).

c. Inspect the maternal side for cysts, tumors, edema, abnormal color, and multiple placentas.

d. Inspect the maternal side for infarcts and the extensiveness of the infarct formation.

e. Examine the maternal side for intactness (see Figure 74-4). To do this, place the placenta on a flat surface, maternal side up. Use a 4 × 4 gauze to wipe off blood and extraneous material in order to clearly visualize the placental surface.

To identify a cotyledon missing from the margin of the placenta or a missing accessory lobe, wipe off the margin of the placenta and run your finger around the edge of the placenta. It should feel smooth. Any area of roughness should be investigated thoroughly because roughness is indicative of torn placental tissue. Examine the placental margin closely for torn or intact blood vessels leading into the membranes in order to identify a missing or intact succenturiate

FIGURE 74-4 Midwife examining the maternal side of the placenta. The placenta is intact.

lobe. Compare this with your findings from the fetal surface.

A cotyledon missing from the main placental mass is identified by a defect with a rough surface where it tore away. This must be differentiated from a simple tear in the placenta without loss of tissue, which also leaves a rough surface. Differentiation is made by holding the placenta in your hands, maternal surface up, so that the cotyledons fall into place against each other. A missing cotyledon is then readily evident because, as in a jigsaw puzzle, the surrounding pieces will not fit together.

f. Measure and weigh the placenta. This usually is dictated by institutional policy and is not always done. Regardless of policy, if the placenta appears to be of abnormal size, measuring and weighing are indicated. This information is then recorded on the baby's chart.

CHAPTER

75

Postbirth Inspection of the Cervix and Upper Vaginal Vault

This discussion concentrates on the postbirth inspection of the cervix and upper vaginal vault, since generally speaking this inspection is not done routinely and since it involves skills beyond those used in the routine inspection of the vulva, perineum, and lower vaginal tract. This latter inspection is merely a matter of separating the labia and looking, and inserting two fingers into the vagina, applying pressure in different directions, and again looking.

The following considerations and key points apply to both cervical inspection and inspection of the upper vaginal vault:

1. These are uncomfortable, possibly painful, procedures. Therefore you need to do the following:
   a. Forewarn the woman of discomfort or pain and give a brief explanation of why the examination is necessary.
   b. Perform the procedure as quickly as possible.
   c. Provide some form of pain relief if the situation permits and the woman's threshold of pain warrants it.
2. The key to performing an inspection that will indeed allow you to visualize the area in order to obtain accurate information is to insert three or four of your fingers the full length of the vagina and exert strong pressure to compress the vaginal tissue in a direction away from the area you want to inspect. Otherwise, the just distended vaginal walls literally collapse around two fingers and an instrument and obstruct your path of vision. Being able to visualize the area readily also reduces considerably the amount of time it takes to perform the procedure and ensures accurate information.
3. The key to adequate visualization is a good source of light.

Procedure for Cervical Inspection

The following are steps taken in inspecting the cervix:

1. Insert three or four of your fingers, palmar side down, the length of the vagina to just in front of the cervix and exert strong pressure downward on the posterior vaginal wall.
2. Insert a long-length ring forceps and grasp the anterior lip of the cervix with it. Be careful not to mistake a fold of redundant bladder or lax vaginal wall for the anterior lip of the cervix.
3. Now move your fingers the full length of the posterior vaginal wall (i.e., into the posterior fornix) and again exert strong pressure downward on the posterior vaginal wall.
4. Insert a second long-length ring forceps and grasp the posterior lip of the cervix with it.
5. Hold the handles of the two ring forceps in your hand. Pull, if necessary, to bring the cervix more into view. Move the handles of the forceps toward one side of the perineum, thus slightly pulling the cervix so that you can visualize one lateral side of it.
6. Visually inspect the area of the cervix between the two ring forceps on one side.
7. If necessary, confirm your visual inspection by using the index finger of your vaginal hand to feel

the edge of the cervix while continuing to exert vaginal pressure with your remaining fingers.

8. Repeat Steps 5, 6, and 7 above, moving the handles of the forceps toward the other side of the perineum in order to visualize and inspect the other lateral side of the cervix.
9. If there are no cervical lacerations, remove the ring forceps and your vaginal hand.
10. If there is a cervical laceration, move the ring forceps to appropriate placements for repair of the laceration.

Hints and Alternatives

1. Maintain firm contact with the posterior vaginal wall as you insert your fingers. This helps you know precisely where you are, thereby aiding you in correct identification of the multitudinous folds of tissue and keeping your fingers from inadvertently entering a patulous cervix.
2. Be sure to insert your fingers the *full* length of the posterior vaginal wall and press *firmly* downward in order to bring the posterior cervical lip into view. Visualizing and grasping the posterior cervical lip seem to be the most troublesome aspects of the procedure of cervical inspection for the student. Utilizing this technique with your vaginal hand will minimize this problem.
3. If the cervix is very patulous, such as that found in a grand multipara, you may not be able to visualize adequately all of the cervix between the ring forceps placed on the anterior and posterior lips of the cervix. In such an event, you can assure yourself of having inspected the entire circumference of the cervix by walking the ring forceps around the cervix. This is done by placing one ring forceps on the anterior lip of the cervix and the second forceps next to it. Release the first forceps and place it on the other side of the second. Continue to leap-frog the ring forceps around the cervix. This technique can also be used if you are unable to locate the posterior lip of the cervix.

Procedure for Inspection of the Upper Vaginal Vault

The procedure for inspection of the upper vaginal vault includes the following steps:

1. Fold a 4×4 gauze square in fourths and clamp a long-length ring forceps on it.
2. Insert three or four of your fingers, palmar side down, the full length of the posterior vaginal wall.
3. Exert strong downward pressure on the posterior vaginal wall with your fingers.
4. Insert the ring forceps with the gauze on it by sliding it down the top of your vaginal fingers. This helps you avoid the tender anterior structures and keep as much of the gauze as possible away from the vaginal walls, since the gauze is abrasive to them.

   The gauze serves as a sponge to blot the area being exposed of blood and other fluids in order to facilitate visualization. If the gauze becomes saturated, remove the ring forceps, dispose of the saturated gauze, clamp on another gauze, and reinsert the ring forceps.
5.
   a. Locate both your fingertips and the end of the ring forceps in the posterior fornix.
   b. Press with the ring forceps against the cervix and press with your fingers against the vaginal wall.
   c. As you press, move your fingertips and the ring forceps away from each other and inspect the area you visualize between them.
   d. Repeat (b) and (c) after sequentially locating your fingertips and the tip of the ring forceps in each of the lateral fornices and in the anterior fornix.

CHAPTER

76

Manual Removal of the Placenta

Manual removal of the placenta is one of several actions to take in the management of a third stage hemorrhage (see Chapter 32). If at all possible, the woman should have a patent IV and some form of analgesia or anesthesia, as this is an extremely painful procedure.

The woman should be catheterized unless you are sure she has an empty bladder. A full bladder not only impedes your performing a manual removal of the placenta but may also impede resolution of the problem by preventing proper contraction and position of the uterus. An empty bladder also reduces trauma to the bladder during this procedure.

Although it is ideal to use a gauntlet glove on the hand doing the manual removal, the reality is that most hospitals do not have these gloves readily available. If at all possible to do so quickly, you should at least change the glove on the hand you are going to insert into the uterus and double glove. As time is of the essence, however, most clinicians proceed with the gloves they have on but should double glove and make sure the end of the glove is pulled as far up the arm as possible without tearing the glove.

Your *whole* hand (including the thumb) is placed inside the uterus by following the cord to the placenta. See Figure 76-1. Once you have inserted your hand into the uterus, do not bring your hand out until you have separated the placenta from the uterine wall and are bringing out the placenta. Do not go in and out, in and out, as this increases the risk of infection.

Your other hand grasps the uterus (fundus) externally through the abdominal wall (see Figure 76-1). This accomplishes three purposes:

1. Controls the mobility of the uterus
2. Keeps the fundus as contracted and thick as possible, which both facilitates separation and reduces the risk that the internal hand might perforate the uterus
3. Serves as a specific counterforce to your internal hand, which better enables you to feel what you are doing between your two hands

Once you locate the placenta, quickly feel the entire fetal surface of the placenta to obtain an anatomical perception of the size of the placenta and where the cord is inserted in order to get a sense of what you need to do. At the same time, sweep the margin of the placenta to find any area of separation

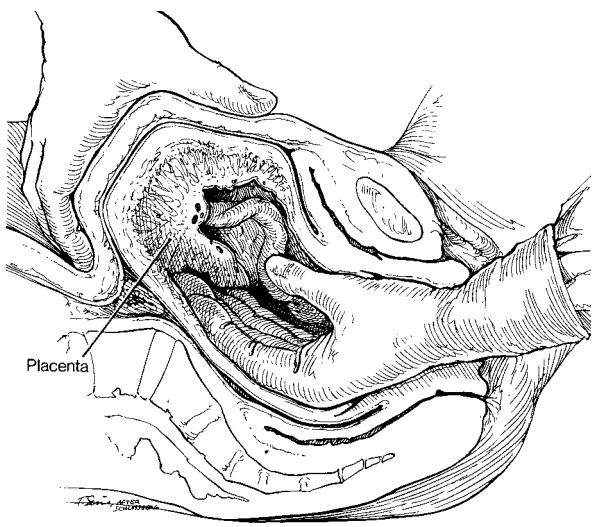

FIGURE 76-1 Manual removal of the placenta.

Source: From Cunningham, F. Gary, Gant, Norman F., Leveno, Kenneth J., Gilstrap, Larry C. III, Hauth, John C., Wenstrom, Katherine D. *Williams Obstetrics*, 21st Edition. McGraw-Hill, New York, 2001. Reproduced with permission of the McGraw-Hill Companies.

that will give you a starting point in the right plane for separating the placenta from the uterus.

The back of your hand is placed against the uterine wall, as this slight cupping of the hand parallels the curve of the intrauterine cavity. Insinuate your fingers between the placenta and the uterus to establish a line of cleavage. Then sweep your hand back and forth from side to side, cutting through the decidua with the outer edge of your little finger, fingertips, and first finger (see Figure 76-1). You will perceive a spongy feeling with a definite give to it as the placenta separates from the uterus. You may need to turn your hand over in order to separate the anterior portion of the placenta. This leaves the back of your hand still against the uterine wall.

The entire placenta should be in the palm of your hand before you bring it out. If you are unsure whether the placenta is totally separated, sweep the uterine wall with your hand, keeping the back of your hand in contact with the uterine wall, feeling for and separating any remaining areas of attachment. Make sure the placenta is totally separated before bringing it out so as not to invert the uterus when you remove your hand (and the placenta).

Bring the entire placenta out at once; don't pull on just a piece, as that piece will simply tear from the rest of the placenta and make assessment of the placenta difficult and potentially inaccurate. Bring the placenta out slowly as your external hand continues to keep the uterus contracted as it empties. The membranes may need to be teased out, which is done the same way as for any delivery of the placenta and membranes (see Chapter 31).

Make sure the uterus is contracted and immediately inspect the placenta, membranes, and cord (see Chapter 74). The placenta should be intact with complete membranes.

Clinicians disagree on whether the uterus should be explored routinely after manual removal of the placenta. Those who argue in favor of routine intrauterine exploration after manual removal of the placenta state that they do it to be sure that all the placenta and membranes have indeed been removed. Those who argue against routine intrauterine exploration after manual removal of the placenta state that such action increases the risks of infection, trauma, and uterine rupture. All clinicians agree that intrauterine exploration is mandatory if the placenta comes out in pieces or is not intact on inspection. See Chapter 77 for the technique of fourth stage intrauterine exploration.

The administration of oxytocin is the last step in manual removal of the placenta. It is given after intrauterine exploration of the uterus (if this is done) to ensure contraction of a now traumatized and possibly exhausted uterus. Further follow-up with a methylergonovine (Methergine) series postpartally (0.2 mg every 4 hours for 6 doses) is done if there is any question of possible retained placental fragments or incomplete trailing membranes.

CHAPTER

77

Fourth Stage Intrauterine Exploration

Intrauterine exploration is one of several actions taken in the management of an immediate (fourth stage) postpartum hemorrhage. If done, intrauterine exploration should be performed as quickly and smoothly as possible, as it is a painful procedure. It is performed when you think there might be placental fragments, cotyledons, or membranes retained in the uterus after the placenta has been expelled. The debate between clinicians as to whether the uterus should routinely be explored after manual removal of the placenta is discussed in Chapter 76.

The woman should be catheterized unless you are sure she has an empty bladder. This will reduce trauma to the bladder during this procedure. It also ensures that a full bladder will not be displacing the uterus, thereby decreasing the ability of the uterus to contract properly.

Wrap one 4 × 4 gauze around two (or four) fingers. A gauze is used because it provides a rougher surface than your gloved hand. A rougher surface helps pick up any placental fragments or ragged membranes which your uncovered gloved hand would just slip over. *One* gauze is used as a routine in order to best keep track of the gauze to be sure no gauze is left inside the uterus or vagina. Your thumb holds the end of the gauze against the side of your first finger.

Your *whole* hand (including your thumb) is placed inside the uterus. Your other hand grasps the uterus externally through the woman's abdominal wall for the same reasons this is done during manual removal of the placenta (see Chapter 76).

Once you have inserted your hand in the uterus, keep it there until you have explored the entire inner surface of the uterus. Do not repeatedly go in and out, in and out, as this increases the risk of infection.

Use the back of your hand to sweep the inside of the uterus. Cupping your hand inside the uterus will cause the outer surface (back) of your hand to conform with the inner contour of the uterus.

Sweep the entire uterus. You will need to turn your hand over in order to do this and keep the back of your hand in contact with the uterine wall. Carefully use the tips of your fingers to separate any cotyledons. The movements of your intrauterine hand should be well counterbalanced by your external hand in the precise area in order to better feel what you are doing and reduce the risk of perforating the uterus.

When you have explored the entire intrauterine cavity, slowly withdraw your hand. Look at what you bring out and identify everything as either blood clots, placental tissue, or membranes. If you are *not sure* that you got everything out in the process of bringing out your hand, unwrap and discard the gauze on your hand, wrap *one* fresh gauze around your hand as before, and go back in *once*. Quickly sweep the uterus, bring your hand out slowly, and identify whatever you bring out.

Unwrap and discard the gauze from around your fingers. Mentally note that you have done this so you will have no question later of having left this gauze in the uterus or vagina.

Massage the uterus with your external hand. The uterus should be well contracted.

Oxytocin is administered after fourth stage intrauterine exploration to ensure continuing contraction of the uterus. Some clinicians will also follow up with a postpartal series of methylergonovine (Merthergine) 0.2 mg every 4 hours for 6 doses.

CHAPTER

78

Bimanual Compression

Bimanual compression is one action used for controlling immediate postpartum hemorrhage. (See Chapter 34.) It is well named because it literally involves the midwife compressing the uterus between his or her two hands. Bimanual compression is accomplished as described in the following paragraphs and illustrated in Figure 78-1.

One hand is inserted into the vagina and then doubled up into a fist. The fist is placed into the anterior fornix, *palmar side up*. It is important that the fist be positioned palmar side up because this position provides the proper directional thrust and allows you to use greater power behind the fist for compression. Pressure and massage are then applied inward and upward against the anterior wall of the uterus, largely in the area of the lower uterine segment and the corpus (body) of the uterus.

At the same time, the other hand presses deeply into the abdomen behind the uterus. The open abdominal hand, palmar side against the uterus, then

FIGURE 78-1 Bimanual compression of the uterus. Note the position of the hands.

Source: From Cunningham, F. Gary, Gant, Norman F., Leveno, Kenneth J., Gilstrap, Larry C. III, Hauth, John C., Wenstrom, Katherine D. *Williams Obstetrics*, 21st Edition. McGraw-Hill, New York, 2001. Reproduced with permission of the McGraw-Hill Companies.

applies pressure and massage in an in-and-downward direction against the posterior wall of the uterus, largely in the area of the fundus and the corpus of the uterus.

The in-and-upward thrust of the vaginal fist and the in-and-downward thrust of the abdominal hand compress the uterus between the two hands. This compression of the uterus places direct pressure on the bleeding uterine vessels and also stimulates the uterus to contract, which will also compress the vessels by virtue of the uterine musculature arrangement through which the arteries and veins course.

Bimanual compression is continued until uterine contraction is ensured and bleeding is diminished. This can be tested for by momentarily releasing the pressure on the uterus and then evaluating the uterine consistency and amount of bleeding.

CHAPTER

79

Cutting an Episiotomy and Repairing Episiotomies and Lacerations

An episiotomy is a surgical incision of the perineal body. The factors to be considered in deciding whether to cut an episiotomy are discussed in the chapter dealing with management of the second stage of labor (Chapter 28). The discussion here pertains to the knowledge and skills necessary for cutting and repairing episiotomies, cutting and repairing a defibulation, and repairing various lacerations, and to specific techniques involved in these skills.

Relevant Anatomy

A thorough knowledge of pelvic muscles and structures is essential to proper cutting and repair of episiotomies and repair of lacerations. Structures of the perineum are discussed in Chapter 56. Pertinent pelvic muscles and their location are as follows and as illustrated in Figure 79-1.

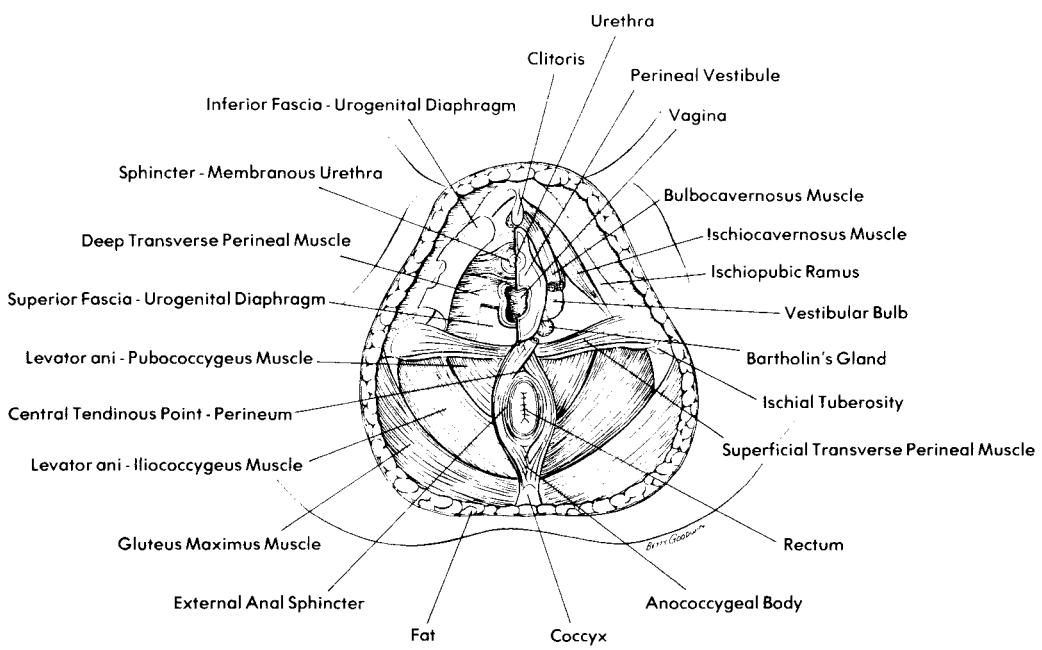

FIGURE 79-1 Muscles of the perineum and related structures.

The muscles of the perineum include the bulbocavernosus, ischiocavernosus, superficial transverse perineal, deep transverse perineal, sphincter of the membranous urethra, and external anal sphincter. The central tendinous point of the perineum is also a part of the perineum. Table 79-1 gives the boundaries and functions of each of these muscles and the central tendinous point of the perineum [1, 2].

The urogenital diaphragm is located between the inferior rami of the pubis and the ischium (ischiopubic ramus) which, with the symphysis pubis, comprise the anterior triangle of the pelvic outlet. It is a musculomembranous sheath that serves as the anterior portion of the pelvic floor musculature. Muscles of the perineum that are superficial to the urogenital diaphragm are the bulbocavernosus, ischiocavernosus, and superficial transverse perineal.

The urogenital diaphragm consists of the inferior fascia (which lies immediately beneath the superficial muscles) and the superior fascia (which is the posterior fascia of the urogenital diaphragm). Between these two layers of fascia, and therefore within the urogenital diaphragm, are the deep transverse perineal muscle and the sphincter of the membranous urethra. The urethra and the vagina are openings through the urogenital diaphragm.

The pelvic diaphragm consists of the levator ani and coccygeus muscles and their fascia (see Figure 79-2). These combine with the piriformis and obturator internus muscles to comprise the muscles within the pelvis. Together they serve as the most inferior portion of the body wall. As such they give support to the pelvic viscera, confine the contents of the abdomen, and close the abdominopelvic cavity. They also exert a sphincteric action on the vagina and rectum. The coccygeus, piriformis, and obturator muscles are much too far posterior and lateral to be involved in either episiotomies or lacerations of the vagina or perineum, and so are not described here.

The muscle comprising the largest portion of the pelvic floor is the levator ani. Because it is a broad muscle and because of its attachments, it is often described as a hammock of muscle. Its superior attachments are anterior to the pelvic brim on the pelvic surface of the superior ramus of the pubis, medial to the medial surface of the ischial spine, and more posterior to the fascia of the obturator muscles. The muscle fibers sweep across the pelvic cavity at varying degrees of direction, with some crossing the sides of the urethra and vagina and others sheathing the rectum between the external and internal sphincter. They are separated from each other anteriorly by the passage between them of the urethra, vagina, and rectum. Posteriorly most of the muscle fibers simply become continuous with their counterparts from the other side in the area between the rectum and the coccyx; some blend with muscle fibers of the rectum; others insert posteriorly into the anococcygeal body and the coccyx.

The levator ani has two major groupings of muscle fibers: (1) the pubococcygeus and (2) the iliococcygeus. Of these two, the iliococcygeus, arising in part from the ischial spine and inserting in the anococcygeal body and the coccyx, is too far posterior and lateral to be involved in either episiotomies or lacerations of the vagina or perineum.

The pubococcygeus group of muscle fibers arises from the pelvic surface of the superior ramus of the pubis on either side of the pelvis. The muscle fibers extend posteriorly as they descend in the pelvis on either side of the urethra, vagina, and rectum and sheath these structures. They are separated by the interlevator cleft (genital hiatus), which accommodates the passage of the urethra, vagina, and rectum. The anterior, or medial, muscle fibers of the pubococcygeus form musculofascial extensions, which support these organs and insert into the posterior aspect of the urogenital diaphragm and the central point of the perineum. The majority of the muscle fibers pass horizontally posterior around the rectum with a lesser number of superficial, anterior fibers inserting into the anococcygeal body and a greater number of deep, more posterior, fibers forming a sling in the space between the rectum and the coccyx by joining and blending with the muscle fibers from the other side.

In effect, then, there are three layers of muscles from outside to inside starting at the perineal body and vaginal introitus and following an imaginary pathway paralleling the posterior and lateral walls of the vagina. These three layers are as follows:

Layer 1: bulbocavernosus and superficial transverse perineal

Layer 2: deep transverse perineal

Layer 3: pubococcygeus of the levator ani

Layer 1 contributes with other muscles to the makeup of the central point of the perineum. Layers 2 and 3 have muscle and fascial fibers that extend to the posterior aspect of the central point of the perineum.

TABLE 79-1 Muscles of the Perineum

Muscle	Boundaries	Function
Bulbocavernosus	There are two bulbocavernosus muscles, one on either side of the vaginal orifice; posteriorly they attach to the central tendinous point of the perineum and the inferior fascia of the urogenital diaphragm; anteriorly they insert into the corpora cavernosa clitoridis; laterally they surround the orifice of the vagina, covering the vestibular bulbs and Bartholin's glands on either side.	Known as the sphincter vaginae, their contraction reduces the size of the vaginal orifice; the anterior muscle fibers contribute to clitoral erection.
Ischiocavernosus	There are two ischiocavernosus muscles, one on either lateral boundary of the perineum; posteriorly they arise from the inner surface of the ischial tuberosities; anteriorly they cover and insert into the sides and posterior surface of the crus clitoridis; laterally they extend from the clitoris to the ischial tuberosities along the ischial ramus, from which they derive some of their fibers.	Maintain clitoral erection
Superficial transverse perineal (transversus perinei superficialis)	There are two superficial transverse perineal muscles, which generally follow the transverse diameter of the pelvic outlet; they arise from the inner and anterior surface of the ischial tuberosity of the superior ramus of the ischium by a small tendon; they insert into the central tendinous point of the perineum.	Fix the location of the central tendinous point of the perineum
Deep transverse perineal (transversus perinei profundus)	There are two deep transverse perineal muscles, which are broader than the superficial transverse perineal muscles; they arise from the inferior ramus of the ischium; they insert into the sides of the vagina.	Help to fix the vagina
Sphincter of the membranous urethra (sphincter urethrae membranaceae)	There are two sphincters of the membranous urethra muscles, consisting of external and innermost fibers; they arise from the margin of the inferior ramus of the pubis on either side; they cross the space of the pubic arch, pass around all sides and encircle the urethra, and unite with the muscle fibers from the other side by blending with them.	Urethral sphincter
External anal sphincter (sphincter ani externus)	The external anal sphincter consists of two strata of fibers (superficial and deep), which together form one flat plane of muscular fibers; it arises from the anococcygeal body, which is a tendinous band extending from the tip of the coccyx to the posterior margin of the anus; it passes around, encircles, and surrounds the anal canal; it inserts in the central tendinous point of the perineum.	Anal sphincter; helps to fix the location of the central tendinous point of the perineum
Central tendinous point of the perineum	A fibromuscular structure in the midline between the vagina and the anus and at the base of the urogenital diaphragm; the tissue is fibrous because it is the point of fusion of both the superior and inferior fascia of the urogenital diaphragm and the external perineal fascia and Colles' fascia; it has muscular fibers because it is a common point of attachment for a number of muscles whose fibers blend together into the central tendinous point of the perineum, among them the bulbocavernosus, superficial transverse perineal, some fibers of the deep transverse perineal, external anal sphincter, and the levator ani-pubococcygeus.	Common point of attachment for a number of layers of fascia and muscles

Cutting an Episiotomy

There are two types of episiotomies: (1) the midline (medial) and (2) the mediolateral, which may be to the left or to the right (see Figure 79-3). The following principles should be observed, regardless of which type is cut:

1. The presenting part of the fetus is protected from injury.
2. A single cut in any direction is far preferable to repeated snipping because the latter will leave jagged edges.
3. The episiotomy should be large enough to accomplish the purpose for cutting it.
4. The cut should be timed to avoid lacerations (too late) and unnecessary blood loss (too soon). The perineum should be bulging, the vaginal orifice distended by approximately a 3-centimeter diameter of fetal presenting part between contractions, and delivery of the presenting part should be expected to occur within the next two to four contractions.

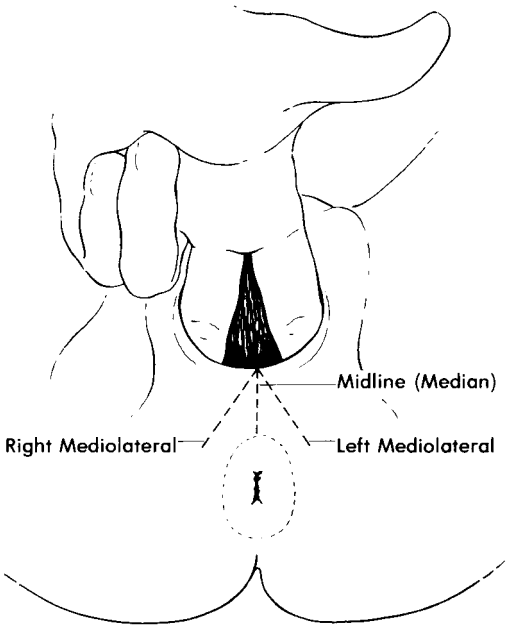

FIGURE 79-3 Types of episiotomy.

Midline Episiotomy

The midline episiotomy, cut into the central tendinous point of the perineum, separates the two sides of the bulbocavernosus and superficial transverse perineal muscles. Depending on the depth of the cut, the two sides of the deep transverse perineal muscle may also be separated. The technique for cutting a midline episiotomy follows.

Procedure	Rationale
1. Place your index and middle fingers into the vagina, palmar side down and facing you. Separate them slightly and exert outward pressure on the perineal body (Figure 79-3).	**1.** This protects the presenting part in two ways: **a.** Your fingers are against the fetal presenting part and are thick enough that scissors properly placed between them will not touch the baby. **b.** The outward pressure directs the perineal body away from the baby. The pressure also flattens the perineal body a bit more, making it easier to incise in a single cut.
2. The blades of the scissors are placed in a straight up-and-down position so that one blade is against the posterior vaginal wall and the other blade is against the skin of the perineal body, with the point where the blades cross at the midline of the posterior fourchette.	**2.** A midline episiotomy is cut in the middle of the central tendinous point of the perineum from the posterior fourchette down to the external anal sphincter.
3. a. With your vaginal fingers and with your thumb of the same hand on the outside of the perineal body, palpate for and locate the external anal sphincter.	**3. a.** A midline episiotomy cuts to, but not into or through, the external anal sphincter. Knowing the location of the external anal sphincter removes any hesitation you may feel in cutting an adequate episiotomy due to fear of accidentally cutting through the sphincter.
b. Adjust the length of the blades of the scissors on the perineal body to the projected length of the incision.	**b.** The length of the incision should be adequate to accomplish the purpose for cutting it. Knowing the location of the external anal sphincter informs you as to the maximum length possible.

Procedure	Rationale
4. Cut.	
5. Sponge, observe, and palpate again for the external sphincter. Evaluate if another cut in this plane is needed.	**5.** The sharpness or dullness of the scissors may affect the efficiency of the first cut.
6. Cut again, if needed.	**6.** Avoid snipping. Two cuts should accomplish the incision in this plane even if the scissors are dull.
7. Evaluate the extent of the incision into the vagina. Feel for a band of tight, restricting vaginal tissue just inside the introitus.	**7.** This band is frequently felt in primigravidas and may be a vestige of the hymenal ring.
8. Extend the vaginal side of the incision, if needed, or if the band of tissue is there and needs to be incised. Extension is accomplished by now pressing downward with your two vaginal fingers, holding them apart to splint the incision line and in far enough to extend beyond the projected lengthening of the incision line. Bring the scissors from above the back side of the hand to slide between the fingers and make the cut.	**8.** The vaginal side of the incision usually needs extending since the cut on that side usually does not go as far as on the skin side when the perineal body is incised. Sliding the scissors between your fingers protects the fetal presenting part.
9. Apply pressure with 4 × 4 sponges to the incision.	**9.** This will staunch any bleeding.

Mediolateral Episiotomy

The technique of cutting a mediolateral episiotomy is the same as that for cutting a midline episiotomy with the exception of the direction of the cut and, therefore, the placement of the scissors for cutting. It does not matter if a mediolateral episiotomy is cut to the left or to the right. It is easier for a right-handed learner to repair a left mediolateral episiotomy and vice versa. A mediolateral episiotomy is cut at a slant starting at the midline of the posterior fourchette with the points of the scissors directed toward the ischial tuberosity on the same side as the incision. Take care to palpate for the external anal sphincter, to direct the cut far enough laterally to avoid the sphincter, and, preferably, to leave approximately 1 centimeter of levator ani muscle between the incision and the sphincter for repair. Also take care not to start the cut on the lateral aspect of the fourchette or direct the cut too far laterally, in order to avoid the Bartholin's gland on that side.

A mediolateral episiotomy cuts into the central tendinous point of the perineum, through the bulbocavernosus and the superficial and deep transverse perineal muscles, and into the pubococcygeus (levator ani) muscle. How much of the pubococcygeus muscle is cut depends on the length and depth of the incision. Usually it is a larger cut than the midline episiotomy because it usually is performed when more space is needed than is available between the posterior fourchette and the external anal sphincter.

Aids to Wound Healing

Wound healing involves three phases: inflammation, proliferation, and maturation [3]. Wound healing is facilitated by actions taken at different times in the maternity cycle, as follows.

Antepartally

1. Prevention of nutritional deficiencies
2. Prevention of anemia

Intrapartally

1. Prevention of maternal exhaustion and dehydration
2. Strict adherence to aseptic technique
3. Prevention of unnecessary further trauma to the incisional tissues, such as might be caused by any of the following:
   a. use of an eyed needle pulling a double strand of suture through the tissue when an eyeless or swaged-on needle (atraumatic suture) pulling a single strand of suture could be used instead

   b. use of suture with suture gauge and needle size larger than needed
   c. inappropriate use of a traumatic cutting needle rather than an atraumatic round needle
   d. misplacement of stitches, requiring removal and replacement
   e. placement of stitches too close together
   f. tissue strangulation resulting from too tight stitches
   g. repeated unnecessary sponging, prodding, and probing of the wound
   h. use of instruments that crush tissue
4. Removal of blood clots and debris before closure
5. Establishing visible hemostasis before closure to avoid formation of hematomas
6. Precise approximation of tissues
7. Closure that obliterates all dead space

Postpartally

1. Diet high in protein and vitamin C
2. Perineal cleanliness
3. Warm sitz baths. A moist environment facilitates rapid epidermal healing [3].

These actions are aimed at the prevention of infection, tissue devitalization, and tissue trauma; provision of tissue building and healing nutrients; and increased circulation to the area.

Manipulation of Equipment

The following hints may ease some of the awkwardness and mistakes experienced when first learning how to suture.

Sutures

1. Use suture with a swaged-on needle.
2. Sutures may come with a curved cutting needle swaged onto one end and a curved, circular, noncutting needle swaged on to the other end. Holding the two needles in one hand, gently straighten the suture and cut it in half. Remove the half with the cutting needle on it from your immediate working area.
3. In order to prevent the length of suture from dangling or dragging across areas of contamination, keep the excess suture gathered up in the palm of the hand holding the needleholder.
4. Never place a clamp or the needleholder on the junction of the needle with the suture, or on the suture itself, except for an end that is to be cut off after tying a knot with an instrument tie. Such an action weakens the suture.

Needle

1. The needle is held by clamping the needleholder on the portion of the needle closest to the suture without being on the junction of the two.
2. The needle is clamped by the tip of the needleholder.
3. The needle is clamped so that its curve is at a 90° right angle to the needleholder.

Needleholder

1. When taking a stitch, you have the most control of the needleholder and most latitude for wrist action if you hold it so that the thumb holes are in the palm of your hand (hold them there with your ring and little fingers), your thumb and middle fingers are on either lateral side of the shaft, and your index finger is on one side (usually the upper) of the broad side of the shaft.
2. Use the same hand position on the needleholder for pulling the needle through the tissue after reclamping the needleholder on the tip (point) of the needle for this purpose.
3. When doing an instrument tie, hold the needleholder by inserting your thumb and middle finger in the holes provided for this at the hand end of the needleholder and placing your index finger on the broad side of the shaft. Your two remaining fingers help hold the excess suture in the palm of your hand.

Stitching with a Curved Needle

Wrist action, combined with entry into tissue with the point of the needle, is the key to success for stitching with a curved needle.

1. Be sure to use the point of the needle in inserting it into tissue, even though this seems to direct the needle in a direction opposite from where you wish to bring the needle out. A common mistake is to try to insert the needle by holding and pointing it in the direction and shape of the stitch to be taken. In so doing, you are actually attempting to insert the needle with the side of its tip—which is why the skin seems so tough and the needle so dull.
2. Start the stitch by holding the needle with its curved midportion up and then turn it even further until you can enter the tissue with the point of the needle. This means that your hand will be holding the needleholder shaft so that the back of your hand is up and then further

pronated as the needle point is positioned for entry.

As the needle enters the tissue, rotate your wrist and hand approximately 180° so that the needle follows the necessary directional path for exit and making the stitch.

3. The principle to use in pulling a curved needle through tissue is to follow the curve of the needle. If you pull straight up after reclamping the needleholder on the tip of the needle, you will meet resistance and traumatize the tissue. Instead, again using wrist action, simply draw the needle through in the direction of the curve of the needle and it slips through the tissue with ease. One caution with this maneuver: Be careful not to poke the woman with the point of the needle, which is now directed for entry again with this completion of the circle.

Knots and Suture Stitches

Knots

An essential skill in repairing episiotomies and lacerations is knowing how to tie knots, whether used for starting and ending a series of suture stitches or for interrupted stitches.

The knot used is the square knot. You can do either hand ties or an instrument tie or both. It does not matter which method you use for tying a knot as long as you become proficient in doing it that way. There are advocates of each. Those who know how to do both hand ties and an instrument tie have the advantage of being able to use whichever will be easier for any given location.

Skill in tying knots is a matter of much patient and repetitious practice. The learner is encouraged to study *The Knot Tying Manual* [4], which clearly illustrates both methods of tying a square knot. Use the practice board that accompanies this monograph. Pay particular attention to the rules for tying knots, on page 5 of the manual.

Suture Stitches

There are four basic suture stitches used in repairing an episiotomy: (1) blanket (continuous locked), (2) interrupted, (3) continuous, and (4) continuous mattress (Figure 79-4). In addition, a crown stitch may be used to repair the bulbocavernosus muscle. Knowledge of and skill in these various suture stitches will also enable you to repair any perineal, vaginal, cervical, periurethral, and clitoral lacerations, including third and fourth degree perineal lacerations. Following is a description of each of these suture stitches as done by a right-handed person. If you are left-handed, simply reverse the direction of the horizontal stitching. This section only discusses the mechanics of doing these sutures; use of these stitches in the repair of an episiotomy, defibulation, or laceration is described later in the chapter.

Blanket (Continuous Locked) The blanket, or continuous locked, suture stitch is used for closing the vaginal mucosa. After placing an anchoring stitch and knot (one end of the suture in the knot is cut short, the other end continues for the suture stitches), proceed as follows (see Figure 79-4):

1. Move the anchoring knot to the left side of the anchoring stitch.

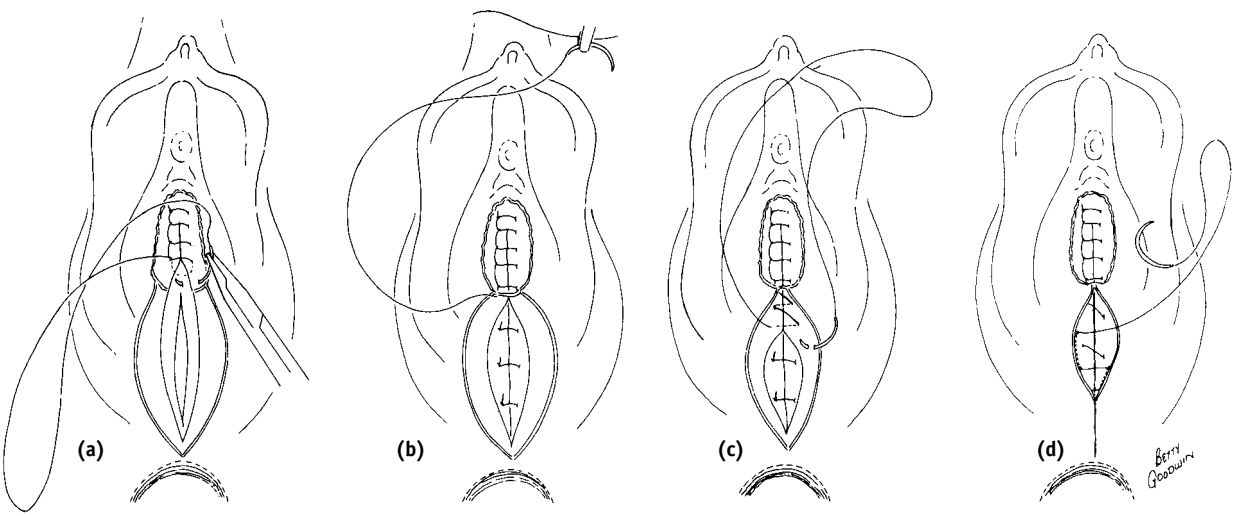

FIGURE 79-4 Suture stitches. (a) blanket (continuous locked); (b) deep interrupted; (c) continuous unlocked; (d) mattress.

2. Hold the suture down along the left side of the incision line.
3. Make sure the entry and exit points of this stitch are precisely across from each other.
4. Take a bite on the right side of the incision.
5. Bring the point of the needle just beneath the tissue surface in the midline of the incision.
6. Continue the bite to the left of the incision.
7. Exit the needle between the incision and the suture to the left of it (this locks the stitch).
8. Pull the needle and suture through.
9. Repeat Steps 2 through 8 for as many stitches as are needed.

Interrupted Interrupted stitches are used for deep muscle repair. An interrupted stitch is a single stitch with a knot (both ends cut short). It is taken from right to left, with the entry and exit points directly across from each other (see Figure 79-4).

Continuous A continuous suture is used for closure of the subcutaneous layer. The continuous suture is exactly like the blanket suture except that it is *not* a locked stitch (see Figure 79-4). Therefore, instead of holding the suture down along the left side of the incision line (Step 2 of the blanket suture stitch), hold it up alongside the stitches already taken and above where the stitch is being taken.

Continuous Mattress A continuous mattress suture stitch is used for the subcuticular closure of an episiotomy or laceration. Therefore, it is described here as an ascending line of subcuticular suture stitches because this is how they are placed when closing the perineal skin in an episiotomy or laceration repair (see Figure 79-4). The stitches can, of course, go in either direction and can be used as the final layer of stitches in repairing deeper periurethral lacerations. From the anchoring point, proceed as follows:

1. Take a shallow bite on the left side of the incision line, inserting and exiting the needle approximately "one cell layer" beneath the skin layer, in a perpendicular line on the same side of the incision. The depth of the bite between the entry and exit points can be greater than the one cell layer.
2. Pull the needle and suture through.
3. Take a shallow bite on the right side of the incision line. The entry point should be directly across from the exit point of the preceding stitch on the left side of the incision line. Again, the entire stitch is on the same side of the incision in a perpendicular line. And again, the entry and exit points are approximately one cell layer beneath the skin layer, with the depth in between being somewhat greater.
4. Pull the needle and suture through and bring the skin edges together.
5. Return to the left side of the incision line and repeat Step 1. The entry point should be directly across from the exit point of the preceding stitch on the right side of the incision line.
6. Repeat Steps 2 through 5 for as many stitches as are needed.

Although some may find it easier to use a straight needle to do a subcuticular closure with the mattress stitch, it is not suggested. Doing so means cutting off the swaged-on curved needle and using an eyed straight needle. Use of an eyed straight needle means that an unnecessary double strand of suture will be going through the tissue, which is contrary to one of the previously described actions to aid wound healing. With practice, it is possible to become proficient and comfortable in doing this stitching with the curved needle.

Crown Stitch The crown stitch is used to reunite the cut bulbocavernosus muscle. Its purpose is to reduce gaping of the vaginal introitus and to facilitate the return of good muscle tone by deliberate approximation of this muscle. This, in turn, facilitates enjoyable sexual relations for both the female and the male. Care must be taken, however, only to closely approximate the muscle in repairing it; pulling and stitching the two sides together tightly may have the reverse and adverse effect of causing dyspareunia. Study the following steps in relation to Figure 79-5.

1. Enter the tissue at the upper left side of the perineal incisional line. Be sure to start this stitch far enough away from the skin edge to allow for both subcutaneous and subcuticular closure over the completed crown stitch.

   Direct your needle so that after entry it follows a sequence of swinging up, laterally, down, and medially to where it exits in the same plane, only further down, in which it entered.

   The amount of lateral thrust must be carefully judged. It must be enough to catch the retracted cut end of the bulbocavernosus muscle but no more than this. The more lateral you go, the more vascular the area you are getting into and the greater the risk of unknowingly nicking a blood vessel. Subsequent slow seepage will result in a hematoma, which may evidence itself

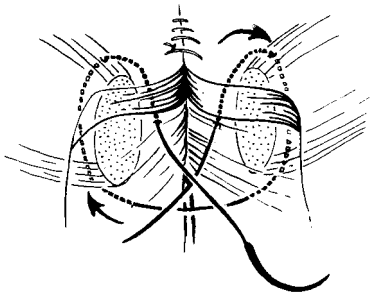

FIGURE 79-5 Crown stitch. Reuniting the divided bulbocavernosus muscle.

approximately an hour later. This is a rare happening that can be avoided by simply going only as far laterally as needed and not exaggerating this part of the stitch.

2. Check that you have indeed included this side of the bulbocavernosus muscle in this half of your stitch by grasping the two ends of the suture a short distance from the tissue and pulling down on them. If you have the bulbocavernosus muscle, you should see the entire left side of the perineum from the clitoris to your stitch pull down as you pull on the suture ends. If this does not happen, pull the suture on through and try again or get someone more experienced to put the stitch in. If you do see the pulling and know that you have the bulbocavernosus muscle on the left side, then proceed to the next step.
3. Enter the tissue at the lower right side of the perineal incisional line directly across from your exit point on the left side of the incisional line.

   Direct your needle so that after entry it follows a sequence of swinging laterally in, up, down, and medially to where it exits in the same plane, only further up, in which it entered, and directly across from the entry point on the left side of the perineal incisional line.

   Again judge carefully the amount of lateral thrust as explained in Step 1.
4. Check that you have caught the right side of the bulbocavernosus muscle using the same technique as described in Step 2. You should see the entire right side of the perineum from the clitoris to the right half of your stitch pull down as you pull on the suture.
5. Tie your knot so that the cut ends of the bulbocavernosus muscle are closely joined, but not too tightly. The placement of the two halves of the stitch ensures the approximation of the muscle.
6. Cut both of the suture ends close to the knot.

Principles of and Thoughts About Episiotomy and Laceration Repair

The repair of an episiotomy or laceration should be as artistic as you are capable of making it. An "artistic" repair is one that is done with special care, for a result that not only serves the woman well functionally but is cosmetic as well.

All repairs should, of course, have good functional results. Specifically, the repair should restore the structure of the pelvic musculature and its support to the pelvic organs. An effective repair provides for prophylactic gynecology, particularly in years to come, against cystoceles, rectoceles, and uterine prolapse. It also promotes sexual satisfaction by providing a musculature base for Kegel exercises to build on in reducing the vaginal laxness created by tissue stretching during childbirth. Also, there should be good bowel control and sphincter tone in the event the external anal sphincter was severed. Good functional results also include *not* creating functional problems during the process of repair, for example, not creating fistulas by misplacing stitches, thus providing a channel between orifices; or not creating sexual problems by placing stitches in the hymenal ring; not approximating tissue anatomically, or reuniting the bulbocavernosus muscle too tightly—all of which can cause dyspareunia.

The artistry relates to the cosmetic results. Cosmetic results are important because an episiotomy and lacerations do constitute an assault on the woman's body which, like any type of surgery or injury elsewhere on the body, affects the woman's self-image and body concept. Further, the perineum has become a much more visible portion of the woman's body both to herself and to her sexual partner. Her body should not be disfigured by careless repair of episiotomies or lacerations. The perfect repair results in a scar the breadth of a hair and with all aspects of the perineum in precise anatomical alignment without wrinkles, puckers, or overlapping skin edges. It may not always be possible or within the individual clinician's ability to achieve perfection—but it is a goal to aim for. It has been observed that midwives who do needlework

(e.g., sewing, embroidery, needlepoint) generally have an advantage in doing the fine needlework in episiotomy and laceration repair.

Adequate anesthesia is an essential prerequisite to episiotomy or laceration repair. The area of repair is physically sensitive and the woman is likely to be psychologically sensitive about the procedure as well. You need to recognize and respect this sensitivity as evidenced by concern that the woman not feel pain during the repair. Pudendal block or local infiltration for repair will provide adequate anesthesia and is described in Chapters 68 and 69. You should instruct the woman to differentiate between pressure and pain since she may still feel pressure even though not feeling pain.

The aids to wound healing listed earlier that are pertinent during the actual repair are presented again below with further elaboration:

1. Strict adherence to aseptic technique. This includes changing gloves and redraping if necessary; using an extra sterile glove over the sterile glove(s) you already have on your examining hand for checking the rectum and discarding the extra glove immediately after use; and positioning a sterile drape (hand towel) across the rectal area and below, to beneath the level of the table or bed, in order to provide a noncontaminated field in the event suture drops to that level and brushes against whatever is there.
2. Prevention of unnecessary further trauma to the incisional tissues. Examples of unnecessary further trauma include the following:
   - **a.** use of an eyed needle pulling a double strand of suture through the tissue when eyeless or swaged-on needles pulling a single strand of suture through the tissue are available.
   - **b.** use of a suture with suture gauge and needle size larger than needed. The following are generally used for episiotomy and laceration repairs:
     - **(1)** 4-0 chromic catgut is used for (a) repair of the anterior wall of the rectum in fourth degree lacerations, (b) repair of clitoral lacerations, or (c) repair of any other place when very fine sutures are desired.
     - **(2)** 3-0 chromic catgut is used for (a) repair of the vaginal mucosa, (b) the subcutaneous stitches, (c) the subcuticular stitches, and (d) repair of periurethral lacerations.
     - **(3)** 2-0 chromic catgut is used for (a) repair of the external anal sphincter, (b) repair of cervical lacerations, (c) repair of lateral vaginal wall lacerations, and (d) deep interrupted stitches of pelvic muscles. (These may also be repaired with 3-0 chromic catgut if the cut or laceration is not too extensive.)

       It helps when selecting suture gauge to remember that muscle requires a stronger suture. The larger the gauge number, the finer the suture (e.g., 4-0, 6-0, 8-0) and the smaller the gauge number the heavier the suture and the stronger the tensile strength of the suture (e.g., 2-0, 1-0).

       The size and type of needle usually used is the atraumatic, swaged-on General Closure needle. An atraumatic swaged-on G-I needle may be used for very fine, tiny stitches, as might be indicated in repairing a clitoral laceration.
   - **c.** inappropriate use of a traumatic cutting needle rather than an atraumatic round needle. A cutting needle is triangular and each edge is a cutting edge. Many clinicians believe that a cutting needle is not needed for the repair work under discussion. They prefer a round needle, which has a tapered point and will go through soft tissues easily with less trauma than a cutting needle. There is also less chance of nicking or lacerating a blood vessel with a round needle than with a cutting needle. Other clinicians believe that since the cutting needle is designed for the tougher, less vascular tissues it is valid to use a cutting needle for placing stitches in subcutaneous and subcuticular tissues.
   - **d.** unnecessary, excessive number of needle punctures caused by either
     - **(1)** misplacement of stitches, requiring removal and replacement or
     - **(2)** too many stitches, too close together. Too many stitches also means excessive suture in the wound, which slows the healing process by causing an inflammatory reaction to foreign material. You should carefully plan your stitches before you stick the woman. Good visualization facilitates proper placement of stitches.
   - **e.** tissue strangulation because stitches are too tight. Tissue strangulation devitalizes the tissue and, if the stitches are so tight that circulation is inadequate, may even cause the tissue to slough.
   - **f.** unnecessary repeated sponging and probing of the wound. This can cause further trauma and disrupt clotting, especially if the sponge is used to rub rather than blot. Constant

probing and sponging usually result from anxiety and insecurity. This is common in the learner, who should make a conscious effort not to sponge and probe repeatedly.

g. use of instruments that crush tissue, specifically, the use of pickup forceps. Learn to use them so you can hold tissue securely with them without crushing the tissue. Forceps with teeth allow for gentle grasping of tissue.

3. Removal of blood clots and debris prior to closure. If blood clots and debris are stitched over they can become foci for bacterial growth, inflammatory reaction, and tissue and repair breakdown.

4. Establishing visible hemostasis prior to closure. This avoids the formation of hematomas that can totally disrupt a repair with infection and tissue and repair breakdown. All significant bleeders, whether pumping or oozing, should be tied off before you begin the repair.

5. Precise approximation of tissues, the closure of which obliterates all dead space. Dead space weakens the tissue's healing ability and its function when healed. It also provides a non-pressure-producing spot conducive to hematoma formation and nonconducive to hemostasis. As such, it may also be a focus for bacterial growth and infection. It is also important that dead space not be created by allowing knots to slip while they are being tied. They should be snug enough to ensure approximation but not tight, which might cause tissue necrosis.

A suture often used in repair of episiotomies and lacerations is chromic catgut. Catgut is an absorbable suture as it is made from animal tissue (sheep intestine) and is composed primarily of collagen. As such it is a foreign protein in the human body and is dissolved by digestive enzyme action (proteolysis). Chromic catgut is catgut that has been treated with chrome salts. The function of the chrome salts is to delay the process of proteolysis by which catgut is absorbed, thereby extending the length of time the suture holds the tissue together during the healing process. Plain catgut will absorb in approximately one week and will begin to lose its strength in about 3 days. Chromic catgut delays absorption for 10 to 40 days, depending on the amount of chrome salts used, but generally will retain its strength for 2 to 3 weeks. This gives support to the wound for a longer period of time while it is healing. Absorbable suture is used because artificial support is not needed indefinitely. Catgut has the disadvantage of causing marked tissue inflammatory reaction. This, in turn, can produce edema, which places tension on the sutures and may cause tissue necrosis. The result of this is excessive scarring, which means a weaker functional repair. This inflammatory reaction can be minimized by using only sufficient suture to ensure hemostasis, closure of dead space, and approximation of the tissues—and not one stitch more. Artistry does *not* mean excessive decorative stitchery.

Hemostasis is one of the purposes for doing episiotomy and laceration repair. It is accomplished not only by tying off both pumping and oozing bleeders, by closure that eliminates dead space, and by not using a cutting needle, as mentioned before, but also by the following:

1. Probing the depth of the wound before stitching in order to identify the true depth that needs repair beneath the mucosal layer

2. Starting any line of suture at least 1 centimeter beyond the apex of the wound in order to include any retracted blood vessels

3. Using types of suture stitches that facilitate hemostasis in the most vascular areas, such as the blanket (continuous locked) suture stitch

In doing episiotomy and laceration repair it is imperative that you have good visualization of the field. Good visualization is achieved by positioning the woman properly, which may mean in lithotomy position in stirrups for extensive lacerations and complex repairs; proper positioning of light to illumine the field; proper exposure of the field (which may mean asking someone to scrub in to hold retractors and instruments, such as for cervical lacerations or high vaginal lacerations); use of a tamponade to provide a field that is clean and dry—that is, without a continual uterine blood flow obscuring the field; and positioning yourself properly for maximum efficiency in visualization and manipulation of tissues, materials, and equipment.

Finally, a happy balance has to be struck between the learner's need for time to perform an episiotomy or laceration repair without feeling rushed and the woman's need to have her legs down and together. If a woman is in stirrups, she should be in stirrups no longer than absolutely necessary. Being in stirrups over time can fatigue and become uncomfortable for the woman. Being in stirrups also impairs circulation, which if continued for a long time may be a causative factor in postpartal thrombophlebitis. A total of $1^1/_2$ hours should be considered the maximum amount of time any woman should have to be in stirrups. One effective way of handling this situation is for the learner to have a

set amount of time for doing the repair, after which any work not yet done will be completed by an experienced midwife. The learner can then pace himself or herself in accord with his or her learning needs. It is also possible to do episiotomy or minor repairs with the woman in the dorsal position.

Repair of a Midline Episiotomy

Following are the steps, listed in sequence, to take in repairing a midline episiotomy. As in other skills, this is only one way of doing it; there are other methods. This method is sound and will yield satisfactory functional and cosmetic results. Be open to other methods and individual variations, always seek the underlying rationale, and formulate your own basic methodology and individual variations. The method presented here will give you a valid base from which to develop and experiment and decide whether to continue or change this methodology [5].

1. Insert a tamponade to provide a field free of uterine bleeding. The most common tampon is a tailed, rolled, vaginal gauze sponge. It should be inserted in such a way that both of the following goals are met:
   a. The woman's discomfort during insertion is minimized as much as possible. To do this the tampon should not scrape along the tender and recently traumatized vaginal walls. You can minimize discomfort in three ways:
      (1) Lightly moisten the outside of the tampon to reduce friction and the scratchiness of dry gauze.
      (2) Insert three fingers along the posterior vaginal wall with the fingertips extending into the posterior vaginal fornix and exert strong downward pressure. (This braces the wound and creates space for insertion of the tampon.)
      (3) Insert the tampon by (a) holding it between the palmar surface of the index and middle fingers and the thumb of your inserting hand with the tail tucked into your palm; (b) inserting your index and middle fingers so that the back of them protects the anterior structures and vaginal wall from the gauze tampon; (c) pushing the tampon with your thumb the length of the vagina between the protective splinting and space provided by your two hands; and (d) clamping the tail of the tampon onto the abdominal drape, as a safeguard reminder to remove the tampon when no longer needed.
   b. The tampon should be inserted far enough to be well beyond the apex of the wound to allow for good visualization and room for the first stitch.
2. Identify the following structures and their anatomical juxtaposition both with the episiotomy open and with it gently pushed together with your fingers:
   a. depth of the cut or laceration
   b. vaginal apex of the cut or laceration
   c. hymenal ring
   d. mucocutaneous junction
   e. tissue layers
   f. muscles
   g. rectal sphincter
   h. perineal apex of the cut or laceration
3. Repair the vaginal mucosa with a 3-0 chromic catgut suture using an atraumatic (swaged-on) needle.
   a. Place your anchoring stitch approximately 1 cm above (beyond) the vaginal apex of the cut to catch any retracted blood vessels and provide hemostasis.
   b. Tie a knot after taking the anchoring stitch. Cut off the short end close to the knot.
   c. Plan ahead the number of stitches you will need between the anchoring stitch and a stitch placed right behind the hymenal ring.
   d. Close the vaginal mucosa with the other end of the suture using the blanket (locked continuous) suture stitches (see Figure 79-4 and the discussion of this stitch earlier in this chapter).
   e. If the incision is deep, do not completely close the vaginal mucosa at this time, as to do so will make it too difficult to get into the area for the deep interrupted stitches.
   f. Close the vaginal mucosa to the mucocutaneous junction (the junction of the vaginal mucosa with the perineal skin).
   g. Do not place a stitch in the hymenal ring, as this may cause dyspareunia. To avoid placing a stitch in the hymenal ring yet carry on the closure of the vaginal mucosa, do the following:
      (1) Lock the stitch immediately behind (inside) the hymenal ring by inserting the needle on the same side of the incision as you just exited for that stitch.
      (2) Swing the needle through the tissue underneath the hymenal ring.

(3) Exit on the same side, only now in front of the hymenal ring.

(4) Continue closure of the vaginal mucosa as before.

h. The first one or two blanket stitches should consist of bites large enough to close the cut in the area completely. Thereafter, the stitches include only the vaginal mucosa. The apex of the cut and the area beneath the vaginal mucosa will be closed next with the deep interrupted stitches.

i. After closing the vaginal mucosa, clamp the needle and the remaining suture onto the abdominal drape to be used later for the subcutaneous and subcuticular closure.

4. Repair the bulbocavernosus muscle with a crown stitch (see Figure 79-5 and the procedure earlier in this chapter). Use a 2-0 chromic catgut suture with an atraumatic (swaged-on) needle.

5. If the cut is quite deep, you may prefer to put in a layer of deep stitches first; you can sequentially then (a) finish closure of the vaginal mucosa, (b) repair the bulbocavernosus muscle with the crown stitch, and (c) put in a second layer of deep stitches. In a cut or laceration this deep, the first layer of deep stitches would close the deep transverse perineal muscle and the second layer of deep stitches would close the superficial transverse perineal muscles.

6. Repair the superficial transverse perineal muscles with deep interrupted stitches (see Figure 79-4 and the discussion of this procedure earlier in this chapter). Use 2-0 chromic catgut suture with an atraumatic (swaged-on) needle. Again, before taking any stitches, plan the number of deep interrupted stitches that will be needed to effect hemostasis, close dead space, and approximate the tissue. Bring the point of the needle just beneath the tissue surface in the midline or apex of the cut after taking half the stitch. This ensures closure of the area without dead space. You can then continue to the other side.

7. After placing the deep interrupted stitches, especially if the cut was deep enough to require two layers of deep interrupted stitches, put another glove on top of the glove already on your examining hand. Do a rectal examination to determine whether any of the stitches accidentally entered the rectum. Discard the cover glove after completion of the examination, as it is grossly contaminated.

   If a stitch is in the rectum, the episiotomy repair must be taken apart to the extent of identifying which stitch it is and removing it. Such a stitch is removed because it is a path for contamination and bacteria from the rectum, thereby being the potential cause of infection and development of a sinus tract or fistula. Discovery now entails much less in the way of taking apart and redoing the episiotomy repair with its additional trauma to the tissues than would discovery later. You can avoid placing stitches in the rectum if you take care to direct the bite of the needle laterally and straight back, *not* down.

8. Repair the perineal subcutaneous fascia. Use the same suture for this repair as you used for repair of the vaginal mucosa, unclamping the needle from where you attached it to the abdominal drape in Step 3(i) above.

   a. Start the suture line of continuous stitches at the upper end of the perineal body as follows:

      (1) Lock the stitch at the mucocutaneous junction by inserting the needle on the same side of the incision as the exit of the last stitch.

      (2) Swing the needle through the vaginal mucosa on that same side.

      (3) Exit in the perineal subcutaneous fascia on the same side.

   b. Close the subcutaneous fascia using the continuous suture stitches (see Figure 79-4 and the discussion of this procedure earlier in this chapter).

   c. Again, before taking any stitches, plan the number of stitches you will need before the last one, which is placed differently; see (e) below.

   d. Take care to leave sufficient and equilateral room on both sides for the final layer of subcuticular stitches.

   e. The last stitch is placed differently since its exit point becomes the start of the layer of the subcuticular suture stitches. Therefore, from the entry point, instead of going straight across as with the preceding stitches, come through the subcutaneous tissue on the same side, going a little beneath the perineal apex to include any retracted blood vessels, and exit one cell layer underneath the skin precisely at the perineal apex.

9. Close the skin edges of the episiotomy or laceration with a layer of subcuticular suture stitches. For this repair use the remainder of the same 3-0 chromic catgut used for repair of the vaginal mucosa and the subcutaneous fascia. Subcuticular closure is done using the mattress suture stitch (see Figure 79-4 and the discussion of this procedure earlier in this chapter). Start

the suture line on the side of the incision opposite the side on which the last subcutaneous continuous stitch was taken.

10. Tie off the suture as follows:
    a. When the mucocutaneous junction is reached and the skin edges are completely closed, take a stitch through the perineal subcutaneous fascia and swing the needle on up through the vaginal mucosa, exiting just in front of the hymenal ring.
    b. Take a final stitch in front of the hymenal ring for the purpose of creating ties with which to knot the suture. Try to place this stitch so that the cut ends of the knot will not be sticking the woman. The entry point of this stitch should be on the same side as, and close to the exit point of, the preceding stitch, and the exit point should be straight across on the opposite side.
    c. Do *not* draw the suture all the way through the tissue with this stitch. Instead, leave a length of suture, actually a loop, to tie with.
    d. Cut the needle off the other end if you desire.
    e. Tie your knot slightly loose to allow for some edema resulting from inflammatory reaction to the suture.
    f. Cut the ends short.
11. Remove the tampon gently and quickly. Protect the vaginal suture line with the fingers of one hand while removing the tampon with your other hand.
12. Do a vaginal examination:
    a. Inspect the vaginal suture line.
    b. Make sure all foreign objects (e.g., sponges) have been removed.
    c. Remove any blood clots in the vaginal fornices.
    d. Help contract the uterus.
    e. Check for hematomas.
13. Do a rectovaginal examination to feel the rectovaginal wall and perineal body muscle support after repair.
14. Do a rectal examination to ensure that there are no rectal stitches and to check for hematomas. Discard this glove.

Repair of a Mediolateral Episiotomy

The repair of a mediolateral episiotomy, irrespective of which side it is on, is essentially the same as the repair of a midline episiotomy insofar as the type of suture stitches used and their sequence is concerned. There is, however, one important difference—the angle of the cut. The mediolateral episiotomy was cut on a slant in relation to the perpendicular midline of the perineum. This affects repair in two ways:

1. In a mediolateral episiotomy the medial aspect of the incision tends to retract more than the lateral aspect. Therefore, be careful when taking stitches in the medial half of the cut to secure the tissue involved without entering the rectum.
2. Stitching from side to side of the incision must be done in accord with the angle of the incision (on a slant) and *not* done straight across as though at right angles to a perpendicular midline. Stitching on a slant is facilitated by holding the needleholder parallel to the edges of the incision. In a mediolateral episiotomy there will be more tissue on the lateral side than on the medial side of the incision; therefore, care must be taken in aligning and approximating the tissues. This is done by including more tissue in the lateral bite and half of the stitch than in the medial bite and half of the stitch and recognizing that the interval between the stitches on the medial aspect of a row of suture stitches will be closer together than the interval between the stitches on the lateral aspect of a row of suture stitches.

Keeping this important difference of angle in mind, repair the mediolateral episiotomy in the same sequence of suture stitches and steps as you use for repair of a midline episiotomy (see the discussion of this procedure earlier in this chapter):

1. Insert a tamponade.
2. Identify the pertinent structures.
3. Repair the vaginal mucosa.
4. Repair the bulbocavernosus muscle.
5. Repair the pubococcygeus and deep transverse perineal muscles with one layer of deep interrupted stitches.
6. Repair the superficial transverse perineal muscle with another layer of deep interrupted stitches.
7. Do a rectal examination to check for sutures in the rectum.
8. Repair the perineal subcutaneous fascia.
9. Close the skin edges.
10. Tie off the suture.
11. Remove the tampon.
12. Do a vaginal examination.
13. Do a rectovaginal examination.
14. Do a rectal examination.

Repair of First and Second Degree Lacerations and Sulcus Tears

First degree (1°) lacerations are those that involve the vaginal mucosa, posterior fourchette, and perineal skin. Second degree (2°) lacerations are those that involve the vaginal mucosa, posterior fourchette, perineal skin, and perineal muscles. Muscle involvement depends on the depth and direction of the tear, therefore possibly involving any or all of the following: bulbocavernosus, superficial transverse perineal, deep transverse perineal, and pubococcygeus of the levator ani.

Sulcus tears are a type of second degree laceration in which the vaginal mucosa and underlying tissue lacerate along one (unilateral) or both (bilateral) sides of the posterior column of the vagina instead of up the middle. The posterior column of the vagina is a longitudinal ridge of the inner surface of the lining extending the length of the vagina. The lateral edges of the column as they meld into the lateral vaginal walls create a slight groove (sulcus) from which a laceration extending any distance up this groove derives its name.

Repair of first degree lacerations depends on their extent. Some vaginal nicks or skid marks barely lacerate the vaginal mucosa and will heal by themselves without stitches since the edges approximate and stay together once the woman's legs are together again. More extensive first degree lacerations can be repaired using the blanket suture stitch for the vaginal mucosa, the continuous suture stitch for the perineal fascia, and the continuous mattress suture stitch for subcuticular closure of the skin edges.

Repair of second degree lacerations uses the same sequence of suture stitches and Steps (1 to 14) as repair of episiotomies. However, lacerations often are jagged wounds with ragged edges, making approximation of tissue more difficult. Care must also be taken to place all stitches in accord with the angle of the wound, recognizing that the angle may change in a jagged tear.

Repair of sulcus tears differs only in the repair of the vaginal mucosa if it is a bilateral sulcus tear. In this event two apexes and two suture lines of blanket stitches are needed to close the separate tears in the vaginal mucosa. At their common base, one line of suture stitches is tied off with a final stitch and a square knot while the other continues to draw the larger base opening together. Sulcus tears usually are deep lacerations and often necessitate two layers of deep interrupted stitches. To provide better access for placing the deep interrupted stitches, you may want to repair the vaginal mucosa just a stitch or two into the common base of the bilateral tear for approximation of the tissues, then put in your deep interrupted stitches, and then return to complete your repair of the vaginal mucosa.

Repair of Third Degree Lacerations

Third degree (3°) lacerations are those that involve the vaginal mucosa, posterior fourchette, perineal skin, perineal muscles (which ones depending on the depth of the tear); and external anal sphincter. (Some authorities refer to this as a partial third degree laceration, with a complete third degree laceration involving also the anterior rectal wall. Other authorities refer to this latter as a fourth degree laceration; this is the designation used in this text.) Sometimes the equivalent of a third degree laceration is cut deliberately (sphincterotomy). Third degree lacerations may occur in deliveries in which no episiotomy has been cut; however, frequently they are a lacerated extension of a midline episiotomy.

The first step in repair of a third degree laceration is to identify it. This is done as follows:

1. Observe for the ends of the torn external anal sphincter in the open wound. As the torn ends retract, the ends are found flush with, or as dimples in, the lateral walls at the bottom of the perineal aspect of the wound near the surface. The muscle fibers of the sphincter are obviously different from the surrounding fascia and look rough and stringy.
2. The experienced midwife can often tell by palpating in the open wound whether the rectal sphincter is intact. However, if you are not sure, put another glove over the glove already on your examining hand and put a finger in the woman's rectum. You should be able to palpate the sphincter between your finger inside the rectum and your thumb outside the rectum or to feel its absence anteriorly in the area of the perineal laceration. Be sure to discard the cover glove as soon as you finish with your rectal palpation because it is grossly contaminated.
3. Ask the woman to tighten her rectal sphincter if she is able. You can observe the constriction of the sphincter and also feel it close around your palpating rectal finger if it is intact. It is not possible for her to tighten her sphincter if she has had any type of spinal anesthesia or is under the effects of a pudendal block.

4. The final proof is when you grasp each torn end with an Allis clamp and pull them toward each other, causing them to meet by crossing the Allis clamps and thereby demonstrating the drawing up of perineal tissue on both sides.

A lacerated external anal sphincter is repaired with interrupted stitches approximating the torn ends grasped by the Allis clamps. Inclusion of the anterior and posterior fascial layers will strengthen the repair. Use 2-0 chromic catgut suture. The remainder of the repair is the same as for repair of an episiotomy or a second degree laceration. Some midwives prefer to first anchor a 3-0 chromic catgut suture within the inferior apex of the skin extension of the laceration and take a few subcuticular stitches, then lay this suture aside until the end. They do this in order to avoid later difficulty, which sometimes arises from being unable to visualize this apex after repair of the sphincter.

After repairing the sphincter and before continuing with the remainder of the repair, do a rectal examination to make sure that you have not placed any suture through the rectal mucosa. If you have, that suture will have to be removed so that it does not become a pathway for infection or cause the development of a fistula. Put on a cover glove, which you remove and discard after the examination.

Repair of Fourth Degree Lacerations

Fourth degree (4°) lacerations are those that involve the vaginal mucosa, posterior fourchette, perineal skin, perineal muscles (which ones depending on the depth of the tear), external anal sphincter, and anterior rectal wall. After identifying the tear in the anterior rectal wall and the torn ends of the anal sphincter, begin by repairing the anterior rectal wall. This is repaired in two layers with 4-0 chromic catgut on a swaged-on atraumatic needle:

1. The first layer starts at the apex and consists of a row of interrupted stitches placed in the rectal submucosa to approximate the rectal mucosa without placing stitches in the lumen of the bowel. This suturing requires painstaking care.
2. The second layer covers the first layer and consists of either a row of interrupted stitches or a continuous suture line approximating the overlaying layers of fascia. This layer reinforces the line of repair.

After checking for suture in the rectal lumen, repair the external anal sphincter as described in the preceding section; the remainder of the repair is as described for repair of an episiotomy or a second degree laceration. Special care must be taken in rebuilding the muscle layers of the perineal body, which have been totally rent.

Repair of Periurethral and Clitoral Lacerations

Periurethral lacerations derive their name from the fact that they occur near the urethra. Usually they are longitudinal lacerations that follow, for a variable distance, the general contour of the vestibule of the perineum. They vary in depth as well as in length, with the longest extending into the clitoris. At other times they may be transverse lacerations extending into the labia minora. Their repair depends on their depth or, if superficial, whether they are bleeding (either actively or oozing) or the need for a cosmetic repair. Repair of any periurethral laceration close to the urethra should be preceded by insertion of a urinary catheter to prevent accidental closure of the urethra.

Small superficial periurethral lacerations will heal spontaneously without stitches, as the edges of the tear will be approximated when the woman's legs are together again. If you are unsure whether a laceration fits this category, you may take a single interrupted stitch in the middle of the laceration to facilitate this approximation. Any laceration that is oozing must be repaired. Larger periurethral lacerations can be repaired with interrupted sutures. However, it is more cosmetic to use a mattress suture, or, if the laceration is deep, a layer of continuous suture covered with a subcuticular closure using mattress suture stitches.

All periurethral lacerations should be repaired with 3-0 chromic catgut on a swaged-on needle, except clitoral lacerations, for which 4-0 chromic catgut is used. Such repairs challenge the ingenuity and artistry of the clinician for a cosmetic result since they often involve jagged skin edges. Because of this, there is no precise pattern or sequence of stitches to use, as there is for repair of the other lacerations and for episiotomies. Instead, you have an arsenal of skills in various suture stitches, a knowledge of the pertinent anatomy, a gentle approach, and a caring philosophy.

Repair of Cervical Lacerations

There are two keys to quick and easy repair of cervical lacerations:

1. *Good visualization.* This means positioning the woman properly, proper placement of the light source, retraction of the vaginal wall, effective use of the ring forceps on the cervix to bring the cervix and its laceration into full view, and a well-contracted uterus so obscuring bleeding is minimal.
2. *An extra pair of hands.* An assistant is invaluable in this situation to hold the retractors that will enable good visualization.

Cervical lacerations more than approximately 1 centimeter in length should be repaired in order to prevent possible future problems that might occur if the lacerations were left unrepaired—erosions, chronic ascending infections, and so forth. Repair is with 2-0 chromic catgut on a swaged-on needle. Cervical lacerations that extend into the lower uterine segment require repair by the physician.

Approximation of the two sides of the tear is facilitated by the placement of a ring forceps on each side of the laceration. These should be close enough to the edges to be of use but far enough away from the edges that the bites of the stitches can be taken without sewing through the ring of the forceps and thereby including it in a stitch. On longer lacerations you can avoid forceps impingement for a while by clamping the ring forceps only on the lower portion of the laceration, which means they will be out of the way during repair of the upper reaches of the laceration.

Cervical lacerations are repaired with either interrupted stitches, a continuous suture, or a blanket (continuous locked) suture. The first stitch should be placed approximately 1 cm above (beyond) the apex of the laceration to catch any retracted blood vessels. Care should be taken in the placement of each stitch approximating the two sides of the tear that only one side of the cervix is included in the stitch, thereby maintaining the patency of the cervical canal.

Defibulation and Repair

Defibulation is the reversal of infibulation. Infibulation is the WHO Type III classification of female genital mutilation [6] in which the clitoris and labia minora and inner surface of the labia majora are excised. The incised sides of the labia majora are then stretched toward each other and stitched together, creating a false hood of skin over the urethra and anterior part of the vaginal orifice, which narrows the vaginal opening and leaves only a small opening at the introitus through which menstrual blood and urine dribble. In addition to a number of medical and gynecologic complications, female genital mutilation doubles the risk of the mother dying during childbirth [7]. The major obstetrical problem is obstruction from the resulting anatomy and scar tissue necessitating the need for defibulation or "anterior episiotomy." This can be done because the scar tissue that forms during the healing process from infibulation does not fuse with the underlying tissue of the female genitalia [8]. Cesarean section is not indicated solely on the basis of infibulation.

During the last two decades, the immigration of women from various African and Middle Eastern countries that practice female circumcision/female genital mutilation/female genital cutting has led to the presence of thousands of women residing in the United States who have been infibulated. When these women present for health care when pregnant, midwives will need to know how to provide culturally competent care [8, 9]. Part of that care is defibulation for childbirth.

Discussion of defibulation needs to be initiated early in pregnancy and involve the husband. Provision of counseling, either nondirectional or against re-infibulation, includes information on the medical risks and starts at the time of discussing the necessity for defibulation. The knowledge of medical risks is critical in the decision-making process. It will take time for a woman to think this through and to begin her psychological adjustment to differences in the way her genitals look and feel after defibulation. Fears and apprehensions must be thoroughly explored and usually involve societal and marital concerns. Separate counseling with the husband may be advisable followed by a counseling session with the couple to arrive at a mutual decision [9].

Defibulation should either be done during the second trimester under local anesthesia or when it becomes necessary during the second stage of labor. Doing it earlier in labor only subjects the woman to increased pain and increased potential of infection and bleeding [9]. Second trimester defibulation has

the advantage of being able to assess the pelvic organs and pelvic anatomy more accurately, monitor the progress of labor, and more readily perform urinary catheterization if indicated [7]. The major disadvantage depends on when prenatal care started and if the woman and her husband have had sufficient time to process information and develop trust in their health care provider. Most defibulations take place toward the end of second stage at the same time an episiotomy would be cut.

To perform a defibulation during late second stage labor, insert one or two fingers at the introitus upward underneath the hood that was formed from the infibulation. Perform local infiltration for anesthesia along an anterior central line the same way you would locally infiltrate the perineal body for an episiotomy (see Chapter 69). Insert the blunt end of bandage scissors in front of the fingers and cut the skin/scar tissue anteriorly for 2 to 3 inches (5 to $7^1/_2$ centimeters) taking care not to injure or cut any intact clitoral parts under the top of the hood [9, 10]. Your finger should protect the urinary meatus.

There usually is minimal bleeding as this is scar tissue. However, any remaining scar tissue lacks the ability to be flexible and to stretch and may also tear in unpredictable ways. Therefore, midwives should be prepared to cut a generous episiotomy to provide more room posteriorly and take the tension off of the scarred anterior tissue [11]. This is particularly necessary for those women who now may be better nourished and having larger babies than they might have had in their own country. Cultural food taboos for pregnant women are often a means of attempting to control birth weight, and the diet of all immigrant women needs to be carefully checked for adequate amounts of protein, calories, and iron [11].

The two sides of the wound may need to be sutured at the edges in order to keep them apart so that in the healing process they do not form a "pseudo-infibulation" [12]. This allows for a larger introitus, freedom of urinary and menstrual blood flow, and increased comfort during sexual intercourse. Suturing of each cut edge is done with a continuous locked or unlocked stitch with 4-0 chromic catgut suture [9, 13]. The episiotomy is repaired as described in the procedures discussed earlier in this chapter. Postpartum care should include sitz baths.

CHAPTER

80

Physical Examination of the Newborn

TABLE 80-1 Physical Examination of the Newborn

Normal	Significance	Abnormal	Significance
Color good indicator of overall status of infants, especially cardiopulmonary system: Inspection			
Pink; in dark-skinned infants, mucous membranes should be pink	No cardiopulmonary compromise	Duskiness or cyanosis (other than acrocyanosis)	Poor circulation or respiratory difficulty or distress
Acrocyanosis of hands and feet during first 24 hr of life	Sluggish peripheral circulation caused by transition to the cool extrauterine life	Acrocyanosis lasting longer than first 24 hr	Poor peripheral circulation; may have cardiac compromise
Reddish hue (especially noted immediately after birth)	Adjustment in oxygen levels in extrauterine environment	Plethora	Elevated hematocrit or hemoglobin levels, polycythemia levels, or hyperviscosity of blood
		Pale	Cardiopulmonary compromise or failure
Ecchymosis over presenting part (to differentiate between cyanosis and ecchymosis, apply pressure to darkened area; cyanotic area blanches, whereas ecchymotic area remains dark)	Pressure over presenting part, causing bruising and trapping of blood in external tissue layers		
Mongolian spots over buttocks, may extend to sacral region (usually in dark-skinned infants)	Hyperpigmentation		
Jaundice after first 48 hr of age, receding by days 4–5 (peak will occur later in preemie, may be after day 4)	Physiologic jaundice; transition of blood supply to liver, increased RBC count with decreased lifespan of cells, decreased plasma protein level, and decreased glucuronyl transferase that aids in bilirubin conjugation	Jaundice on day 1 or after day 4	Isoimmunity such as Rh, ABO incompatibility, polycythemia, enzyme deficiencies, excessive bruising or bleeding, Hirschsprung's disease, pyloric stenosis, other intestinal obstructions that increase blood supply or shunt blood to the liver; maternal diabetes, SGA

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
General appearance indicative of nutritional status, infant maturity, and general well-being: Inspection			
Well-formed and rounded, with presence of subcutaneous tissue; no obvious anomalies	Good nutritional status; generally healthy	Little or no subcutaneous tissue, wasting muscle, loose skin, thin extremities, anomalies	Malnourished or with a variety of congenital defects, such as cleft lip and/or palate, omphalocele, gastroschisis, meningomyelocele; infant stressed in utero
Vernix	Increases with gestational age		
Lanugo	Decreases with gestational age		
Posture: Inspection			
Fetal position: fists clenched; arms adducted, flexed; hip abducted; knees flexed (extension of extremities may be normal in preemie but abnormal in full term, as extension of legs and then flexion occurs as development progresses); flexion moves upward to arms; spinal column straight	Full term	Opisthotonos (neck in extension)	Brain damage, birth asphyxia; neurological abnormality
		"Frog position" of legs	Prematurity
		Bulge or curvature of the spinal column	Spina bifida or meningomyelocele
Spontaneous, symmetrical movement, may be slightly tremulous (flexion and extension should be equal bilaterally)	Full-term newborn activity	No movement; or asymmetrical, irregular, tremulous (jerky motions, unequal movement)	Birth asphyxia; neurological dysfunction; prematurity; drug-induced birth injury
Muscle strength and tone: Inspection			
Strength and tone strong	May be full term	Strength and tone weak, hypotonia, or flaccid	Birth asphyxia or prematurity
Palmar grasp strong	Good overall strength; may be full term	Palmar grasp weak	Prematurity
Alertness and cry: Inspection			
Mood ranges from quiet to alert; consolable when upset	Normal newborn activity	Not easily aroused, not very alert	Prematurity; stressed; septic; states of wakefulness from neurological problem
Cry: strong	Strong; no increased intracranial pressure	Weak, high-pitched, or absent	Brain damage or increased intracranial pressure
		Raspy	Upper airway problem
		Expiratory grunt	Respiratory distress
		Unilateral drooping of mouth when crying	Nerve damage

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Cardiopulmonary system: Inspection			
Respiratory effort: easy, unlabored rhythm; may be irregular, but periods of apnea >15 sec are abnormal; abdominal breathing	No respiratory distress or difficulty	Dyspnea: accessory muscle retraction (substernal, supracostal, intercostal, supraclavicular); flared nostrils, stridor, or grunting	Respiratory distress or difficulty
Respiratory rate: 40–60 breaths per minute	Normal rate	Apnea lasting >15 sec and accompanied by duskiness, cyanosis, or respiratory rate >60 breaths per minute	Prematurity; respiratory difficulty; sepsis; tachypnea in C-section or in full-term infants may be transient (from retention of lung fluid)
Symmetrical excursion of thorax	Normal respiratory pattern	Asymmetry or unequal chest excursion	Diaphragmatic hernia; pneumothorax; phrenic nerve damage
Anteroposterior diameter normal	Normal respiratory pattern	Exaggerated anteroposterior diameter: ratio greater than 1:1, barrel chest; hyperinflation equal without exaggeration	Respiratory distress
Cardiopulmonary system: Auscultation			
Clear breath sounds, equal bilaterally, anteriorly, and posteriorly; a few rales may be present the first few hours after birth because of residual fetal lung fluid; no color changes or cyanosis should accompany this finding	Clear lung fields	Rales after first day; rhonchi; expiratory grunting; wheezing Unequal breath sounds	Lung congestion; respiratory distress; pulmonary edema; pneumonia Pneumothorax or diaphragmatic hernia
Heart rate: 100–160 beats per minute; regular, without murmurs (initially may hear slight murmur until ductus arteriosus closes)	Normal cardiac rhythm without significant abnormalities	Bradycardia <100 beats per minute or tachycardia >160 beats per minute; murmur (usually heard at left sternal border or above apical pulse)	May be secondary to respiratory difficulty; increased workload on the heart; prematurity; sepsis; congenital heart defect with or without cyanosis
Cardiopulmonary system: Palpation			
No bruit in cranium or abdomen	No arteriovenous malformation	Bruit either in abdomen or cranium	Arteriovenous malformation
Apical pulse at fourth or fifth intercostal space, midclavicular line, left anterior chest (point of maximum impulse at fourth intercostal space just right of midclavicular line, may be shifted to the right during the first few hours of life)	Normal position of cardiac pulse; no shifting; without cardiomegaly	Displaced apical pulse	May have cardiac defect or cardiomegaly

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Cardiopulmonary system: Palpation (continued)			
No thrill	No increased cardiac activity	Thrill after first few hours of life	Increased cardiac activity
Blood pressure: average systolic rate 28–32 weeks: 52; 32–36 weeks: 56; full term: 63; BP equal in all four extremities	Normal cardiac output; good circulation; possibly no cardiac defect	Decreased blood pressure	Shock or hypovolemia
		Unequal blood pressure in the extremities, especially between upper and lower extremities	Cardiac defect: coarctation of the aorta
Cardiopulmonary system: Percussion			
No increased tympany over lung fields	Normal lung field borders	Increased tympany over lung fields	Hyperinflation of the lungs
Skin: Inspection			
Moist, warm to touch, no peeling	Normal, well hydrated	Dry, peeling, cracked	Postmature infant
		Wrinkled	Intrauterine growth retardation
		Gelatinous with visible veins (transparent skin and visible veins disappear with increasing gestational age)	Prematurity
Vernix (thick, white cheesy material)	Increases with gestational age	No vernix	Prematurity
Scant lanugo (fine hair over body)	Full term; decreases with gestational age	Abundant lanugo	Prematurity
Milia	Blocked sebaceous glands (common in newborns)		
Erythema toxicum	Newborn rash over body, usually on days 1–3	Nevus flammeus	Hyperpigmentation
		Meconium staining	Fetal distress
		Petechiae	Hematopoietic disorder
		Edematous, shiny, taut skin	Kidney dysfunction, cardiac failure, and/or renal failure
		Skin tags	Extra folds of skin, overgrowth of tissue; sometimes associated anomalies
Mottling	May be normal reaction to immaturity of organ systems	Mottling	May be abnormal if associated with cold stress, color changes, bradycardia
Skin: Palpation			
Warm (axillary temperature 35.5–36.5°C)	Normal range	Cool (<35.5°C)	Poor peripheral perfusion; prematurity
		Warm (>37°C)	Hyperthermia or fever

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Head: Inspection			
Normocephalic in proportion to body (head circumference for average full-term newborn is 32–38 cm)	Normal	Microcephalic	Congenital syndromes or decreased brain growth as with substance abuse
		Hydrocephalic	Blockage of the passage of CSF such as in meningomyelocele; or excessive production of CSF
		Anencephaly	Absent cerebral tissue and/or scant or absent skull
		Encephalocele	Brain and spinal cord that have herniated
		Bradycephalic	Premature closure of coronal suture line; AP diameter shortened and lateral growth increased
		Craniosynostosis	Premature closure of suture lines
		Molding: cranial distortion lasting 5–7 days	Excessive pressure on cranium during vaginal delivery
		Overriding sutures	Excessive pressure on cranium during vaginal delivery
		Caput succedaneum	Edematous region of scalp extending over suture lines, resulting from pressure on presenting part during vaginal delivery
		Cephalhematoma	Trapping of blood in tissues not crossing the suture lines and lasting up to 8 weeks
		Forceps marks; edematous or reddened areas	Forceps delivery
Head lag: not greater than 10 degrees in full term (pull newborn up, supporting the arms, from supine to sitting position; grade degree of head lag by position of head in relationship to trunk—part of gestational age exam)	Head lag: decreases with maturity	Head lag: greater than 10 degrees; little or no support of head	Hypotonia or prematurity
Hair distribution: over top of head, with single strands identifiable	Full term	Hair distribution: fine, fuzzy, may be over entire head	Prematurity

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Head: Palpation			
Without masses or soft areas over skull bones	Normal	Masses or soft areas such as craniotabes over parietal bones	May be normal variation if no abnormality present
Head: Auscultation			
No bruit	Normal	Bruit	Cerebral arteriovenous malformation
Fontanelles: Inspection and palpation			
Anterior fontanelle (open until 12–18 months): diamond shaped, 5 × 4 cm along the coronal and sagittal sutures	Normal	Craniosynostosis	Premature closure of suture lines may result from brain growth retardation
Posterior fontanelle: triangle shaped, very small, 1 × 1 cm along sagittal and lambdoidal suture lines; or closed at birth	Normal	Bulging fontanelle; usually the anterior fontanelle	Increased intracranial pressure
		Sunken fontanelle	Dehydration
Facies: Inspection			
Eyes on line with ears; nose midline	Normal	Low-set ears; asymmetry of features	Congenital syndromes such as Down syndrome, or genetic defect
		Wide-eyed, worried	Postmature; SGA; or intrauterine growth retardation
		Hypertelorism >2.5 cm	Congenital syndrome: genetic disorders
		Hypotelorism <2.5 cm	Trisomy 13
Oral cavity: Inspection			
Mouth: midline of face, symmetrical	Normal	Mouth: drooping or slanting unilaterally with crying; movement of mouth	Seventh cranial nerve damage; facial nerve damage
Mouth: shape and size in proportion with face	Normal	Birdlike mouth: shortened vermilion border	Fetal alcohol syndrome
		Wide mouth (macrostomia)	Metabolic disorder
		Small mouth (microstomia)	Down syndrome
Mucous membranes: moist, pink	Well hydrated and oxygenated	Mucous membranes: dry, dusky	Dehydrated or poorly oxygenated
Chin shape and size in proportion with face	Normal	Micrognathia	Pierre Robin syndrome
Lips completely formed, pink, moist	Normal	Cleft lip	Congenital anomaly: failure of midline fusion during first trimester
Palate: no arching; intact (determine by palpating)	Normal	High-arched palate	Turner's syndrome
		Cleft palate	Failure of midline fusion during first trimester

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Oral cavity: Inspection (continued)			
Tongue: size in proportion with mouth	Normal	Macroglossia	Hypothyroidism
Tongue: midline	Normal: no neurological dysfunction	Tongue: deviation from midline	Cranial nerve damage
Uvula: midline rises with crying	Normal function of glossopharyngeal and vagus nerves	Uvula: not midline or does not rise with crying	Neurologic dysfunction
Gag reflex: present (reflexes generally develop from head to toe during gestation)	Normal neurologic function of glossopharyngeal and vagus nerves	Gag reflex: absent	Neurologic dysfunction
Sucking reflex: present and strong when nipple or finger offered	Normal maturity and intact hypoglossal nerve	Sucking reflex: absent	Prematurity or brain dysfunction
Rooting reflex: present when cheek is stroked, infant turns toward stroking	Normal maturity and intact trigeminal nerve	Rooting reflex: absent	Prematurity or brain dysfunction
Salivation without excess	Normal	Excessive salivation	Tracheoesophageal fistula; esophageal atresia
Nose: Inspection			
Position: midline	Normal	Position: off midline	Congenital malformation or syndrome
		Flattened nasal bridge	Congenital syndromes
		Beaked	Treacher Collins syndrome
		Enlarged or bulbous	Trisomy 13
Nares: bilaterally present	Intact	Nares: not present bilaterally	Congenital malformation or syndrome
Nares: patent (occlude neonate's nostrils one at a time while holding mouth closed; infant should be able to breathe through one side at a time; passing a catheter into newborn's nares, one at a time, also demonstrates patency)	Normal	Nares: not patent	Nasal obstruction; choanal atresia
Grimace or cry in response to strong odors passed under nose	Normal; intact olfactory nerve	No response to strong odors passed under nose	Olfactory nerve damage
Nose: Auscultation			
Nares (with a stethoscope auscultate for breathing, one side at a time): breathing detected bilaterally	Patent	Nares: breathing not detected bilaterally	Not patent; nasal obstruction

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Eyes indicate many systemic problems: Inspection			
Sclera: clear	Normal	Sclera:	
		Yellow	Jaundice
		Hemorrhages	Birth trauma
		Blue	Osteogenesis imperfecta
Conjunctiva: clear	Normal	Conjunctiva:	
		Hemorrhage	Birth trauma
		Pink	Conjunctivitis, may be chemical, caused by silver nitrate
Iris: colored evenly, bilaterally	Normal	Iris: Brushfield's spots (these gold flecks may be normal if not found with other anomalies)	Down syndrome or congenital syndrome
		Coloboma (opening of pupil that extends into iris on one side)	May be associated with congenital malformation (internal)
Pupils: equal bilaterally and reactive to light (examination done in darkened room with penlight or flashlight; if done with newborn in incubator or in nursery, shield infant's eyes as much as possible)	Normal: intact oculomotor nerve	Pupils: unequal bilaterally; nonreactive	Brain damage or increased intracranial pressure
Cornea: clear	Normal: intact	Cornea:	
		Hazy	Prematurity
		Milky	Congenital cataracts possibly due to congenital rubella
Retina: transparent	Normal: intact	Retina:	
		Areas of pigmentation	Damaged retina
		Blood vessels without clear demarcation, or tortuous	Retinal hemorrhage
Lacrimal duct: patent	Normal	Lacrimal duct: blocked or absent	Congenital obstruction
Blink reflex: reactive (responds to bright light)	Intact optic nerve	Blink reflex: nonreactive or absent	Facial nerve paralysis or optic nerve damage
Red reflex: present	Lens intact	Red reflex: absent	Congenital cataracts
Eyelids: without ptosis or edema	Normal; intact oculomotor nerve	Eyelids:	
		Edema	Birth trauma
		Ptosis	Oculomotor nerve damage
		Epicanthal folds	Down syndrome or cri du chat syndrome

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Eyes indicate many systemic problems: Inspection (continued)			
Doll-eye response: present (with infant in supine position, turn head from one side to the other: eyes move to side opposite the side to which head is turned)	Normal: intact trochlear, abducens, and oculomotor nerves	Doll-eye response: absent	Damage to trochlear, abducens, and oculomotor nerves
Eye position: without slant	Normal	Eye position:	
		Slant upward	Down syndrome
		Slant downward	Treacher Collins syndrome
		Sunset eyes (downward slope of pupils below lids)	Hydrocephalus
Ears: Inspection			
Position: ears in straight line with eyes; vertical angle that is greater than straight vertical line; without slant	Normal	Position: set below eyes; ears slant, internally or externally rotated	Down syndrome
Skin tags: absent	Normal	Skin tags: present	Congenital renal anomaly
Cartilage formation: well-curved pinna, sturdy, stiff cartilage, instant recoil	Normal	Cartilage formation: flattened or folded, slow recoil	Prematurity
Neonate startles or cries in reaction to loud noise or snapping fingers	Hearing intact: auditory nerve intact	Startles or cries in reaction to loud noise or snapping fingers; absent or little response (infant can be tested further with other hearing tests)	Deaf or decreased hearing
Otoscopic examination (this examination is often omitted since it is difficult to perform and may be potentially harmful if the examiner is not skilled; ear should be pulled down and back for examination): umbo (cone) of light present, pearl-gray tympanic membrane may have vernix; membrane is movable without bulging	Normal: intact ear without infection	Otoscopic examination: umbo of light dull or absent; dull or immobile tympanic membrane	Congenital malformation; infection
		Red membrane	Infection
		Blue membrane	Hemorrhage
		Bulging membrane	Infected: otitis media
Neck: Inspection			
Shape: symmetrical	Normal	Shape: asymmetrical	Fetal position
Head: turns from side to side equally, full range of joint motion	Normal	Shape: asymmetrical	Fetal position
Short: without excessive skin	Normal	Short and webbed	Down syndrome

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Neck: Inspection (continued)			
Tonic neck reflex: asymmetrical and present but decreases (place infant in supine position; turn head to one side with body restrained; extremities on side to which head is turned are extended, but extremities on other side are flexed: newborn's attempt to right head when turned to side tests accessory nerve)	Normal	Tonic neck reflex: asymmetrical and strongly present	Prematurity
		Tonic neck reflex: symmetrical	Neurologic dysfunction
Neck: Palpation			
Thyroid: midline	Normal	Thyroid: enlarged	Goiter (rare)
Lymph nodes: not palpable	Normal	Lymph nodes: palpable	Congenital infection
No masses	Normal	Mass in neck	Cystic hygroma
		Sternocleidomastoid enlarged	Torticollis: birth or in utero injury resulting in hematoma of sternocleidomastoid muscle
Carotid: pulse rate strong and regular (do not massage carotid artery or neck: can result in reflex bradycardia)	Normal cardiac and circulatory function	Carotid: pulse rate weak or absent	Cardiac defect or circulatory problem
Clavicles: even and without "lumps" along bones; symmetrical	No fractures	Clavicles: fracture or lump felt; uneven; asymmetrical	Birth injury
Abdomen and thorax: Inspection			
Chest circumference: 30–36 cm	Average for full-term neonate	Chest circumference <30 cm	Prematurity; or SGA
		Chest circumfernce >36 cm	Barrel chest: respiratory difficulty; or LGA
Equal excursion of diaphragm	Normal	Unequal excursion of diaphragm	Phrenic nerve damage
Ribs: symmetrical	Normal	Ribs: asymmetrical	Birth injury or congenital syndrome
Breast: nipple spacing on line without extra nipples	Normal	Breast: nipple spacing not on line, or extra nipples	Congenital syndrome
Areola: raised and without discharge	Full term	Areola: flat and/or discharge	Prematurity or discharge from hormonal influence
		Hypertrophy	Maternal hormonal influence
Abdomen: rounded, contoured, symmetrical	Normal	Abdomen: scaphoid	Diaphragmatic hernia

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Abdomen and thorax: Inspection (continued)			
		Distended (if suspected, measure the abdominal girth every 4 hr to detect changes)	Intestinal obstruction, renal problem; ascites: edema caused by a variety of problems, including congenital kidney or cardiac defects, prematurity, fetal hydrops
		Distention in left upper quadrant	Pyloric stenosis or duodenal or jejunal obstruction
		Asymmetrical	Abdominal mass
Umbilical cord: 3 vessels (2 arteries, 1 vein)	Normal	2 vessels (1 artery, 1 vein)	Internal congenital anomalies possible
Bluish-white	Normal	Meconium-stained	Distress in utero
		Reddened with discharge	Infection
		Thick cord	LGA
		Small cord	SGA or malnourished
		Mass	Hernia
		Hernia of the cord through which abdominal viscera, intestines, sometimes other organs enter	Omphalocele
		Hernia (lateral to the cord may contain abdominal content)	Gastroschisis
Abdominal musculature: strong	Normal	Abdominal musculature: weak	Prune-belly syndrome, may have associated problems, including hypoplastic kidneys
		Visible abdominal wall defect over bladder areas	Exstrophy of the bladder
No visible peristaltic waves	Normal bowel activity	Visible peristaltic waves	Intestinal obstruction; usually not present immediately after birth
Abdomen and thorax: Auscultation			
Bowel sounds: present	Normal	Bowel sounds:	
		Absent	Obstruction
		Hyperactive (unless just after feeding)	Hypermotility
Abdomen: no bruit	Normal	Abdomen: bruit	Arteriovenous malformation
Renal: no bruit	Normal	Renal: bruit	Renal artery stenosis
Abdomen and thorax: Palpation			
Xiphoid process: present	Normal: intact	Xiphoid process: absent or depressed	Fracture (sometimes due to resuscitation)
Ribs: without masses or crepitous	Intact, without defects or "air leaks"	Ribs: masses or crepitous	Fractures or mass; subcutaneous air due to air leaks from pulmonary dysfunction

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Abdomen and thorax: Palpation (continued)			
Breast tissue: 1 cm	Normal: full term	Breast tissue: <1 cm, may be ″5 mm	Prematurity
Abdomen: soft and not tender; without masses	Normal	Abdomen; tense, rigid, tender, masses	Intestinal deformity or obstruction; renal or urinary tract deformity
		Separation of abdominorectus muscles (diastasis recti)	Common in newborns especially premature
Kidneys: 4–5 cm in length; right kidney lower than left, found in abdomen and posteriorly in lumbar or flank area (palpate with newborn's legs flexed in fetal positon to relax infant)	Normal	Kidneys: enlarged	Polycystic
		Absent	Potter's association
Liver: sharp edge just above right costal margin; firm	Normal	Liver:	
		Below right costal margin	Respiratory distress or congestive heart failure
		Hard	Liver damage or cardipulmonary problems
Spleen: 1 cm below left costal margin	Normal	Spleen: absent or not palpable	Congenital heart problems
Bladder; not distended (unless just prior to void)	Normal kidney and urinary tract system	Bladder: distended; may be visible above pubic bone	Urinary tract obstruction
Groin: femoral pulse rate strong and regular bilaterally	Normal	Groin: femoral pulse rate weak or absent bilaterally	Coarctation of the aorta
		Bounding femoral pulses	Patent ductus arteriosus
No hernias or groin masses	Normal	Groin masses	Inguinal hernia
Abdomen and thorax: Percussion			
Gastric bubble: just below left costal margin and toward midline; tympanic	Normal	No tympany	Esophageal atresia or gastric deformity
Abdomen: tympanic except dull over liver, spleen, and bladder	Normal liver, spleen, bladder, no masses (indicated by dullness)	Abdomen: increased tympany	Increased presence of fluid or air
		Increased areas of dullness (if liver or spleen is enlarged, dullness extends below the costal margins; if bladder is enlarged, dullness extends toward umbilicus: be sure to reexamine after void)	Masses or enlarged abdominal organs, located where the dullness is increased
Genitourinary tract: Inspection of female newborn			
Labia majora: present and extend beyond labia minora	Full term	Labia majora: smaller than labia minora	Prematurity
Labia minora: present and well-formed	Full term	Labia minora: larger than labia majora	Prematurity

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Genitourinary tract: Inspection of female newborn (continued)			
Clitoris: present, may be enlarged	Full term or prematurity		
Urethral meatus: present in front of vaginal orifice	Normal	Urethral meatus: displaced	Urinary malformation
Vagina: patent with or without white discharge	Normal	Vagina: not patent, with or without slight bleeding	Hormonal influence
Genitalia: distinguishable as female or male	Normal	Genitalia: not clearly distinguishable as to sex, may have organs of both sexes	Ambiguous genitalia; endocrine problems
Perineum: smooth	Normal	Perineum: dimpling or extra opening	Urinary or genital malformation, or urinary fistula
Anus: midline, patent (test by inserting small finger)	Normal	Anus: shifted anteriorly or posteriorly	Anal defect
		Nonpatent or dimpling	Imperforate anus
Anal wink: present (light stroking of anal area produces constriction of sphincter)	Normal sphincter	Anal wink: absent	Poor muscle strength of sphincter
Genitourinary tract: Inspection of male newborn			
Penis: straight; proportionate to body (length: 2.8–4.3 cm)	Normal	Penis:	
		Curved	Chordee
		Enlarged	Renal problems
Urinary meatus: midline and at tip of glans (if neonate is uncircumcised, gently retract the foreskin; if circumcised, also check for edema or bleeding)	Normal	Urinary meatus:	
		Displace to ventral surface	Hypospadias
		Displaced to dorsal surface	Epispadias
Urinary stream: straight from penis (first void should occur no later than 24 hr postnatally)	Normal urinary pattern	Urinary stream:	
		Not straight	Urinary obstruction or malformation
		From opening in abdomen or perineum	Urinary fistula
		Failure to void within first 24 hr of life	Renal or urinary obstruction or malformation
Testes and scrotum: full, numerous rugae	Full term	Testes and scrotum: flaccid, smooth, or few rugae	Prematurity
Darkly pigmented	Normal	Bluish testes or scrotal sac	Torsion of the testicles
		Enlarged or edematous	Hydrocele or breech delivery
		Dimpling	Torsion of the testicles
Perineum: smooth	Normal	Perineum: dimpling or extra opening	Urinary or genital malformation, or urinary fistula
Anus: midline, patent (test by inserting small finger)	Normal	Anus: shifted anteriorly or posteriorly	Anal defect

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Genitourinary tract: Inspection of male newborn (continued)			
		Nonpatent or dimpling	Imperforate anus
Anal wink: present (light stroking of anal area produces constriction of sphincter)	Normal sphincter	Anal wink: absent	Poor muscle strength of sphincter
Genitourinary tract: Palpation of male newborn			
Testes descended on at least one side	Full term	Testes not palpable (may be found high in the inguinal canal)	Prematurity or undescended testes
Upper extremities: Inspection			
Length: in proportion to each other; lower extremities and body symmetrical	Normal	Length: shortened extremities or asymmetrical	Diabetic mother; congenital syndrome; maternal drug use
Full range of joint motion: (includes abduction, adduction, internal and external rotation, flexion, extension as applicable to joint; full flexion of upper extremities comes with maturity)	Normal	Limited range of joint motion	Birth injury or trauma
		Limited range of flexion	Prematurity
Full range of joint motion:			
Shoulder	Normal	Limited range of motion or flexion of shoulder	Dystocia; brachial plexus damage
Clavicles	Normal	Limited range of motion of clavicles	Clavicle injury; osteogenesis imperfecta
Elbow	Normal	Limited range of motion or flexion of elbow	Birth injury or fetal position
Wrist (test for square window by flexing infant's wrist on forearm, then measure angle according to gestational examination chart—i.e., 0-degree angle for term)	Normal	Limited range of motion or flexion of wrist	Birth injury or fetal position
		Square window: angle greater than 0 degrees	Prematurity
Hand—grasp reflex: present, strong, equal bilaterally	Normal; maturity	Hand: grasp reflex: weak or absent, or unequal bilaterally	Hand injury or fetal position; prematurity or birth injury
Scarf sign: elbow short of midline (grasp infant's hand and gently pull hand around neck toward the opposite shoulder; observe position of elbow to chest; grade position according to gestational chart)	Maturity	Scarf sign: elbow beyond midline	Prematurity

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Upper extremities: Inspection (continued)			
Arm recoil (quickly flex neonate's forearms for 5 sec, then pull them to full extension and release; recoil time is graded)	Maturity	Arm recoil: slow	Prematurity
Palm: no simian creases	Normal	Palm: simian creases	Down syndrome
Fingers: 10 digits and without webbing; equal spacing	Normal	Fingers:	
		More than 10 digits (polydactyly)	May be part of syndrome
		Webbed, digital tags (syndactyly), or unequal spacing	Congenital syndrome
Carpals and metacarpals: present and equal bilaterally	No fractures; bone formation normal	Carpals and metacarpals; absent or unequal bilaterally	Fractures or absence of bone, may be associated with congenital syndromes
Nails: extend beyond nailbeds	Normal; full term	Nails: short; spoon shaped	Congenital syndromes, fetal alcohol syndrome
		Absent	May have absent radius
		Meconium-stained	Fetal distress
Upper extremities: Palpation (in the presence of a fracture may produce crying or facial grimace; observe infant's response)			
Nailbeds: pink, brisk capillary refill (″3 sec), equal bilaterally	Normal peripheral perfusion, normal oxygenation	Nailbeds: dusky, or slow capillary refill (>3 sec), bilaterally	Poor peripheral perfusion or oxygenation
Clavicles: without fractures or pain; symmetrical	Normal	Clavicles: asymmetrical or pain on palpation	Fractures, shoulder dystocia, brachial plexus damage, or palsy
Humerus, radius, and ulna present; symmetrical and without fractures	Normal bone formation	Humerus, radius, and/or ulna absent, or asymmetrical	Absence of any of these bones may be associated with syndromes
		Painful fractures	Birth injury
Pulses: brachial and radial strong and equal bilaterally and in comparison with femoral pulses	Good peripheral perfusion, without obvious cardiac defects	Pulses: brachial and/or radial weak, absent, or unequal bilaterally	Poor peripheral perfusion, possible cardiac defects
Lower extremities: Inspection			
Length in proportion to body and equal bilaterally; limbs straight	Normal extremity length	Length not in proportion to body; short or unequal; limbs not straight, leg internally rotated or bowed	Congenital syndrome; diabetic mother
Ten toes and without webbing; equal spacing	Normal	More than 10 digits or with webbing or unequal spacing	May be associated with congenital syndromes
Feet: straight	Normal	Feet: turned valgus	Absent fibula or fetal position
		Feet: turned varus	Absent tibia or fetal position

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Lower extremities: Inspection (continued)			
Ankle dorisiflexion: 0-degree angle (foot is flexed back on ankle, then angle between foot and ankle is measured)	Maturity	Ankle dorsiflexion: angle >0 degrees, may be up to 90 degrees in very premature	Prematurity
Popliteal angle: ″90 degrees (flex newborn's leg, then flex thigh; next release and extend leg; measure angle of knee)	Maturity	Popliteal angle: >90 degrees and ″180 degrees in very immature infant	Prematurity
Heel-to-ear maneuver (gently pull leg to ear without forcing; heel will not reach ear but only near shoulder area in full-term infant)	Maturity	Heel-to-ear maneuver: heel reaches ear, or just short of the ear	Prematurity
Nails: extend to end of nailbed	Normal; maturity	Nails: do not extend to end of nailbed	Prematurity
Nailbeds: pink; brisk capillary refill (″3 sec)	Good peripheral perfusion	Nailbeds: dusky, or slow capillary refill (>3 sec)	Poor peripheral perfusion
		Pedal edema	Pressure due to fetal position, also can be associated with poor peripheral perfusion, syndromes such as Turner's syndrome
Plantar creases: cover the sole of foot	Maturity	Plantar creases: few or only anterior third of sole of foot	Prematurity
Buttocks: creases symmetrical	Normal hips	Buttocks: creases asymmetrical	Congenital hip dysplasia
Lower extremities: Palpation (in the presence of a fracture may produce crying or facial grimacing; observe infant's response)			
Fibula, tibia, trochanter, and femur: present and equal bilaterally	No fractures; bone formation normal	Fibula, tibia, trochanter, and/or femur: absent or unequal bilaterally	Fractures or absence of bone, may be associated with congenital syndromes
Tarsals and metatarsals present and equal bilaterally	No fractures; bone formation normal	Tarsals and/or metatarsals absent or unequal bilaterally	Fractures or absence of bone, may be associated with congenital syndromes
Full range of joint motion (includes abduction, adduction, internal, and external rotation, flexion and extension as applicable to respective joints of legs, knees, ankles, feet, toes)	Normal; maturity	Limited range of joint motion	Birth injury or trauma
		Flexion of legs, knees, ankles, feet, toes is limited	Prematurity

TABLE 80-1 Physical Examination of the Newborn (*continued*)

Normal	Significance	Abnormal	Significance
Lower extremities: Palpation (continued)			
Hips: without clicks and full range of joint motion (Ortolani's maneuver: flex newborn's hips and knees, then abduct and adduct hip to detect a slipping of the hip out of the acetabulum or an uneven motion unilaterally; Barlow's maneuver: flex newborn's hips and knees, then place finger on the femur and trochanter, put hip through full range of joint motion and listen for audible click)	Normal range of joint motion and no clicks	Hips: limited range of motion or positive result of Ortolani's or Barlow's maneuvers	Congenital hip dysplasia
Knee jerk or patellar reflex: present, symmetrical	Normal; mature	Knee jerk or patellar reflex: absent, weak, or asymmetrical	Neurological deficit or prematurity
Plantar reflex: present and symmetrical	Normal; mature	Plantar reflex: absent, weak or asymmetrical	Neurological deficit or prematurity
Back: Inspection			
Spinal column: straight	Normal alignment	Spinal column: curved	Altered alignment that should gradually resolve if resulting from fetal positioning
No visible deviations or defects	Intact	Visible defects: mass, dimple, or bulge with or without a tuft of hair	Spina bifida
		Open spinal defect or may be covered with tissue, involving the meninges and spinal cord or just spinal cord	Meningomyelocele
		Sinus tracts present	Pilonidal cysts
Back: Palpation			
Vertebrae present, without enlargement or pain	Normal spinal column	Vertebrae with bulge, enlarged area, or pain	Mass, bulge, or cyst; fracture of a vertebrae; spina bifida; occult meningomyelocele or pilonidal cyst
Anus: see genitourinary tract			
Buttocks: see lower extremities

CHAPTER

81

Circumcision

VIVIAN H. LOWENSTEIN, CNM, CRNP, MSN, CERTIFIED MOHELET

Male circumcision is the removal of the foreskin of the penis. The decision to circumcise or not is made by the parents of the newborn baby. Circumcision is usually done on the first day of life by a licensed health provider or on the eighth day in a religious ceremony performed by a recognized attendant. Ritual circumcision of newborn males is practiced by the Jewish and Muslim religions. It symbolizes a covenant with God following the tradition of Abraham in Genesis Chapter 17.

Male circumcision continues to generate a number of controversies. These include whether or not it should be done, the use of pain relief, and the role of the Certified Nurse-Midwife/Certified Midwife in offering this service. Some midwives have chosen to provide this service to parents, yet questions continue concerning whether this surgical procedure is within a CNM's/CM's scope of practice, can be included in clinical guidelines, and is covered by malpractice. Circumcision is considered within a midwife's scope of practice when it has been determined that there is a need for providing this procedure to the clientele they serve. The midwife should follow the ACNM *Guidelines for the Incorporation of New Procedures into Nurse-Midwifery Practice* when initiating this procedure into practice [1]. Midwives performing newborn circumcision need to be aware of current state legislation in this area and attempt to clarify or change it when it restricts midwives from providing this service. Additionally, midwives should review the process of credentialing within institutional clinical guidelines to ensure it is included on the list of midwifery skills.

Whether the midwife performs circumcisions or not, counseling and resources should be provided to parents in a nonbiased manner with an accurate knowledge base. The decision to have a newborn son circumcised is sometimes a difficult one. Midwives can support the parent's decision-making process by introducing current and accurate information and affording them time to come to a consensus whether to have it done or not. This information should be offered during prenatal care (at 28 weeks), early pregnancy, childbirth, and baby care classes. Information that should be included to help parents make a decision includes cultural and religious reasons, as well as medical research and recommendations. The informed consent for parents should include the risks and benefits, the current status of the methods of relieving pain during circumcision, how the procedure is done, common complications and post circumcision care.

The American Academy of Pediatrics Task Force issued a new Circumcision Policy Statement in March 1999. The Task Force came to this conclusion:

> Existing scientific evidence demonstrates potential medical benefits of newborn male circumcision; however, these data are not sufficient to recommend routine neonatal circumcision. In the case of circumcision in which there are potential benefits and risks, yet the procedure is not essential to the child's current well-being, parents should determine what is in the best interest of the child. To make an informed choice, parents of all male infants should be given accurate and unbiased information and be provided the opportunity to discuss this decision. It is legitimate for parents to take into account cultural, religious, and ethnic traditions, in addition to medical factors, when making this decision. Analgesia is safe and effective in reducing the procedural pain associated with circumcision; therefore, if a decision for circumcision is made,

procedural analgesia should be provided. If circumcision is performed in the newborn period, it should only be done on infants who are stable and healthy. [2]

Circumcision is performed in the home, in birth centers, and in hospitals. It is considered a safe procedure given adequate training and experience. The incidence of complications, including bleeding and infection, is less than 1 percent [3, 4]. Other risks include cutting too much or too little of the foreskin, injury to the top of the penis, or side effects caused by local anesthesia (if it is used).

Learning the skill of circumcision includes developing an understanding of male genital anatomy, observing an experienced skilled practitioner perform the procedure, being supervised while doing the first ten circumcisions, and having a means for evaluation/feedback. When beginning to learn the procedure of circumcision, the midwife should have the support of and the ability to collaborate with others who are experienced. In some situations a more experienced practitioner may need to assess the genitalia for abnormalities or help decide whether the circumcision should be postponed (e.g., for a preterm newborn). As with other technical procedures, the more practice the midwife acquires, the better her or his skill will be. The midwife will find that the safety of the procedure depends on being able to observe and learn techniques from others, on providing informed consent and parental counseling, and on the continued self-evaluation of her or his own practice. The practitioner that performs circumcisions must be respectful that this is a surgical procedure that is being done to a healthy newborn.

Relevant Male Genital Anatomy

The delicate nature of newborn circumcision requires that the midwife be knowledgeable about and have a high regard for newborn male genitalia.

The foreskin (prepuce) is the outer layer or fold of skin covering the glans of the penis (Figure 81-1). The foreskin is attached to the glans of the penis ventrally at the frenulum. A small blood vessel lies beneath the frenulum. During intrauterine development, the inner preputial epithelium begins to separate from the epithelium of the glans. Although retraction of the foreskin is minimal at birth, this normal physiological separation continues throughout childhood [2, 5]. The opening at the top of the prepuce is the preputial ring. Phimosis is a stenosis of the preputial ring; the prepuce cannot be retracted even though there may be complete separation of the foreskin and glans.

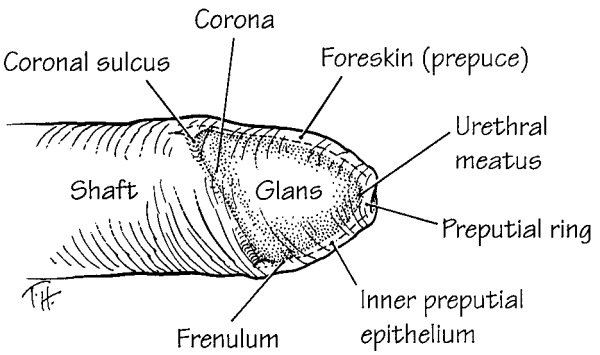

FIGURE 81-1 Anatomy of the penis.

The corona is the upper portion of the glans. The coronal sulcus is the boundary between the glans and the shaft of the penis. The correct excision of foreskin is at the level of the coronal sulcus [6]. The urethral opening (meatus) normally is located at the central top of the glans. When the urethral meatus is in the ventral or dorsal plane, the condition is known as hypospadias, and the circumcision should not be done.

Circumcision Instruments

There are a variety of clamps available specifically for performing circumcisions. The most popular are the Gomco clamp (Figure 81-2) and the Mogen clamp (Figure 81-3).

The advantages of the Gomco clamp are threefold: (1) it includes a bell that protects the glans; (2) it is associated with decreased bleeding and infection rates; and (3) it allows visualization of the glans to assess penile anomalies, since a dorsal slit is necessary for application of the bell. If an anomaly is noted the circumcision is not done. The dorsal slit can be approximated and sutured since the foreskin may be required for reconstructive surgery. The disadvantages of the Gomco are that it involves more parts, requires more steps in the procedure, and it takes more time.

The Plastibell clamp is similar to the Gomco clamp. It has a small grooved plastic ring that remains on the penis after the circumcision has been done. The ring usually sloughs off within a week. The Plastibell has a higher incidence of infection [3].

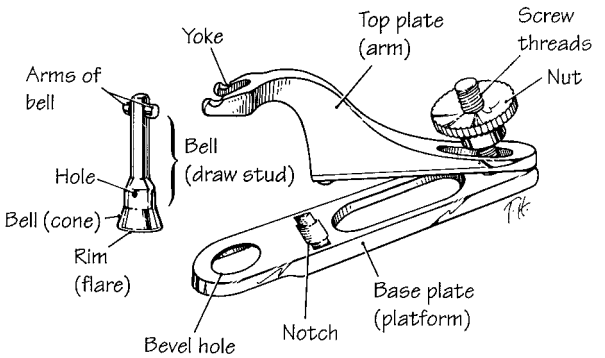

FIGURE 81-2 Gomco clamp.

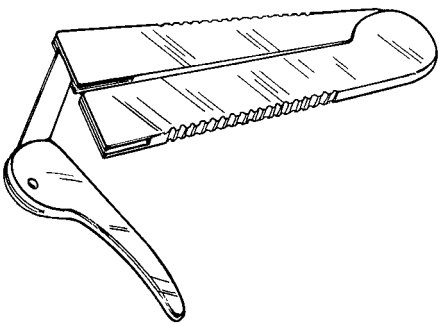

FIGURE 81-3 Mogen clamp.

The Mogen clamp (often used by Mohelim to perform ritual circumcision) has the advantage of enabling the clinician to perform the procedure very quickly since there are fewer steps. Using a Mogen has the distinct disadvantage of making the circumcision a "blind" procedure. The glans of the penis cannot be seen and thus is at risk of being cut. Anomalies may not be discovered until after the circumcision. The midwife should observe the use of different clamps in order to be able to provide accurate information to parents and to choose the method that appears most safe and comfortable for use.

Pain Relief

It is apparent through observation and clinical research that the procedure is painful to the newborn. The research has shown that there are physiologic changes in the neonate during the procedure, which includes changes in heart rate, blood pressure, oxygen saturation, and cortisol levels [7–11]. Yet in the past, neonatal circumcision was usually performed with no anesthesia. It is now recommended by the American Academy of Pediatrics that analgesia be given to the newborn before performing the procedure [2]. The methods of pain relief that have been investigated for circumcision include the subcutaneous ring block, dorsal penile nerve block (DPNB), topical anesthesia, and sucrose flavored pacifiers. The risk of the method of pain relief to the neonate must also be considered.

The subcutaneous ring block is reported to be the most effective method of pain relief for neonatal circumcision [12]. First described by Broadman et al. [13] as postcircumcision analgesia, it is now used before performing a circumcision. The injection forms a circumferential ring at the shaft of the penis near the base [2, 12, 13, 15, 16], or at the midshaft [2, 14] (Figure 81-4). The subcutaneous injection is given at the midline in a lateral direction. A 26- or 27-gauge needle is used to inject 0.8 mL of 1% lidocaine (without epinephrine), after aspirating the syringe. The circumcision can then be performed after waiting 3 to 8 minutes. There have been no reports of complications for this method [2, 14].

The dorsal penile nerve block developed by Kirya and Werthmann [17] is a subcutaneous injection into the subpubic space where the dorsal nerves traverse. The dorsal nerve branches off of the pudendal nerve and extends to the corpora cavernosa, skin, glans, and frenulum of the penis [15]. The dor-

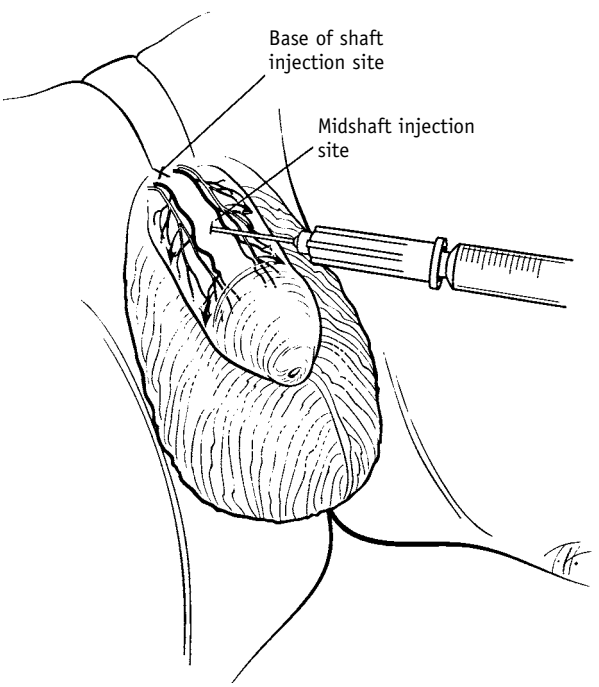

FIGURE 81-4 Subcutaneous ring block at midshaft and base of shaft injection sites.

sal arteries run medially and close to the nerves (Figure 81-5). This makes aspirating the syringe important to prevent intravascular injection. A 27-gauge needle is used to inject the 0.4 mL of 1% lidocaine (without epinephrine) at both the 10 and 2 o'clock positions at the base of the penis (Figure 81-6). The subcutaneous injection is directed laterally in a posterior direction, 3 to 5 millimeters on each side, until Buck's fascia is entered. It is important to control the direction and depth of the needle in order to avoid injury of underlying penile structures. After aspiration, the local anesthetic is injected. The anesthetic effect should occur within 3 to 5 minutes [2, 11, 14]. The most common complication is bruising [8, 18]. Other rare complications include hematoma and local skin necrosis [16].

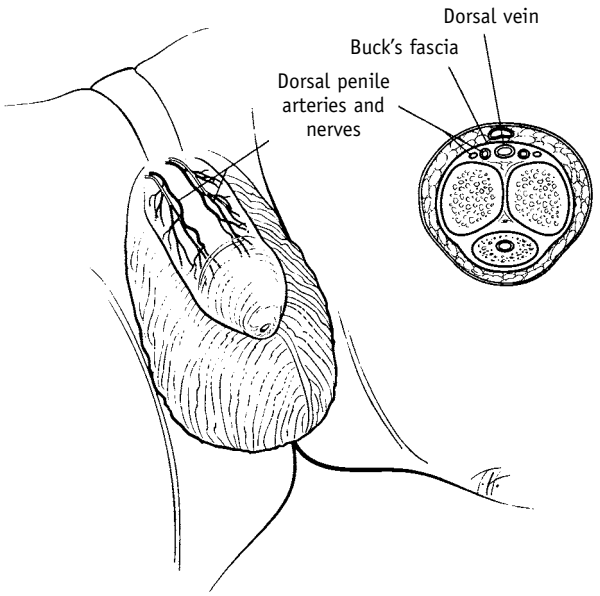

FIGURE 81-5 Anatomy of the dorsal nerves, vein, and arteries.

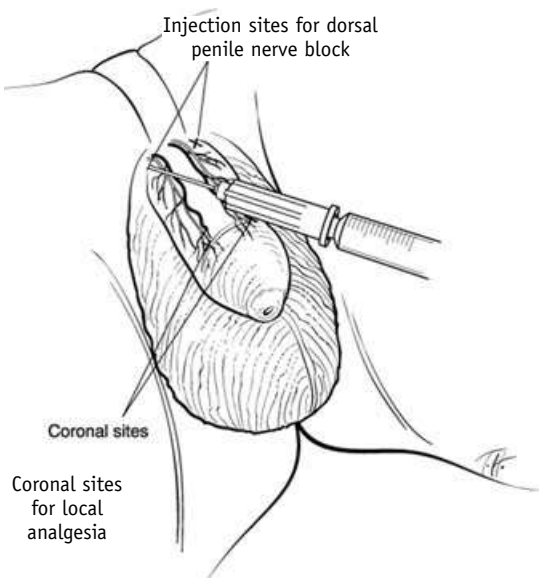

FIGURE 81-6 Dorsal penile nerve block sites and local analgesia corona sites.

Local analgesia, given at the corona, has been reported to be as effective as a DPNB [19]. At the level of the corona, after aspirating the syringe, an injection of 0.4 mL of 1% lidocaine (without epinephrine), is given at the 10 and 2 o'clock positions on each side of the foreskin [14, 19].

Topical or spray forms of local anesthetic may also be used prior to the circumcision. Studies have shown that topical 2% lidocaine or EMLA cream (a eutectic mixture of local anesthetics that contains 2.5% lidocaine and 2.5 percent prilocaine) will provide some relief [20, 21]. The dose of EMLA cream is 1 to 2 grams, applied to the distal area of the penis 60 to 90 minutes before the circumcision [2, 12, 14, 22]. The effect is superficial, since the anesthetic is applied only to the skin layer of the foreskin. When used prior to a DPNB, the topical local anesthetics were reported to decrease the neonate's distress from the injection [22]. There is a risk of methemoglobinemia when using EMLA on a newborn, because prilocaine can oxidize hemoglobin to methemoglobin. This was found when the dose of EMLA was greater than 3 grams or when the newborn was given other drugs (sulfonamides or salicylates) which have the potential to cause methemoglobinemia [2, 12, 14].

Noninvasive interventions that have been studied include giving acetaminophen (Tylenol) and pacifiers. Plain and sucrose flavored pacifiers have been shown to be effective in reducing crying [23, 24]. The nipple is dipped in a 24 percent sucrose solution (1 packet of table sugar in 10 mL of tap water). This is similar to giving the baby gauze dipped in wine to suck on prior to ritual circumcision. Acetaminophen has been found to provide postoperative relief when given 2 hours prior to the circumcision and again 4 hours after the procedure. The dose of infant acetaminophen drops is 15 mg/kg (0.15 mL/kg) [14, 25].

It should be noted that babies' distress often begins when they are put on a board and restrained. This distress might be reduced by swaddling the baby's upper body and having an attendant hold the baby's legs or minimizing the time the baby is restrained on a board. A restraint chair that is padded and physiologically adapted to the newborn has been found to decrease the baby's distress [26].

Procedure	Rationale
Preparation	
1. Counseling should begin during prenatal care, when parents should be provided with the information and resources to make a decision about circumcision if the child should be male. Informed consent is then required postpartum. The midwife should assess the parents' need for information and provide it and assess the parents' commitment to their decision to circumcise the newborn. The practitioner performing the circumcision is responsible for obtaining the informed consent. Counseling should cover what male circumcision is; medical research and recommendations [2]; religious and cultural beliefs; possible complications and risks; care of the uncircumcised and circumcised penis; signs and symptoms of complications; and whom to contact with questions or concerns.	**1.** The decision to circumcise a newborn son requires information on cultural beliefs and medical benefits and risks and clarification of any misconceptions. The time available during prenatal care offers the parents the opportunity to consider their feelings and beliefs regarding circumcision. The midwife should be supportive of the parents and help them communicate with one another to decide what is best for their child. If the father of the baby is not available the woman should be encouraged to seek support from her family or others who can help her make the decision.
Before the procedure is done, talk to the parents about how long the procedure will take and when it will be done and give them the option of being present. Plan to do the circumcision before a feeding and tell the mother that after the circumcision the baby will feed well.	Parents are very concerned about the safety of their son. Acknowledging their feelings and concerns and telling them what to expect helps to comfort them.
2. The circumcision can be performed 12 to 24 hours after the birth. Before the circumcision is performed, the following must be done to maintain safety.	**2.** The first 12 hours of life are transitional and provide the opportunity for observation of the newborn. This time period also ensures that the baby has been given vitamin K to prevent bleeding problems.
a. Review the mother's prenatal and intrapartal records, being alert for family history of blood dyscrasias, congenital anomalies, or perinatal complications that may have an effect on the health of the newborn (i.e., severe/chronic anemia, infections, birth trauma). It is recommended that the midwife also ask the parents for any health history that may not be documented in the records.	**a.** Review of the maternal and newborn records is necessary to screen for potential or existing problems. Any abnormalities should be discussed with the pediatrician involved in the care of the newborn.
b. The newborn record should be reviewed for a physical assessment (with attention to any documented abnormalities), laboratory tests (CBC, cultures) and feeding and voiding patterns.	**b.** This will screen for congenital anomalies, bleeding abnormalities, or infections. Feeding and voiding patterns should indicate the functioning of the gastrointestinal and urinary systems.
3. Set up and check all equipment; the required sterile equipment includes the following: **a.** three straight mosquito hemostats **b.** a small blunt probe **c.** povidone-iodine (Betadine) solution **d.** cotton or small gauze pads **e.** a 2 × 2 gauze pad with $^1/_2$ teaspoon of Vaseline spread on it **f.** Vaseline gauze dressing	**3.** When the midwife is systematic in setting up the equipment and knows that everything is in working order, the procedure can be done quickly, smoothly, and safely.

Procedure	Rationale
g. Gomco clamp: size 1.1 for a smaller penis and 1.3 for a normal size; have both readily available	
h. a scalpel and blade	
i. small scissors with pointed end	
j. gloves	
k. three towels/drapes	
l. a small vial of 1:1000 epinephrine	
Required nonsterile equipment includes a board or wrapping to restrain the baby's arms and legs and a pacifier or an assistant to soothe the baby. Have adequate lighting and a table that is at a comfortable height.	The midwife must be able to have a clear view of the genitalia with minimal eye or back strain.
4. Check the baby's ID name bands and the informed consent form.	**4.** This ensures proper identification and adequate documentation that the parents (or mother) acknowledge that they understand and agree to the performance of the circumcision.
5. Wash your hands.	**5.** This decreases the risk of infection.
6. Position and restrain the baby. Boards, cloth, or blanket restraints are available.	**6.** The arms and legs of the baby thus will not interfere with the procedure.
7. Check the baby's ID bands one more time before starting the circumcision.	**7.** Reconfirm the identity of the neonate.
8. Put on sterile gloves and mask (wearing a gown or lab coat is at the discretion of the midwife).	**8.** This maintains asepsis.
9. Push the foreskin back gently to identify the opening of the urinary meatus and to assess the degree of adhesions that may be present. Also look at the foreskin and size of the penis to assess the size of the Gomco clamp to be used. Check for any abnormalities and estimate how much of the foreskin will be removed. Approximately two-thirds of the foreskin should be removed.	**9.** An initial assessment of the adhesions and size of the penis allow you to determine the size of the Gomco clamp and whether the circumcision can be done. Do not perform the circumcision if the penis is too small or any abnormalities are noted. Excising too little or too much of the foreskin may result in complications that require additional surgery.
10. Put small sterile drapes around the genital area. Clean the genital area using the cotton balls soaked in povidone-iodine. Begin cleaning from the tip of the penis downward to the area surrounding the penis.	**10.** This sets up a sterile field and decreases the risk of infection.
Removing Adhesions	
11. Gently grasp the anterior foreskin with one mosquito hemostat at the 11 o'clock position and another at the 1 o'clock position (Figure 81-7). Use the small blunt probe and separate the adhesions between the foreskin and the glans of the penis. To release remaining adhesions, place another mosquito hemostat between the foreskin and the glans, opening the hemostats gently anteriorly and then on each side.	
Adhesions should be removed to the level of the coronal sulcus. Be especially careful not to traumatize the posterior frenulum or the urethral meatus.	

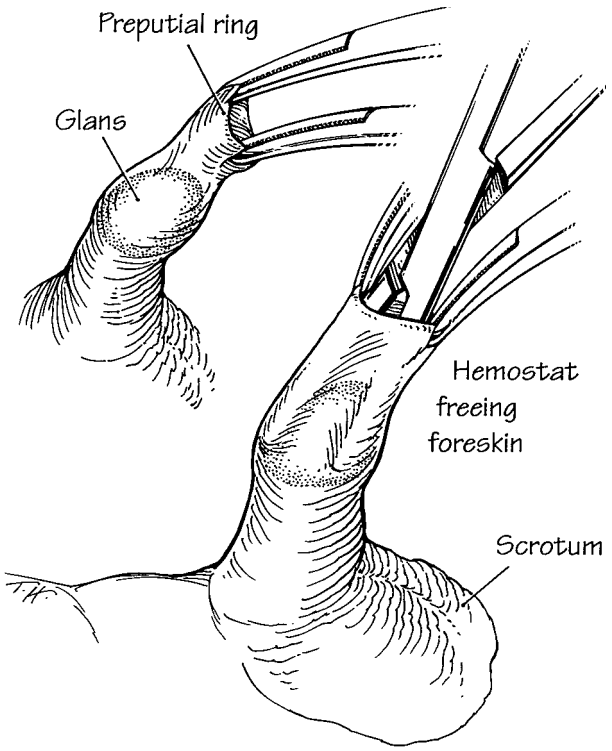

FIGURE 81-7 Removing adhesions (Step 11).

Procedure	Rationale
12. Using the same small hemostat, place it midline on the anterior foreskin measuring slightly less than the amount of foreskin to be cut for the dorsal slit. The distance is approximately halfway between the preputial ring and the corona. Keep the tip of the hemostat pointed slightly upward. Lock the hemostat tightly, but gently, closing it one notch at a time. The baby will probably be crying at this time if he hasn't already started. The midwife should focus on doing the procedure smoothly and quickly to minimize the amount of time the baby feels pain.	**12.** The mark made by the hemostat is where the dorsal slit incision will be made. The dorsal slit is cut (Step 14) to provide room for putting the bell of the Gomco clamp over the glans (Step 16). The hemostat should be angled slightly upward to avoid trauma to the glans.
Gomco Clamp Technique	
13. After approximately 1 minute remove the hemostat. The mark made by the hemostat should look blanched and very thin.	**13.** The hemostat should make the skin very thin and provide an area of hemostasis.
14. Hold the two mosquito hemostats in one hand. With the other hand pick up the small scissors and cut the mark made by the hemostats (to the apex of the mark) (Figure 81-8).	**14.** The dorsal slit serves as a means for inserting the bell of the Gomco clamp. The apex of the incision is also a guide for the placement of the base of the Gomco.
15. Gently push the foreskin downward and with the blunt probe remove any remaining adhesions anterior to the coronal sulcus. Pull the foreskin upward to its original position over the glans.	**15.** Adhesions should be removed prior to excising the foreskin. This will ensure proper healing.

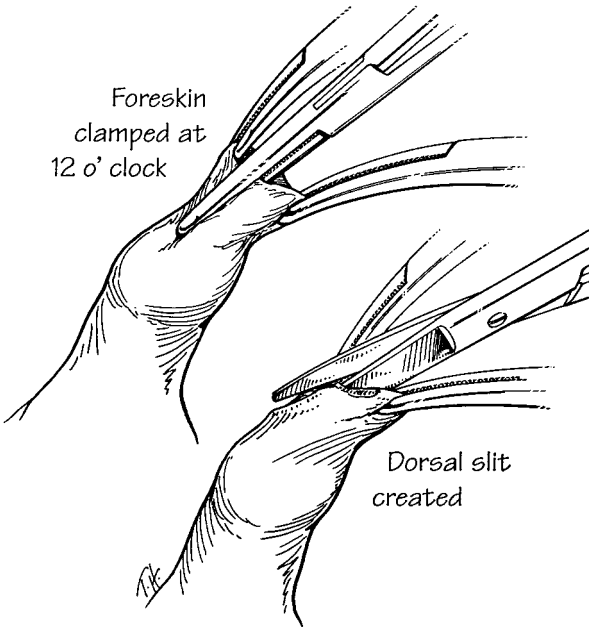

FIGURE 81-8 Gomco technique (Step 14): Cutting the dorsal slit.

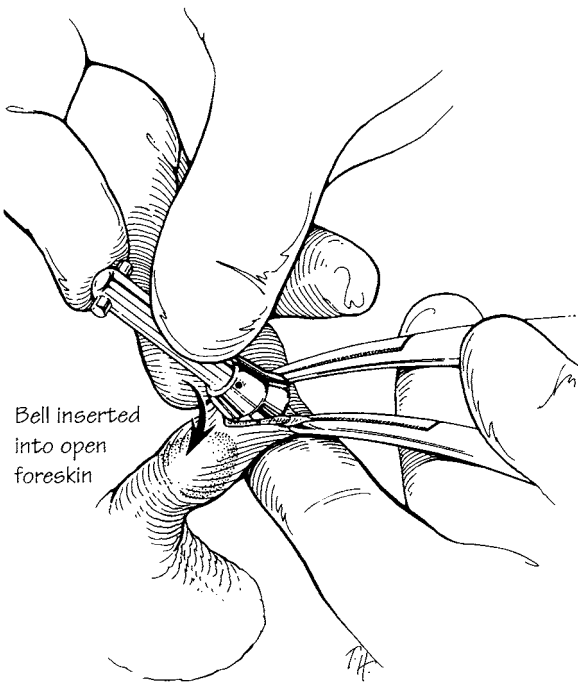

FIGURE 81-9 Gomco technique (Step 16): Inserting the bell of the Gomco clamp inside the foreskin and over the glans of the penis.

Procedure	Rationale
16. Hold the two hemostats in one hand. Insert the bell of the Gomco clamp over the glans of the penis, placing it first inside the anterior foreskin then inside the posterior foreskin (Figure 81-9).	**16.** The bell of the Gomco clamp protects the glans of the penis from amputation.
17. One of two techniques can be used to slip the foreskin through the hole of the Gomco clamp. The midwife has the choice of using a hemostat or one stitch of silk suture. Either technique should enable the midwife to fit the Gomco clamp over the bell.	**17.** Either technique holds the bell in place and also facilitates pulling the foreskin through the hole of the Gomco clamp.
a. *Hemostat technique:* With the mosquito hemostat, secure the two edges midway between the top and the bottom of the incision so the bell of the Gomco is held in place. Take the other two hemostats off the foreskin. Place the opening of the Gomco clamp over the tip of the penis. With another hemostat, grasp the two edges of the anterior foreskin (which is being held by the hemostat) through the opening of the clamp (Figure 81-10). Remove the lower hemostat before pulling the foreskin through the base plate.	
b. *Suture technique:* Using 1.0 or 2.0 silk suture, make one stitch on the anterior inner aspects on each side of the incision, so the bell of the Gomco is held in place. Tie a	

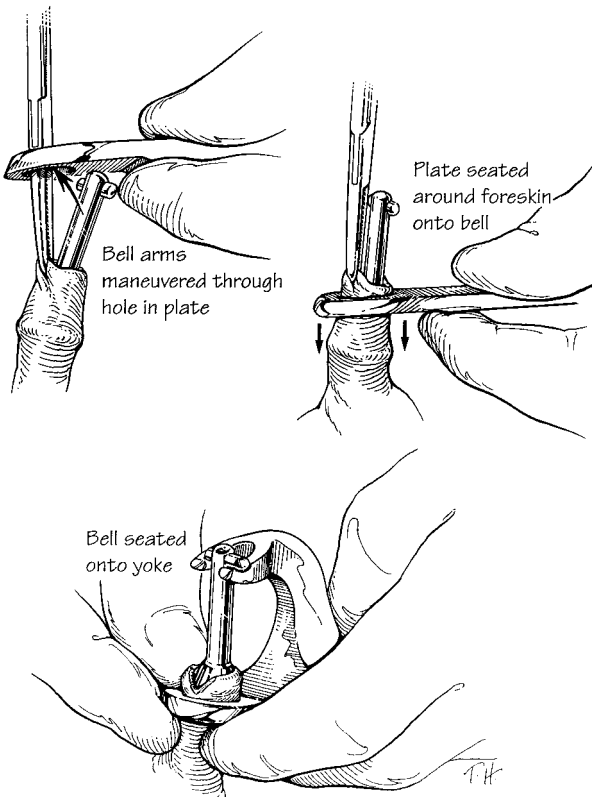

FIGURE 81-10 Gomco technique: (Step 17a) Hemostat technique of slipping the foreskin through the hole in the Gomco clamp. (Step 18) Securing the arms of the bell into the yoke of the top plate.

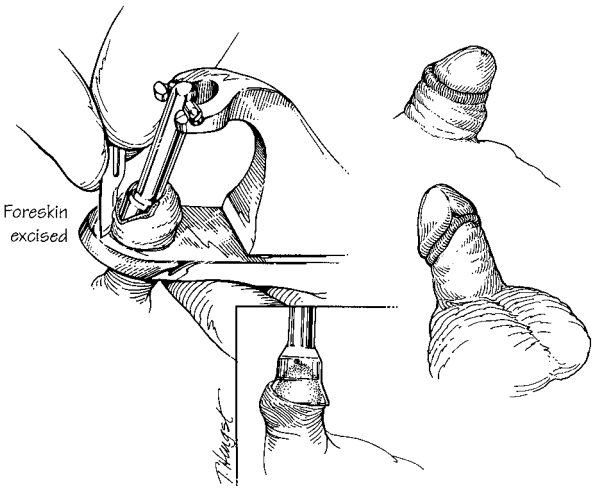

FIGURE 81-11 Gomco technique: (Step 19) Excising the foreskin. (Step 21) Removing the bell. (Step 22) The completed circumcision.

Procedure	Rationale
loose knot. Place the opening of the Gomco clamp over the tip of the penis. With a hemostat, pull the silk suture (which is holding the incision of the foreskin) through the bevel opening of the clamp.	
18. Set the base of the clamp in place by securing the arms of the bell into the yoke of the top plate (Figure 81-10) and the top plate in alignment with the notch in the base plate. The apex of the incision should be visible anteriorly at the front of the Gomco clamp. The base of the clamp should be angled slightly upward on the ventral side. Make sure that the foreskin above the base plate is even all around. When the clamp is in proper position, turn the screw on the clamp until it is as tight as possible.	**18.** If the Gomco clamp is not correctly aligned, there is risk of cutting the foreskin incorrectly and of the clamp slipping in the middle of the procedure. The ability to see the apex of the dorsal slit assures the midwife that the excision of the foreskin will be accurate. Angling the clamp ensures that less foreskin will be cut from the posterior aspect, which protects the frenulum and decreases the risk of bleeding. The tightness of the clamp will affect the degree of hemostasis.
19. Cut the foreskin from around the plate of the Gomco clamp (Figure 81-11). The blade of the scalpel should be above the base plate. Holding the scalpel securely, be attentive to the position of the blade. The cut should be made with a smooth technique that removes all of the foreskin above the base plate of the Gomco clamp.	**19.** The midwife should be focused and conscious of where the blade is in relation to the baby's body to maintain safety. The skin incision should be smooth, with no irregular edges so that it will heal well.

Procedure	Rationale
20. Leave the Gomco clamp on for another minute. Hold the base of the clamp without moving it. If you note any bleeding, leave the clamp on for 2 more minutes. Have a 2 × 2 gauze ready to apply pressure to the area if needed after the Gomco is removed.	**20.** This enhances hemostasis and also allows the midwife to observe for bleeding. If any bleeding is noted, the midwife should be prepared to manage the situation in a timely manner.
21. Unscrew the clamp to release the base from the bell. Remove the base of the Gomco clamp and put it back on the sterile tray. To remove the foreskin from the bell, moisten a cotton ball with a small amount of povidone-iodine and gently push the foreskin away from the bell (Figure 81-11).	**21.** The inner membrane of the foreskin may adhere to the bell, in which case pulling the bell off will hurt the baby.
22. When the bell is removed, inspect the penis, especially the posterior area, for bleeding.	**22.** There should not be any bleeding visible. The glans of the penis will have a very reddened, raw appearance and the edges of the foreskin should fall just below the glans (Figure 81-11).
a. If there is any active bleeding, apply pressure to the area with a gauze pad. If the bleeding does not stop with a minute or two of pressure, put a small amount of epinephrine on a gauze pad and apply it with pressure to the area.	**a.** Pressure to the area of bleeding affords time for the blood to clot. Epinephrine enhances the clotting of blood but also may have cardiovascular effects if absorbed [27].
b. The midwife should not hesitate to request assistance if the above measures do not stop the bleeding. A pediatrician or consulting doctor should be contacted if the bleeding continues.	**b.** Most bleeding is minor and can be stopped by applying pressure or topical epinephrine. If the bleeding is significant, the midwife should consult to determine if any other treatment will be necessary.

When bleeding occurs it is usually related to (1) cutting too much foreskin from the posterior aspect of the penis (severing the frenulum or a blood vessel near it), or (2) the Gomco clamp's not being tightened enough to attain hemostasis.

Application of the Dressing

23. Wrap the Vaseline gauze loosely around the glans and edges of skin. Put a 2 × 2 gauze covered with a small amount of Vaseline (approximately $^1/_2$ teaspoon) over the Vaseline gauze. Loosen the baby from any restraints and put on a clean diaper.	**23.** The Vaseline gauze enhances healing and prevents irritation and infection. Urinary retention may be caused by a tightly wrapped dressing. The additional gauze helps to keep the area protected.
24. Hold the baby and soothe him with a gentle voice and rocking. When the baby appears calm, wrap him in a blanket and put him in a crib. The baby may be comforted by the parents, if they are present.	
25. Put the scalpel blade and any needles used in a sharps disposal container and then separate all the equipment that needs sterilization.	**25.** This prevents accidents, especially for nurses or technicians who may be assisting in the cleaning and sterilizing of the equipment
26. Take the baby to the parents if they were not present for the circumcision. The following information should be offered to the parents orally and in writing:	**26.** When the midwife offers clear explanations and information, the parents will be able to understand it and will feel secure about caring for their newborn. A translator should be requested if the midwife does not speak the parents' language. If written material is given to the parents, it should also be in a language they understand.
a. how the baby seemed to tolerate the procedure	
b. the appearance of the dressing and the penis	

Procedure	Rationale
c. that the baby will probably need comfort in the next 24 hours (swaddling and being held) and may feel discomfort during voiding or when the diaper is changed	
d. that the baby may need to suck more often after the circumcision but should have normal feeding patterns	
e. that even though it may take a while for the baby to urinate after the circumcision (4–6 hours) the baby should continue to have 6 to 8 wet diapers a day	
f. how and when to change the dressing (It's very supportive to be present the first time the mother changes the diaper, so you can show her what the penis looks like and provide reinforcement for her ability to care for the baby.)	
g. procedure for bathing the baby	
h. normal healing and signs and symptoms of infection	
i. how to contact the midwife with any questions and/or concerns regarding the circumcision	
Answer any questions that the parents may have now and provide them with written information.	
27. When the parents' questions have been answered, write a note in the baby's chart documenting the procedure, including an assessment of the genitalia, the size of the Gomco clamp used, how the baby tolerated the procedure, whether bleeding was present, what was done to stop any bleeding, the dressing used, and all teaching that was done with the parents. The midwife should sign her or his name and credentials legibly.	**27.** Documentation of the procedure communicates to other health professionals what was done, the outcome, and the identity of the midwife who performed the circumcision. From a medical legal viewpoint, making the information in the note comprehensive provides a basis for review.
Follow-up	
28. The midwife should talk to the mother 24 to 48 hours after the circumcision to assess how the baby is doing, how the circumcision looks, and how the mother is feeling about caring for the circumcision.	**28.** A visit or phone call supports the mother in providing postcircumcision and normal newborn care. A postoperative assessment also decreases the risk of serious complications.

Postcircumcision Care and Parental Instruction

The midwife should provide the parents with the information needed to help them care for the baby and to feel confident to know that the circumcision is healing well. This includes the length of time that it normally takes for the penis to heal, what it will look like, when to change the dressing, and how to bathe the baby.

After the circumcision, the glans of the penis appears to be reddened and the remaining foreskin is at the level of or just below the coronal sulcus. Within 24 hours there may be some edema of the foreskin and a small amount of serosanguinous drainage. Healing should be apparent after one to two days; by then the glans and edges of the skin are less reddened and most babies have much less discomfort when diapers are changed. It usually takes a week for healing to be complete. Let the

parents know that the baby may be irritable for the first 24 hours, especially when the diaper is changed. The baby may be soothed by wrapping him in a blanket (swaddling) and holding him.

Parents should be reminded that hand washing before and after changing the diaper is necessary to decrease the risk of infection. The initial Vaseline gauze dressing should be left on for the first 24 hours. If it falls off or is soiled when the diaper is changed, the Vaseline gauze should be replaced. After 24 hours the Vaseline dressing from around the penis should be removed. Each time the diaper is changed, a clean 2 × 2 gauze pad with approximately 1 teaspoon of Vaseline spread on it should be put over the penis. The dressing should stay moist to help the circumcision heal and to prevent it from sticking to the diaper. The midwife should make sure that the parents have all the supplies they need to change the dressings for one week (an extra Vaseline gauze dressing, 2 × 2 gauze pads, and Vaseline).

The midwife should explain to the parents that if they see any signs of infection or sense there is something wrong with the baby that may be related to the circumcision, they should call the midwife who performed the circumcision. If they are unable to contact the midwife, the baby's pediatric nurse practitioner or pediatrician should be called. Signs and symptoms that may indicate an infection include redness, swelling, a pustular drainage from the penis, fever (over 101° F), lethargy, or not feeding or voiding as expected. The parents should be reassured that complications are rare, but they should call for any questions or concerns.

If the parents call, the midwife needs to determine whether the baby needs to be seen or not. In most cases it is safe practice for the midwife to see the baby to determine if there is a complication or a need for consultation and to recognize the parents' concern. In some situations, healing is slower than usual or there is more drainage than expected. Warm water gauze soaks on the penis twice a day or more frequent dressing changes may be needed to enhance healing.

Sponge baths are recommended for the first two weeks and parents should be taught how to sponge bathe their baby. The parents should be told that for the first few days the circumcised penis should be cleansed with warm water only and kept dry. Nothing other than Vaseline or A & D ointment should be put on the penis, unless an antibiotic ointment is prescribed. They should avoid using soap or alcohol near the penis, since these are especially irritating before the circumcision is fully healed. Tub baths can be done when the umbilical cord has fallen off and the circumcision is well healed.

The last part of the instruction should include time for the parents to ask questions concerning the care of their newborn. Parents should be reassured that they will be able to provide the best of care to their baby, that if something is wrong they will know it, and not to hesitate to call if they have any questions or concerns. Review with them the support that is available through family, friends, and health care providers.

CHAPTER

82

Endometrial Biopsy

WENDY GRUBE, CRNP, MSN
WILLIAM F. MCCOOL, CNM, PhD

Endometrial biopsy (EMB) is a cost effective, safe, and simple method of collecting a histologic sample of the uterine endometrium. A variety of clinical circumstances require investigation of the endometrium (see Chapter 14), especially among women who experience unusual vaginal bleeding as well as those undergoing analysis of infertility. The diagnostic dilatation and curettage (D&C) is no longer considered the "gold standard" for this purpose [1], and the evolution of other sampling devices have allowed EMB to be easily accomplished in an office setting by midwives [2]. Devices currently available for EMB include Endocell, Pipelle, GynoSampler, Novak, and Tis-u-Trap curettes.

Sensitivity and specificity have been noted at 95 to 100 percent for detection of endometrial carcinoma, but sensitivity for detection of other uterine pathology, such as polyps or submucosal fibroids, has been found to be relatively weak at 28 to 44.6 percent [3–5]. This limitation is primarily due to the small surface area of the uterine lining (4.5 to 15 percent) that is capable of being sampled using EMB devices [1]. Combining transvaginal ultrasonography and sonohysterography with EMB can assist with the identification of such structural abnormalities. However, EMB remains an effective method for sampling uterine endometrium for evidence of pathology.

Indications for Endometrial Biopsy [1, 2, 6–9]

1. Identify endometrial cancer or its precursors.
2. Examine thickened endometrium (≥5 millimeters) found on transvaginal ultrasound to rule out hyperplasia.
3. Evaluate abnormal or dysfunctional uterine bleeding.
4. Discover luteal phase defects or other uterine pathology during infertility investigation.
5. Assist in evaluation of atypical glandular cells or endometrial cells found in cervical cytology sampling in appropriate women.
6. Assess the effect of hormonal replacement therapy or tamoxifen on the endometrium. (This indication is not considered necessary by some researchers and clinicians.)

Contraindications and Precautions [2, 6–9]

Contraindications

1. Pregnancy
2. Known or suspected cervical cancer
3. Infection of the vagina, cervix, or uterus (requires evaluation and treatment prior to procedure)

Precautions

1. Blood dyscrasias, coagulation disorders, or the use of medications that may alter clotting require consultation with a provider knowledgeable in hematological disorders
2. History of prosthetic heart valve (requires cardiologist consultation and probable antibiotic prophylaxis)
3. Fever (Temperature >100.4°F) at the time of procedure
4. Severe cervical stenosis, or atypical uterine anatomy (gynecologist consultation or referral)

Potential Side Effects/Complications and Preventive Measures [2, 6–9]

1. Cramping, uterine spasm, vasovagal response; can be prevented by
   a. prophylactic analgesia with 600–800 mg ibuprofen 60 minutes prior to procedure
   b. eating prior to procedure, thus avoiding hypoglycemic state
2. Uterine perforation; can be prevented by
   a. making sure uterus is nonpregnant or well involuted postpartum
   b. performing thorough pelvic exam prior to procedure to note uterine and cervical size, position and angulation, as well as any structural abnormalities
   c. use of a tenaculum to straighten utero-cervical angle if unable to insert the device into the uterine cavity easily
3. Uterine infection; can be prevented by identification and treatment of any existing genital infections

Procedure and Rationale

Procedure	Rationale
1. Timing of appointment: schedule procedure for day 22 or 23 of menstrual cycle if the purpose of the sample is confirmation of ovulation.	1. Timing is critical when attempting to diagnose luteal phase defects. This is not important when sampling for the detection of cancer or its precursors.
2. Gather equipment needed for the procedure, which includes informed consent, nonsterile and sterile gloves, vaginal speculum of appropriate size, ring forceps and cotton balls or large cotton swabs, antiseptic solution (such as Betadine or Hibiclens), 20 percent benzocaine gel (Hurricaine), scissors, labeled specimen containers with 10 percent formalin, endometrial sampling devices (make sure there are at least two available), and tenaculum.	2. Having all equipment prepared in advance prevents interruption in the flow of care at the time of the procedure.
3. Thoroughly review the health history, which includes date of last menses, contraception and possibility of pregnancy, risk of sexually transmitted infection, known bleeding disorder, medication or supplement use, and allergies.	3. This allows for identification of contraindications or need for further laboratory testing prior to the procedure. Such testing may include pregnancy test, STD diagnostic testing, wet mount, or CBC.
4. Provide education and instruction regarding EMB, and obtain consent. Because this is an invasive procedure, the midwife should spend time with the woman explaining what she should expect.	4. Informing the woman of the reason for the procedure, as well as the risks, side effects, and possible complications, allows her to give informed consent.
5. Offer 600–800 mg ibuprofen 60 minutes before the procedure.	5. Nonsteroidal anti-inflammatory drugs decrease cramping and uterine spasm associated with the procedure.
6. Place the woman in a lithotomy position and perform a bimanual and rectovaginal exam (if needed) for uterine and cervical position and structure (with nonsterile gloves).	6. Knowledge of the anatomic details of size, shape and utero-cervical angulation permits passage of the curette in the appropriate direction minimizing possible perforation of the uterine wall.
7. Insert the appropriately sized speculum.	7. This allows for adequate visualization.
8. Apply antiseptic solution to the cervix with a large swab or cotton ball.	8. The use of an antiseptic solution decreases the risk of infection.
9. Topical anesthetic may be applied to the anterior lip of the cervix and also into the os with a small cotton swab.	9. Anesthetic application lessens pain and cramping associated with the use of the curette or tenaculum.

Procedure	Rationale
10. After changing to sterile gloves, remove the curette (the outer sheath and inner piston) from the sterile package as instructed on the package insert. With the piston fully inserted into the sheath, gently introduce the curette through the cervical os and into the uterine cavity until resistance is felt. (If strong resistance is encountered prior to reaching the fundus, stop the procedure.) If not already in place, a tenaculum placed on the anterior lip of the cervix may be used to straighten the utero-cervical angle. (See Chapter 19, page 503.)	**10.** Maintaining sterile technique minimizes the risk of infection. Gentle introduction of the sampling device, stopping if strong resistance is encountered, and the possible use of a tenaculum to straighten the utero-cervical angle, reduces the likelihood of uterine perforation.
11. If there is difficulty advancing the device through the inner os while using steady, moderate pressure, small cervical dilators can be helpful. Another option is the use of a 3 mm osmotic laminaria, which can be placed in the cervix on the morning of the day of the EMB and removed that afternoon prior to the actual procedure.	**11.** The use of graduated cervical dilators allows access for sampling while preventing trauma or perforation from the use of force. Laminaria provide another means of gentle slow dilation of a stenotic inner cervical os.
12. Once resistance is felt, note the distance the curette has entered the uterus, using the markings located on the sheath. With the tip of the device at the fundus, hold the curette securely and withdraw the inner piston as far as possible.	**12.** Observing the distance the curette has entered the uterus is useful information for determining that the curette has extended beyond the internal os of the cervix. On average, the length of the cervix from external to internal os is 2.5 centimeters, and the total distance from the external os to the wall of the fundus is approximately 6 to 9 centimeters [10–12]. Graduated markings on the sheath indicate insertion depth of the curette. This information can be recorded in any written note that follows the procedure. Withdrawal of the piston creates the suction, or negative pressure, at the tip needed to collect the tissue sample.
13. Move the sheath of the device back and forth, the tip moving from fundus to internal os, while simultaneously rolling it between the thumb and fingers. Avoid having the tip of the device slip back out the internal os into the cervical canal.	**13.** It is important to have a sample that is representative of any pathology existing in the uterus. Movement in all directions allows for collection of cells from the stratum functionalis, as well as stratum basalis of the endometrium.* Prematurely pulling the sheath back through the internal os will result in the loss of suction.

* The endometrium is the mucosal lining of the uterus; it has two layers: (1) stratum functionalis, which is shed during menstruation, and (2) stratum basalis, which remains throughout the menstrual cycle and from which a new stratum functionalis is regenerated with each cycle. These layers are only millimeters thick, depending on timing in the menstrual cycle, and vary from the fundus through the corpus to the isthmus; therefore, movement of the curette in the manner described enables sampling of both endometrial layers.

Procedure	Rationale
14. Complete the simultaneous moving and rolling of the sheath maneuver until the sheath is filled. Both tissue and some blood should be visible. Remove the device. If only blood can be visibly identified within the sheath, after removing the entire curette, place the contents in formalin, and insert another curette into the uterus, sampling until tissue is obtained.	**14.** It is essential to the procedure that endometrial tissue is actually collected, thus allowing for a meaningful histologic evaluation.
15. Once the tissue has been adequately collected, cut the distal tip from the device and place the tip in the labeled formalin container. Gently press the piston back into the sheath to expel the remaining specimen into the same labeled container.	**15.** Cutting the tip from the device allows the sample to be removed intact, without sustaining cell breakup that can occur when it is forced through the tip. Placing the tip of the catheter in the specimen container ensures that any tissue collected in this portion of the device will be analyzed with the remainder of the specimen.
16. Remove the speculum (and tenaculum, if used), but have the woman remain supine for a few minutes prior to getting up and dressed.	**16.** Lying quietly for a few minutes may prevent a vasovagal response from occurring and allows time for cramping to diminish.

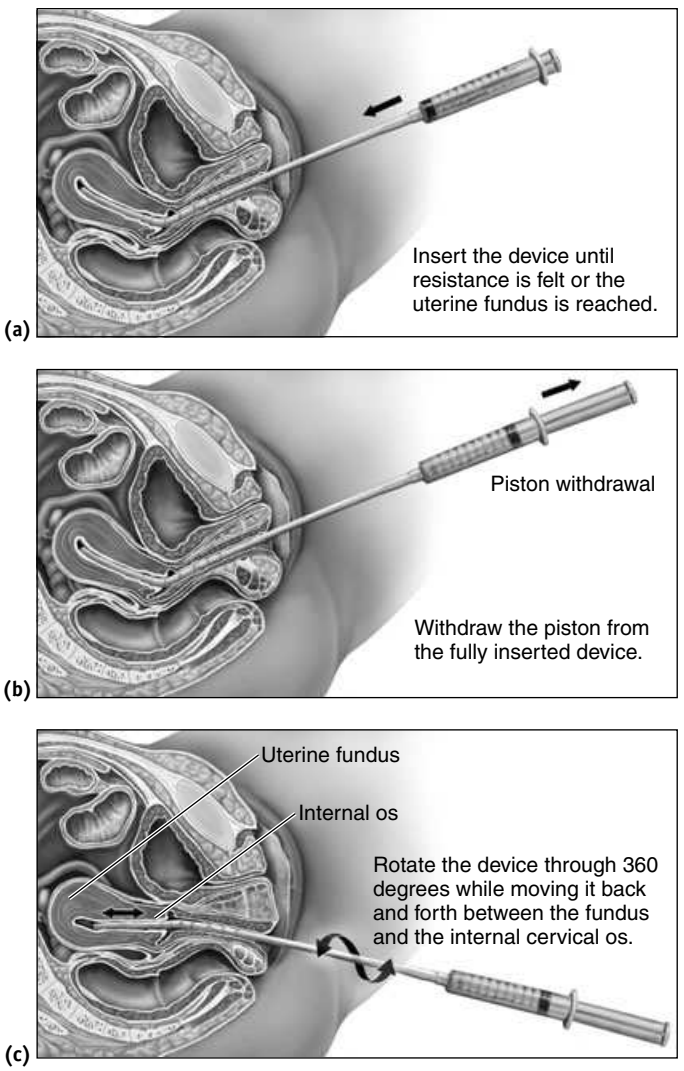

FIGURE 82-1 Endometrial biopsy technique. (a) Insert the device until resistance is felt or the uterine fundus is reached (Step 10). (b) Withdraw the piston from the fully inserted device (Step 12). (c) Rotate the device through 360 degrees while moving it back and forth between the fundus and the internal cervical os.

Procedure	Rationale
17. Instruct the woman to expect some light spotting during the next few days, but to contact the office if she develops bright red or excessive bleeding or clotting, fever, vaginal discharge with a foul odor, pelvic cramping, or pain. She should abstain from sexual intercourse for 2 to 3 days after the procedure.	**17.** Early identification of possible complications (such as endometritis) allows for rapid management and decreased risk of sequelae, such as bacteremia or endocarditis.
18. Document procedure, including any analgesic or anesthetic given, any abnormal findings during examination or procedure, sampling device used, depth of insertion of curette, adequacy of specimen obtained, and the woman's toleration of the procedure.	**18.** Documentation of any procedure is standard of care.

Results and Management

Laboratory findings can vary in language and presentation depending on the laboratory reporting system. In general, the midwife will receive a histology report, which will offer information that can contribute to making a diagnosis regarding the health of the woman's uterine lining. In communicating the findings to the woman, the midwife should ensure that the client understands the results and the possible courses of action to follow. The most common histologic reports received, with suggestions for follow-up, are found in Table 82-1.

TABLE 82-1 Endometrial Biopsy Findings with Probable Diagnoses and Suggested Management

Histology	Probable Diagnosis	Suggested Management	Need for Referral
Inactive endometrium	Hypoestrogenic state	Dependent on clinical indication for EMB	As per protocol for specific clinical indication
Proliferative (estrogen influenced preovulation) or Secretory (progesterone influenced postovulation)	**1.** Diagnoses traditionally labeled as abnormal uterine bleeding (AUB) or dysfunctional uterine bleeding (DUB) (see Chapter 14)	**1(a)** Transvaginal ultrasonography (TVUS) to rule out structural pathology **(b)** Hormonal therapy such as low-dose oral contraceptives, or cyclic therapy	**1(a)** Women with an abnormal TVUS **(b)** No response to hormonal therapy
	2. Confirmation of ovulatory cycle (as part of infertility assessment)	**2.** Continue with infertility assessment, as per protocol	**2.** Per infertility protocol
Cystic or adenomatous hyperplasia	**1.** Infertility	**1.** Refer to fertility specialist, who may suggest ovulation induction	**1.** See previous column
	2. Peri- or postmenopausal woman	**2.** Oral contraceptives or cycling with progestins; repeat EMB in 6 months	**2.** No response to hormonal therapy
Atypical adenomatous hyperplasia	Rule out endometrial carcinoma or precursor	Refer to specialist (e.g., collaborating physician or gynecologic oncologist)	See previous column
Suspicion of cancer	Rule out endometrial carcinoma	Refer to specialist (e.g., collaborating physician or gynecologic oncologist)	See previous column
